ICOM *D-STAR*

ICID5100A

Intuitive touch screen operation, V/U, V/V, U/U Dual receive, DV Dual-watch, GPS Receiver, DV/FM Repeater list function, Dplus reflector linking, Built in CTCSS/DTCS encoder and decoder, UT133 Bluetooth unit (option), VS3 Bluetooth headset (option), Android Application (free download), Menu driven user interface, Enhanced DPRS functions, AM airband dualwatch, 50 watts of output power on VHF and UHF, Weather channel with weather alert, Auto repeater function, Speech function, DTMF via microphone or ID5100 display

JETSTREAM

JT222M

220 MHz 50 Watts

50 Watts of Output Power, 200 Memory Channels, CTCSS, 222-224.995 Mhz, Backlit DTMF Microphone, Alphanumeric Display

YAESU
The radio

FTDX1200

This medium-price HF Transceiver Excels on all fronts. The High Frequency Design Technology it has inherited, ensures "Best-in Class Performance". The Outstanding Operability is Perfect for the DX Scene.

KENWOOD

TS590S

The TS-590S marks a bold new chapter in Kenwood's proud history of manufacturing high-performance transceivers. Featuring a narrow-band Roofing Filter the TS-590S significantly reduces interference from unwanted signals that would be hidden to lesser rigs. With IF AGC based on advanced DSP technology, Kenwood has essentially redefined HF performance.

The ARRL Handbook

For Radio Communications

Ninety-Second Edition

Published by:
ARRL

the national association for Amateur Radio™
Newington, CT 06111 USA

About the Cover:

Michael Dzado, ACØHB designed the "Eight-Channel Remote Control Antenna Selector" shown on the Handbook cover. Using a single control cable to the station, up to eight separate antennas can be selected. The switch can also be used to switch single antennas between several radios.

Michael used special coplanar waveguide design techniques to insure a 50-ohm signal path impedance while providing better than 70 dB of port-to-port isolation.

The Sealed Lead-Acid (SLA) Battery Charger was designed by Bob Lewis, AA4PB to work with batteries in use with the typical amateur transceiver. Commercial SLA chargers are unsuitable for use with a battery experiencing intermittent loads such as during amateur operation so Bob designed a charging circuit to accommodate those conditions. The charger features a maximum bulk-charge current of 500 mA and uses battery voltage to select the proper charging rate.

 - The ARRL Radio Amateur's Handbook — From Its Beginning*
 - 2015 Annual Transceiver Survey

Foreword

Congratulations on your purchase of the *2015 ARRL Handbook*. This 92nd edition of the book continues the technical traditions of Amateur Radio. Topics range from very simple electronics and radio wave basics all the way to sophisticated digital communications protocols. In fact, this book is a lot like the Amateur Radio you hear on the air every day. The more than 700,000 active hams in the United States and more than 3,000,000 around the world use all types of technology to communicate.

If you are just getting into Amateur Radio or wireless technology, you will find the section on Fundamental Theory provides great training on electrical and electronic fundamentals, both analog and digital. The practical side of technology follows with a large section of chapters covering the techniques required of RF circuitry, the types of circuits that are used in radio, receivers and transmitters, and the latest digital topics. Antennas are a critical part of successful radio communication so you'll find chapters showing how they work and how to build practical designs. Other chapters explain transmission lines and illustrate the many ways in which signals propagate from point to point.

Since a big part of Amateur Radio is building, repairing, adapting, and otherwise performing hands-on work with radio technology, the final section of the book covers everything from workshop basics to station assembly and troubleshooting. The book's CD-ROM includes Joel Hallas, W1ZR's Annual Transceiver Survey and several more chapters on Space, Digital, and Image Communication practices and equipment. Many supplemental articles and references are also provided.

One of the primary extra values that is provided on the *Handbook's* CD-ROM is the collection of updated software from Jim Tonne, W4ENE (www.tonnesoftware.com). Jim's professional-quality software is used by hams around the world for a variety of purposes:

Elsie — LC filter designer

SVC Filter Designer — Designs filters using standard value components

OptLowpass Designer — Optimized low-pass filters for amateurs

Helical Filter Designer — Creates high-performance filters for VHF and UHF

Pi-El — A tool to design Pi-L network matching circuits

JJSmith — Use the Smith Chart to design matching circuits

QuadNet — A handy way to design active all-pass circuits for SSB generators

ClassE — Design Class E (switch mode) amplifiers with this tool

Diplexer Designer — Simplifies the job of designing circuits to share antennas

MeterBasic — Design and print custom meter scales

Be sure to open the CD-ROM envelope and install the contents on your computer. The complete *Handbook* is included in searchable PDF form, as well!

The *Handbook* is also full of projects that hams can use to construct a functional and effective station. Projects range from simple accessories and small power supplies to legal-limit amplifiers and high-gain antennas. Mobile and portable stations aren't left out either! There is something for every level of experience and every style of operation.

Here are the new projects you'll find in the pages of this year's *Handbook*:

- Workbench-style bipolar tracking power supply by Bryant Julstrom, KCØZNG, for circuits requiring balanced positive and negative voltages. You can use this supply with op-amps and other analog electronic circuits.

- The Antennas chapter presents a tri-band Moxon-style antenna, a 25-pound beam for 20, 15 and 10 meters easily made from wire and fiberglass. Designed by Brian Machesney, K1LI, for portable operating, it's a great introduction to these popular antennas.

- To help reduce cabling costs, an eight-channel remote antenna switch project is included. You can buy boards and parts from the author, Michael Dzado, ACØHB, or build it yourself.

- Getting power to those antenna-mounted electronics can be a problem, too, or just require yet another expensive run of control cable. A dc power bias-Tee project from Phil Salas, AD5X, solves the problem effectively and inexpensively.

- Carl Luetzelschwab, K9LA, updates us on the status and progress of solar Cycle 24 and Joe Eisenberg, KØNEB, contributes a very valuable table of recommended electronic components for all RF builders.

As Amateur Radio begins its second century, "the *Handbook*" is more relevant, useful, and practical than ever. No matter what type or style of operating you prefer, there is plenty of material here for you. Keep turning the pages and you might find something new catching your eye! You may be a technical professional or student in need of practical electronic and RF know-how — you'll find excellent technical value for the price. Why not take one more step and join the ranks of hams from around the world? After more than 90 editions, the *ARRL Handbook* is still here for you, on your workbench, operating shelf, or technical bookshelf.

Dave Sumner, K1ZZ
Chief Executive Officer
Newington, Connecticut
August 2014

The Amateur's Code

The Radio Amateur is:

CONSIDERATE...never knowingly operates in such a way as to lessen the pleasure of others.

LOYAL...offers loyalty, encouragement and support to other amateurs, local clubs, and the American Radio Relay League, through which Amateur Radio in the United States is represented nationally and internationally.

PROGRESSIVE...with knowledge abreast of science, a well-built and efficient station and operation above reproach.

FRIENDLY...slow and patient operating when requested; friendly advice and counsel to the beginner; kindly assistance, cooperation and consideration for the interests of others. These are the hallmarks of the amateur spirit.

BALANCED...radio is an avocation, never interfering with duties owed to family, job, school or community.

PATRIOTIC...station and skill always ready for service to country and community.

—*The original Amateur's Code was written by Paul M. Segal, W9EEA, in 1928.*

Membership Benefits

Your ARRL membership includes **QST** magazine, plus dozens of other services and resources to help you **Get Started**, **Get Involved** and **Get On the Air**. ARRL members enjoy Amateur Radio to the fullest!

Members-Only Web Services

Create an online ARRL Member Profile, and get access to ARRL members-only Web services. Visit www.arrl.org/myARRL to register.

- **QST Digital Edition** – www.arrl.org/qst
All members can access the enhanced digital edition of *QST* from a web browser. Apps are available for *iOS* and *Android* devices.
- **QST Archive and Periodicals Search** – www.arrl.org/qst
Browse ARRL's extensive online *QST* archive. A searchable index for *QEX* and *NCJ* is also available.
- **Free E-Newsletters**
Subscribe to a variety of ARRL e-newsletters and e-mail announcements: ham radio news, radio clubs, public service, contesting and more!
- **Product Review Archive** – www.arrl.org/qst
Search for, and download, *QST* Product Reviews published from 1980 to present.
- **E-Mail Forwarding Service**
E-mail sent to your arrl.net address will be forwarded to any e-mail account you specify.
- **Customized ARRL.org home page**
Customize your home page to see local ham radio events, clubs and news.
- **ARRL Member Directory**
Connect with other ARRL members via a searchable online Member Directory. Share profiles, photos and more with members who have similar interests.

ARRL Technical Information Service — www.arrl.org/tis

Get answers on a variety of technical and operating topics through ARRL's Technical Information Service. ARRL Lab experts and technical volunteers can help you overcome hurdles and answer all your questions.

ARRL as an Advocate — www.arrl.org/regulatory-advocacy

ARRL supports legislation and regulatory measures that preserve and protect access to Amateur Radio Service frequencies. Members may contact the **ARRL Regulatory Information Branch** for information on FCC rules; problems with antenna, tower and zoning restrictions, and reciprocal licensing procedures for international travelers.

ARRL Group Benefit Programs* — www.arrl.org/benefits

- **ARRL "Special Risk" Ham Radio Equipment Insurance Plan**
Insurance is available to protect you from loss or damage to your station, antennas and mobile equipment by lightning, theft, accident, fire, flood, tornado, and other natural disasters.
- **The ARRL Visa Signature® Card**
Every purchase supports ARRL programs and services.
- **MetLife® Auto, Home, Renters, Boaters, Fire Insurance and Banking Products**
ARRL members may qualify for up to a 10% discount on home or auto insurance.

* ARRL Group Benefit Programs are offered by third parties through contractual arrangements with ARRL. The programs and coverage are available in the US only. Other restrictions may apply.

The American Radio Relay League, Inc.

The American Radio Relay League, Inc. is a noncommercial association of radio amateurs, organized for the promotion of interest in Amateur Radio communication and experimentation, for the establishment of networks to provide communication in the event of disasters or other emergencies, for the advancement of the radio art and of the public welfare, for the representation of the radio amateur in legislative matters, and for the maintenance of fraternalism and a high standard of conduct.

ARRL is an incorporated association without capital stock chartered under the laws of the State of Connecticut, and is an exempt organization under Section 501(c)(3) of the Internal Revenue Code of 1986. Its affairs are governed by a Board of Directors, whose voting members are elected every three years by the general membership. The officers are elected or appointed by the directors. The League is noncommercial, and no one

with a pervasive and continuing conflict of interest is eligible for membership on its Board.

"Of, by, and for the radio amateur," the ARRL numbers within its ranks the vast majority of active amateurs in the nation and has a proud history of achievement as the standard-bearer in amateur affairs.

A *bona fide* interest in Amateur Radio is the only essential qualification of membership; an Amateur Radio license is not a prerequisite, although full voting membership is granted only to licensed amateurs in the US.

Membership inquiries and general correspondence should be addressed to the administrative headquarters: ARRL, 225 Main Street, Newington, Connecticut 06111-1494.

About the ARRL

The seed for Amateur Radio was planted in the 1890s, when Guglielmo Marconi began his experiments in wireless telegraphy. Soon he was joined by dozens, then hundreds, of others who were enthusiastic about sending and receiving messages through the air—some with a commercial interest, but others solely out of a love for this new communications medium. The United States government began licensing Amateur Radio operators in 1912.

By 1914, there were thousands of Amateur Radio operators—hams—in the United States. Hiram Percy Maxim, a leading Hartford, Connecticut inventor and industrialist, saw the need for an organization to band together this fledgling group of radio experimenters. In May 1914 he founded the American Radio Relay League (ARRL) to meet that need.

Today ARRL, with approximately 165,000 members, is the largest organization of radio amateurs in the United States. The ARRL is a not-for-profit organization that:

- promotes interest in Amateur Radio communications and experimentation
- represents US radio amateurs in legislative matters, and
- maintains fraternalism and a high standard of conduct among Amateur Radio operators.

At ARRL headquarters in the Hartford suburb of Newington, the staff helps serve the needs of members. ARRL is also International Secretariat for the International Amateur Radio Union, which is made up of similar societies in 150 countries around the world.

ARRL publishes the monthly journal *QST* and an interactive digital version of *QST*, as well as newsletters and many publications covering all aspects of Amateur Radio. Its headquarters station, W1AW, transmits bulletins of interest to radio amateurs and Morse code practice sessions. The ARRL also coordinates an extensive field organization, which includes volunteers who provide technical information and other support services for radio amateurs as well as communications for public-service activities. In addition, ARRL represents US amateurs with the Federal Communications Commission and other government agencies in the US and abroad.

Membership in ARRL means much more than receiving *QST* each month. In addition to the services already described, ARRL offers membership services on a personal level, such as the Technical Information Service—where members can get answers by phone, email or the ARRL website, to all their technical and operating questions.

Full ARRL membership (available only to licensed radio amateurs) gives you a voice in how the affairs of the organization are governed. ARRL policy is set by a Board of Directors (one from each of 15 Divisions). Each year, one-third of the ARRL Board of Directors stands for election by the full members they represent. The day-to-day operation of ARRL HQ is managed by an Executive Vice President and his staff.

No matter what aspect of Amateur Radio attracts you, ARRL membership is relevant and important. There would be no Amateur Radio as we know it today were it not for the ARRL. We would be happy to welcome you as a member! (An Amateur Radio license is not required for Associate Membership.) For more information about ARRL and answers to any questions you may have about Amateur Radio, write or call:

ARRL AMATEUR RADIO®
www.arrl.org

225 Main Street, Newington, CT USA 06111-1494

160 Meters (1.8 MHz)

Avoid interference to radiolocation operations from 1,900 to 2,000 MHz

80 Meters (3.5 MHz)

60 Meters (5.3 MHz)

5330.5 5346.5 5357.0 5371.5 5403.5 kHz
General, Advanced, and Amateur Extra licensees may operate on these five channels on a secondary basis with a maximum effective radiated output of 100 W PEP. Permitted operating modes include upper sideband voice (USB), CW, RTTY, PSK31 and other digital modes such as PACTOR III as defined by the FCC Report and Order of November 18, 2011. USB is limited to 2.8 kHz centered on 5332, 5348, 5358.5, 5373 and 5405 kHz. CW and digital emissions must be centered 1.5 kHz above the channel frequencies indicated above. Only one signal at a time is permitted on any channel.

40 Meters (7 MHz)

Phone and image modes are permitted between 7.075 and 7.100 MHz for FCC licensed stations in ITU Regions 1 and 3 and by FCC licensed stations in ITU Region 2 West of 130 degrees West longitude or South of 20 degrees North latitude. See Sections 97.305(c) and 97.307(f)(11).
Novice and Technician licensees outside ITU Region 2 may use CW only between 7.025 and 7.075 MHz and between 7.100 and 7.125 MHz. 7.200 to 7.300 MHz is not available outside ITU Region 2. See Section 97.301(e). These exemptions do not apply to stations in the continental US.

30 Meters (10.1 MHz)

Avoid interference to fixed services outside the US.

20 Meters (14 MHz)

17 Meters (18 MHz)

15 Meters (21 MHz)

12 Meters (24 MHz)

10 Meters (28 MHz)

6 Meters (50 MHz)

2 Meters (144 MHz)

1.25 Meters (222 MHz)

* Geographical and power restrictions may apply to all bands above 420 MHz. See *The ARRL Operating Manual* for information about your area.

70 cm (420 MHz)

33 cm (902 MHz)

23 cm (1240 MHz)

All licensees except Novices are authorized all modes on the following frequencies:

2300-2310 MHz	10.0-10.5 GHz *	122.25-123.0 GHz
2390-2450 MHz	24.0-24.25 GHz	134-141 GHz
3300-3500 MHz	47.0-47.2 GHz	241-250 GHz
5650-5925 MHz	76.0-81.0 GHz	All above 275 GHz

* No pulse emissions

KEY

Note:

CW operation is permitted throughout all amateur bands.

MCW is authorized above 50.1 MHz, except for 144.0-144.1 and 219-220 MHz. Test transmissions are authorized above 51 MHz, except for 219-220 MHz

- = RTTY and data
- = phone and image
- = CW only
- = SSB phone
- = USB phone, CW, RTTY, and data.
- = Fixed digital message forwarding systems only

- E = Amateur Extra
- A = Advanced
- G = General
- T = Technician
- N = Novice

See [ARRLWeb at www.arrl.org](http://www.arrl.org) for detailed band plans.

ARRL Handbook

CD-ROM Contents

On the CD-ROM included with this book you'll find this entire edition of the *Handbook*, including text, drawings, tables, illustrations and photographs. Using Adobe *Reader*, you can view, print or search the entire book. Also included is supplemental information and articles, PC board template packages, construction details for many projects, and companion software mentioned throughout. The CD-ROM is included in protective envelope attached inside the back cover of the book.

Supplemental Files for Each Chapter

The CD-ROM provides supplemental information for most chapters of this book. This includes articles from *QST* and other sources, material from previous editions of the *ARRL Handbook*, tables and figures in support of the chapter material, and files that contain PC board layout and other design information to build and test the projects provided in the chapters. The supplemental information is arranged in folders for each chapter.

Companion Software

TubeCalculator, a *Windows* application by Bentley Chan and John Stanley, K4ERO, accompanies the tube type RF power amplifier discussion in the **RF Power Amplifiers** chapter.

The following *Windows* programs by Tonne Software (www.tonnesoftware.com) are provided by Jim Tonne, W4ENE.

ClassEInstall205.exe — Designs single-ended Class E RF amplifiers.

DiplexerInstall210.exe — Designs both high-pass/low-pass and band-pass/band-stop types of diplexer circuits.

HelicalInstall206.exe — Designs and analyzes helical-resonator bandpass filters for the VHF and UHF frequency ranges.

JJSmithInstall210.exe — A graphics-intensive transmission-line calculator based on the Smith chart.

LCInstall267.exe — The free student edition of *Elsie*, a lumped-element filter design and analysis program.

MeterBasicInstall306.exe — Designs and prints professional-quality analog meter scales on your printer. The full-featured version of *Meter* is available from Tonne Software.

OptLowpassInstall204.exe — Designs and analyzes very efficient transmitter output low-pass filters.

PIELInstall217.exe — Designs and analyzes pi-L networks for transmitter output.

QuadNetInstall204.exe — Designs and analyzes active quadrature ("90-degree") networks for use in SSB transmitters and receivers.

SVCFilterInstall212.exe — Standard-value component routine to design low-pass and high-pass filters and delivers exact-values as well as nearest-5% values.

What is Amateur (Ham) Radio?

For more than a century, a growing group of federally licensed radio hobbyists known as Amateur Radio — or “ham radio” — operators has had a front-row seat as radio and electronics have broadened our horizons and touched virtually all of our lives. Hams *pioneered* personal communication, even in the days before the telephone and household electricity were commonplace and the Internet not yet conceived. The word “radio” — or “wireless” — still evokes awe.

Today we enjoy wireless amenities that range from the ubiquitous mobile phone to sophisticated smartphones, tablet devices, and diminutive netbook PCs that go just about anywhere. Personal communication is the goal. The original “personal wireless” communication, Amateur Radio remains vital and active today. In this chapter, Rick Lindquist, WW1ME provides an overview of Amateur Radio activities and licensing requirements.

1.1 Do-It-Yourself Wireless

Amateur (or “ham”) Radio operators have at their fingertips the ability to directly contact fascinating people they may never meet who live in distant places they’ll never visit. They do this without any external infrastructure, such as a cell phone network or the Internet, sometimes using simple, inexpensive — often homemade — equipment and antennas. Since the earliest years of wireless communication, these radio experimenters, largely self-taught, developed and refined the means to contact one another without wires connecting them.

As a radio amateur, you can meet new friends, win awards, exchange “QSLs” (the ham’s business card), challenge yourself and others in on-the-air competitions, educate yourself about radio technology, contribute to your community, travel, promote international goodwill, and continue the century-old wireless communication tradition. Your station is yours and yours alone, and it’s independent of any other communication network.

Let’s take a closer look.

AN AMAZING CENTURY OF HAM RADIO

Today we think of “wireless” as a relatively modern term that applies to a wide variety of electronic devices, but it’s actually been around for more than a century. Wireless communication was a goal of early experimenters in the late 19th century and early 20th century. Equipment and methods for early wireless often were crude and rudimentary — a simple crystal radio (primitive “solid state” technology) to listen, and a spark gap transmitter to send Morse code, coupled with what was then called an “aerial.” Little to no ready-made equipment was available, and parts for these early radio do-it-yourselfers were expensive and hard to obtain. On a good night, their transmissions might even span 50 miles! In the early 20th century, when not everyone had a telephone and calling long-distance was pricey, ham radio was, in more contemporary terms, “really cool technology.”

In 1914, just two years after these early hams were required to hold licenses from the federal government, inventor and industrialist Hiram Percy Maxim, 1AW, and radio enthusiast Clarence Tuska, 1WD, established the American Radio Relay League (ARRL) to bring these US radio hobbyists under one tent to serve their common interests. These two founding fathers of ham radio and their peers would be awestruck to see how the world of Amateur Radio and wireless technology has expanded and evolved in the intervening century.

While Maxim and Tuska were not the first hams, the organization they founded, the ARRL — the national association for Amateur Radio — has championed and sustained these radio pioneers and their successors. Now 100 years down the road — light years in terms of radio science and technology — Amateur Radio continues to adapt to the times. While many traditions continue, today’s ham radio is not the ham radio of yesteryear.

Fig 1.1 — Hams travel around the world, putting rare and unusual locations “on the air” to make thousands of contacts. The VP8ORK team traveled to Antarctica’s South Orkney Islands by sea, operating from tents as shown here. Team members such as Nodir Tursoon-Zadeh, EY8MM came from as far away as Tajikistan to participate. [Lew Sayre, W7EW, photo]

Fig 1.2 — Kristina Whitley displays her excitement after making a contact at W4FOS, the Chesapeake Center for Science and Technology High School Amateur Radio Club station in Chesapeake, Virginia, during the 2011-2012 School Club Roundup. [Photo courtesy Richard Siff, W4BUE]

Fig 3 — Some families boast several generations of Amateur Radio operators. Here, Alaska radio amateur Gary Senesac, AL9A, hams it up with his grandson. Gary was a relative latecomer to ham radio and didn’t get his ticket until he was in his 30s. [Gary Senesac, AL9A, photo]

Fig 1.4 — Hams often provide communication in the wake of natural disasters, when conventional systems such as cell phones or the Internet fail. Following Hurricane Sandy, 17-year-old Kristi Melfi, KC2TMB, organized a distribution center for food, clothing, and supplies. [John Melfi, W2HCB, photo]

Fig 1.5 — NASA astronaut and radio amateur Mike Hopkins, KF5LJG, spent about six months aboard the International Space Station in 2013 and 2014. He spoke to students on Earth as part of the Amateur Radio on the International Space Station (ARISS) program. [NASA photo]

THE ORIGINAL PERSONAL COMMUNICATION

In this age of multiple sophisticated communication platforms, it's not uncommon for people to ask, "Ham radio? Do they still do that?" Yes, "they" do. But, given the proliferation of communication alternatives, the larger question may be, *Why?*

Ham radio is a do-it-yourself (DIY) technological and social medium — *personal* communication with no bills, minutes or data plans. It's personal communication that's "off the grid," a wireless service you can rely on when other services aren't available.

It doesn't cost a lot to get into Amateur Radio and participation is open and accessible to everyone. Hams are mothers, fathers, and children of all ages, ethnic backgrounds, physical abilities, and walks of life who belong to a unique worldwide community of licensed radio hobbyists. Some are even well-known celebrities. All find joy and excitement by experiencing radio communication and electronics on a very personal level across a spectrum of activities.

The Federal Communications Commission (FCC) grants licenses in the Amateur Radio Service. With an emphasis on "service," the FCC has laid down five essential principles underlying Amateur Radio's fundamental purpose (see sidebar "Ham Radio's Rules of the Airwaves"). These recognize ham radio's value to the public as a "voluntary noncommercial communication service, particularly with respect to providing emergency communications." The service also exists to continue and expand Amateur Radio's "proven ability" to advance the state of the radio art, as well as both technical and communication skills. Further, the FCC says, the Amateur Radio Service should help to expand the "existing reservoir of trained operators, technicians, and electronics experts," and continue and extend the radio amateur's "unique ability to enhance international goodwill."

HAMS ARE EVERYWHERE

Spotting a radio amateur can be easy. The driver of that car sporting an "odd-looking" antenna may be a ham equipped for mobile operation. Your neighbor on the next block with the wires strung between trees or, perhaps, a tower supporting what looks like a very large television antenna probably is one too.

Modern technology continues to make ham radio more accessible to all, including those living on tight budgets or facing physical challenges. People lacking mobility may find the world of Amateur Radio a rewarding place to find lasting friendships — on the next block, in the next state, or around the globe.

Hams are ambassadors. For many radio

Ham Radio's Rules of the Airwaves

International and national radio regulations govern the operational and technical standards of all radio stations. The International Telecommunication Union (ITU) governs telecommunication on the international level and broadly defines radio services through the international *Radio Regulations*. In the US, the Federal Communication Commission (FCC) is the federal agency that administers and oversees the operation of nongovernmental and nonmilitary stations — including Amateur Radio. Title 47 of the *US Code of Federal Regulations* governs telecommunication. The Amateur Radio Service is governed by Part 97.

Experimentation has always been the backbone of Amateur Radio, and the Amateur Service rules provide a framework within which hams enjoy wide latitude to experiment in accordance with the "basis and purpose" of the service. The rules should be viewed as vehicles to promote healthy activity and growth, not as constraints that lead to stagnation. The FCC's rules governing Amateur Radio recognize five aspects, paraphrased below, in the Basis and Purpose of the Amateur Service.

- Amateur Radio's value to the public, particularly with respect to providing emergency communication support
- Amateur Radio's proven ability to contribute to the advancement of the radio art
- Encouraging and improving the Amateur Service through rules that help advance communication and technical skills
- Maintaining and expanding the Amateur Service as a source of trained operators, technicians and electronics experts
- Continuing and extending the radio amateur's unique ability to enhance international goodwill

The Amateur Radio Service rules, Part 97, are in six sections: General Provisions, Station Operation Standards, Special Operations, Technical Standards, Providing Emergency Communication and Qualifying Examination Systems. Part 97 is available in its entirety on the ARRL and FCC websites (see the Resources section at the end of this chapter for further information).

Hams on the Front Lines

Over the years, the military and the electronics industry have often drawn on the ingenuity of radio amateurs to improve designs or solve problems. Hams provided the keystone for the development of modern military communication equipment, for example. In the 1950s, the Air Force needed to convert its long-range communication from Morse code to voice, and jet bombers had no room for skilled radio operators. At the time, hams already were experimenting with and discovering the advantages of single sideband (SSB) voice equipment. With SSB, hams were greatly extending the distances they could transmit.

Air Force Generals Curtis LeMay and Francis "Butch" Griswold, both radio amateurs, hatched an experiment that used ham radio equipment at the Strategic Air Command headquarters. Using an SSB station in an aircraft flying around the world, LeMay and Griswold were able to stay in touch with Offutt Air Force Base in Nebraska from around the globe. The easy modification of this ham radio equipment to meet military requirements saved the government millions of dollars in research costs.

More recent technological experimentation has focused on such techniques as software defined radio (SDR). This amazing approach enables electronic circuit designers to employ software to replace more costly — and bulkier — hardware components. It's no coincidence or surprise that radio amateurs have been among those investigators doing the ground-level research and experimentation to bring this technology from the laboratory to the marketplace. Transceivers built on the SDR model now are making inroads within the Amateur Radio community and represent the likely wave of the future in equipment design.

Affirming the relationship between Amateur Radio and cutting-edge technology, Howard Schmidt, W7HAS, was White House Cybersecurity Coordinator from 2009 to 2012. An ARRL member, Schmidt is one of the world's leading authorities on computer security, with some 40 years of experience in government, business and law enforcement. Schmidt credits ham radio with helping to launch his career. "Building ... computers to support my ham radio hobby gave me the technical skills that I needed to ... start doing computer crime investigations and work on the early stages of computer forensics, in turn enabling me to start working on cybersecurity issues," he says. Hams are often found in industry and the military as technology presses ahead.

amateurs, a relaxing evening at home is having a two-way radio conversation with a friend in Frankfort, Kentucky or Frankfurt, Germany. Unlike any other hobby, Amateur Radio recognizes no international or political boundaries, and it brings the world together in friendship.

1.1.1 Making it Happen

A major feature of Amateur Radio's 100-year heritage has been the ham's ability to make do with what's at hand to get on the air. It is in the pursuit of such hands-on, do-it-yourself activities that this *Handbook* often comes into play, especially as electronic components are more plentiful today and circuit designs increasingly complex and creative.

Amateur Radio has always been about what its participants bring *to* it and what they make *of* it. Even today many enthusiasts enjoy making their own radio communication gear. Hams contact each other using equipment they've bought or built, or a combination of the two, over a wide range of the radio spectrum. The methods hams use to keep in touch range from the venerable Morse code — no longer a licensing requirement, by the way — to voice, modern digital (ie, computer-coded) modes, and even television.

The hybridization of Amateur Radio and computers and the Internet continues to blossom, as hams invent ever more creative ways to exploit this technology and make it an essential station component. Today it's possible for a ham to control a transmitting and receiving station via the Internet using nothing more than a laptop or smartphone — even if that station is thousands of miles distant. The wonder of software defined radio (SDR) techniques has even made it possible to create *virtual* radio communication gear. SDRs require a minimum of physical components; sophisticated computer software does the heavy lifting!

1.1.2 Your Ham Radio Comfort Zone

Amateur Radio offers such a wide range of activities that everyone can find a comfortable niche. As one of the few truly *international* hobbies, ham radio makes it possible to communicate with other similarly licensed

aficionados all over the world. On-the-air competition called contesting or “radiosport” — just to pick one activity many hams enjoy — helps participants to improve their skills and stations. Further, ham radio offers opportunities to serve the public by supporting communication in disasters and emergencies, and it remains a platform for sometimes cutting-edge scientific experimentation. Many of those who got into ham radio at a young age credit that involvement with later success in technological careers.

Ham radio's horizon extends into space. The International Space Station boasts a ham radio station, and most ISS crew members are Amateur Radio licensees. Thanks to the program Amateur Radio on the International Space Station (ARISS), suitably equipped hams can talk directly with NASA astronauts in space. Hams also contact each other through Earth-orbiting satellites designed and built by other radio amateurs, and they even bounce radio signals off the Moon and back to other hams on Earth.

Hams talk with one another from vehicles, while hiking or biking in the mountains, from remote camp sites, or while boating. Through a plethora of activities, hams learn a great deal, establish lifelong friendships and,

Fig 1.6 — ARRL Member Jordan Johns, KF7LUA of Idaho was the top scorer in the 7th call area in the 2011 ARRL April Rookie Roundup, a phone contest for newcomers to Amateur Radio. [Photo courtesy Jordan Johns, KF7LUA]

perhaps most important, have a *lot* of fun. Along the way, radio amateurs often contribute a genius that propels technological innovation.

Most likely you're already a ham or at least have experimented with radio and electronics yourself and are thinking about getting your ham license. This *Handbook* is an invaluable resource that reveals and explains the “mysteries” governing electronics in general and in radio — or wireless — communication in particular, especially as they pertain to Amateur Radio.

1.1.3 What's in it for Me?

As a community *of* communities, Amateur Radio can be whatever *you* want it to be. Whether you are looking for relaxation, excitement, enjoyment or a way to stretch your mental (and physical) horizons, Amateur Radio can provide it — even for those with time and money constraints. However it happens, communication between individuals is at the core of nearly all ham radio activities. In its most basic form, ham radio is two people saying “Hello!” to each other over the air, perhaps using inexpensive handheld transceivers or even homemade gear. In “Hamspeak,” a two-way, on-the-air communication is known as a “QSO” — an old radiotelegraph, or Morse code, abbreviation often pronounced “CUE-so.”

Ham radio can also be a group activity. Hams with common interests often gather on the airwaves to share their thoughts and even pictures. These get-togethers are called “nets” or “roundtables,” depending on their formality. When hams meet on the air for an extended on-the-air conversation, they sometimes call it “ragchewing.”

Nets form when like-minded hams gather on the air on a regular schedule. Nets often provide an on-the-air venue to find other hams with similar interests both inside and outside of Amateur Radio. Topics may be as diverse as vintage radio, chess, gardening, rock climbing, railroads, computer programming, teaching or an interest in certain types of radio equipment. Faith-based groups and scattered friends and families may also organize nets. You can find your special interest in *The ARRL Net Directory* on the ARRL website (www.arrl.org/arrl-net-directory).

1.2 Joining the Ham Radio Community

Morse code has been a major player in Amateur Radio's legacy, although it was a roadblock to some. Today it's no longer necessary to learn the code to become an Amateur Radio licensee. You still must hold a license granted by the Federal Communications Commission (FCC) to operate an Amateur Radio station in the United States, in any of its territories and possessions or from any vessel or aircraft registered in the US. There are no age or citizenship requirements to obtain a US Amateur Radio license, and the cost is minimal, sometimes free. Ham radio exams are regularly passed by children not yet in their teens!

The FCC offers three classes — or levels — of Amateur Radio license. From the easiest to the most difficult, they are Technician, General and Amateur Extra Class. Applicants must take and pass a multiple-choice written examination for each license. Official question pools for all ham radio license classes are publically available. The higher you climb the ladder, the more challenging the test and the more generous the operating privileges. To reach the top — Amateur Extra — you must pass the examinations for all three license classes.

1.2.1 Moving Through the Ranks

Most people start out in Amateur Radio by getting a Technician Class license or "ticket," as a ham license is sometimes called. Obtaining a Technician license requires passing a 35 question multiple-choice exam. The test covers FCC rules and regulations governing the airwaves, courteous operating procedures and techniques and some basic electronics. The privileges earned give Technicians plenty of room to explore and activities to try. For some, the Technician is the only ham license they'll ever want or need.

Technicians enjoy a wide, but somewhat limited, range of voice and digital radio operating privileges. These include access to some "high frequency" (HF or short-wave) frequency "bands" or segments of the radio spectrum. Depending upon license class, hams have access to up to 10 distinct HF bands in the range from 1.8 MHz to 29.7 MHz, where most direct international communication happens. (Frequency and wavelength terms are explained in the **Electrical Fundamentals** chapter.) Technicians also have all amateur privileges in the VHF-UHF and microwave spectrum, though, which allow operation on widely available FM voice repeaters. A repeater greatly extends the communication range of low-power, handheld radios or mobile stations too far apart to

communicate with each other directly. The "Tech ticket" is a great introduction to the fun and excitement of ham radio and to the ways of the hobby.

By upgrading to General Class, a Technician licensee can earn additional operating privileges, such as access to all of the Amateur Radio HF bands. Upgrading to General entails passing another 35 question multiple-choice exam. In addition to Technician privileges, Generals enjoy worldwide communication using voice, digital, image and television techniques.

Reaching the top rung of the Amateur Radio ladder — Amateur Extra Class — means passing a more demanding 50 question examination. Amateur Extra licensees enjoy privileges on all frequency bands and communication modes available to hams. The exam may be challenging, but many hams consider it well worth the effort!

1.2.2 Study Aids

You can prepare for the exam on your own, with a group of friends or by taking a class sponsored by a ham radio club in your area. The ARRL offers materials and lesson plans for hams wishing to teach Amateur Radio licensing classes. Anyone can set up license classes. Many Amateur Radio clubs hold periodic classes, usually for the Technician license. The ARRL supports Registered Amateur Radio Instructors, but registration is not necessary to conduct a class. Check the ARRL website, www.arrl.org, for classes, clubs or volunteer examiners (VEs) in your area (more on VEs below).

Help is available at every step. The ARRL publishes study materials for all license classes. Visit the ARRL website or contact the ARRL's New Ham Desk for more information on how to get started. The Resources section at the end of this chapter includes an address and telephone number. The ARRL can help you find ham radio clubs in your area as well as ARRL-registered instructors and local Volunteer Examiner teams. Additional information on the ARRL website includes frequencies hams can use, popular operating activities, and how to order the latest ARRL study guide.

For newcomers seeking to obtain a Technician license, *The ARRL Ham Radio License Manual* includes the complete,

up-to-date question pool, with the correct answers and clear explanations. The manual assumes no prior electronics background. It delves into the details behind the questions and answers, so you will *understand* the material, rather than simply memorize the correct answers.

If you already have some electronics background or just want brief explanations of the material, you might find *ARRL's Tech Q&A* manual a more appropriate choice. It also includes the entire Technician question pool to help you prepare.

When you are ready to upgrade to a General Class license, *The ARRL General Class License Manual* or *ARRL's General Q&A* can help you prepare. In like fashion, *The ARRL Extra Class License Manual* and *ARRL's Extra Q&A* will guide your study efforts for the Amateur Extra Class license. Check the ARRL website for detailed information on these and other license study options.

1.2.3 Taking the Test

While the FCC grants US Amateur Radio licenses, volunteer examiners (VEs) now administer all Amateur Radio testing. Other countries have adopted similar systems. Ham radio clubs schedule regular exam sessions, so you shouldn't have to wait long or travel far once you're ready. Exam sessions often are available on weekends (frequently at ham radio gatherings called "hamfests") or evenings. Most volunteer examiner teams charge a small fee to recover the cost of administering the test and handling the FCC paperwork.

The ARRL is a Volunteer Examiner Coordinator (VEC) and supports the largest VE program in the nation. More information about the VE program is available on the ARRL website.

The questions for each 35 or 50 question test come from a large "question pool" that's specific to each license class. All three question pools — Technician, General and Amateur Extra — are available to the public in study guides and on the

Fig 1.7 — *The ARRL Ham Radio License Manual* contains all the information you need to study for your Technician class license.

Internet. If you're studying, make sure you're working with the latest version, since question pools are updated on a set schedule. The Resources section at the end of this chapter has more information on where to find the question pools.

1.2.4 Your Ham Radio Mentor

Ham radio operators often learn the ropes from a mentor. In ham radio parlance, such an experienced ham willing to help newcomers is called an "Elmer." This individual teaches newcomers about Amateur Radio, often on a one-to-one basis. Your local ham radio club may be able to pair you up with an Elmer who will be there for you as you study, buy your first radio and set up your station — which many hams call their "radio shack" or "ham shack," a term held over from the days when ham stations often were in small buildings separate from the owner's residence. Elmers also are pleased and proud to help you with your first on-the-air contacts.

Elmers who belong to the international Courage Handi-Hams organization (www.handiham.org) focus on making study materials and ham radio station operation accessible to those with physical disabilities. Local Handi-Hams assist such prospective radio amateurs in getting licensed, and the Handi-Ham System may lend basic radio gear to get the new ham on the air.

1.2.5 Your Ham Radio Identity

Ham radio operators know and recognize each other by a unique call sign (some hams shorten this to simply "call") that the FCC

Fig 1.8 — Young Mailie Danilchik, K7MKD, of Poulsbo, Washington, got her license at age 10. Her dad Paul is NT7U, and she said that getting her ham ticket was "a father-daughter bonding project." The cat is still studying for her ham ticket. [Paul Danilchik, NT7U, photo]

ARRL — the national association for Amateur Radio®

The American Radio Relay League (ARRL) is the internationally recognized society representing Amateur Radio in the US. Since its founding in 1914, the ARRL — the national association for Amateur Radio — has grown and evolved along with Amateur Radio. ARRL Headquarters and the Maxim Memorial Station W1AW are in Newington, Connecticut, near Hartford. Through its dedicated volunteers and a professional staff, the ARRL promotes the advancement of the Amateur Service in the US and around the world.

The ARRL is a nonprofit, educational and scientific organization dedicated to the promotion and protection of the many privileges that ham radio operators enjoy. Of, by and for the radio amateur, ARRL numbers some 160,000 members — the vast majority of active amateurs in North America. Licensees can become Full Members, while unlicensed persons are eligible to become Associate Members with all membership privileges except for voting in ARRL elections. Anyone with a genuine interest in Amateur Radio belongs in the ARRL.

The ARRL volunteer corps is called the Field Organization. Working at the state and local level, these individuals tackle ARRL's goals to further Amateur Radio. They organize emergency communication in times of disaster and work with agencies such as American Red Cross and Citizen Corps. Other volunteers keep state and local government officials abreast of the good that hams do at the state and local level.

When you join ARRL, you add your voice to those who are most involved with ham radio. The most prominent benefit of ARRL membership is its monthly journal *QST*, the premiere Amateur Radio magazine issued monthly in print and digital form. *QST* contains stories you'll want to read, articles on projects to build, announcements of upcoming contests and activities, reviews of new equipment, reports on the role hams play in emergencies and much more.

Being an ARRL member is far more than a subscription to *QST*. The ARRL represents your interests before the FCC and Congress, sponsors operating events throughout the year and offers membership services at a personal level. These include:

- low-cost ham equipment insurance
- the Volunteer Examiner program
- the Technical Information Service (which answers your questions about Amateur Radio technical topics)
- the QSL Service (which lets you exchange postcards with hams in other countries to confirm your contacts with them)

For answers to any questions about Amateur Radio, e-mail, call or write ARRL Headquarters. See the Resources section at the end of this chapter for contact information.

Fig 1.9 — This iconic brick building houses W1AW, the station operated by the ARRL in Newington, Connecticut, and known around the world. W1AW memorializes Hiram Percy Maxim, one of the founders of the ARRL. Visitors are welcome and often operate the station. [Rick Lindquist, WW1ME, photo]

Fig 1.10 — Voice modes are the most popular way hams use to communicate with each other. ARRL Emergency Preparedness Manager Mike Corey, KI1U, makes a few single-sideband mode contacts from Maxim Memorial Station W1AW at ARRL Headquarters in Connecticut.

issues when you get your license. Your call sign not only identifies your station on the air, it's an individual ham radio identity, and many hams become better known by their call signs than by their names! Although the FCC still issues hard-copy licenses, once your license and call sign grant appear online in

the FCC's active Amateur Radio Service database, you have permission to operate.

A call sign also identifies the issuing country. US call signs, for example, begin with W, K, N or A followed by some combination of letters and one numeral. Each combination is different. One well-known ham radio call

sign is W1AW, assigned to the Hiram Percy Maxim Memorial Station at ARRL Headquarters in Newington, Connecticut.

FCC-assigned call signs come in several flavors, with the shortest — and typically most desirable — combinations available only to Amateur Extra Class licensees. The FCC routinely assigns initial call signs to new Technician licensees in the longest format. These call signs start with two letters, a numeral from 0 to 9, and three more letters. The first part of a call sign including the numeral is called a *prefix*. The part following the numeral is called a *suffix* and is unique to a specific licensee. Typical prefixes in Canada are VE and VA, while the common prefix in Mexico is XE.

At one time, the numeral indicated a US station's geographical region — 1 for New England, 6 for California and 9 or 0 (zero) for the Midwest. The FCC has made ham radio call signs portable, however — just like telephone numbers. So a call sign with "1" following the prefix may belong to a ham located in Florida.

You don't have to keep the call sign the FCC assigns. For a modest fee, the FCC's *vanity call sign* program permits a ham to select a new personalized call sign from among the database of certain unassigned call signs, based on the applicant's license class.

1.3 Your Ham Radio Station

Amateur Radio costs as much or as little as your budget and enthusiasm dictate. Most hams set up home-based stations. By tradition the room or place where a station is located is your "ham shack," but many thrifty hams carry their stations with them in the form of relatively inexpensive handheld transceivers, some quite compact. Without requiring any antenna beyond the one attached to the radio itself, such radios can accompany you when you're out and about or traveling.

On the other end of the scale, radio amateurs serious about radio contesting or DXing (contacting distant stations in other countries) often invest in the latest equipment and extensive antenna systems. Most hams fall somewhere between these extremes. They have a modest equipment complement, simple wire antennas between two trees and maybe a small "beam" (directional antenna) on a backyard tower or mast. Whatever your investment level, you'll be able to talk around the world.

Fig 1.11 — Some hams enjoy building their own equipment, and many are quite good at repurposing or recycling outdated technology. Richard Calhoun, W6DZT, built this power amplifier in a discarded personal computer enclosure, bought through an online auction site for a few dollars. [Richard Calhoun, W6DZT, photo]

1.3.1 How Much Does It Cost?

Early radio amateurs generally built their own gear, mainly out of necessity; there were no well-stocked radio emporiums in the early 20th century. Constructing ham radio equipment from kits became popular in the mid-20th century, and several manufacturers still provide parts kits and circuit boards to make it even easier to build equipment yourself. A lot of hams still enjoy designing and building their own equipment (called “homebrewing”) and the resulting cost savings. Many of these amateurs proudly stand at the forefront of technology and keep up with advances that may be applied within or even outside the hobby. Indeed, the projects you’ll find in this *Handbook* provide a wide variety of equipment and accessories that make ham radio more convenient and enjoyable.

Today’s radio amateurs most often start out using off-the-shelf commercially-made transceivers purchased new or on the used

Fig 1.12 — Amateur Radio has brought a new level of social activity to the Collington continuing care community in Maryland. Formation of a community radio club means that downsizing retirees now can continue to enjoy ham radio, as Karl Edler, KB3US (left) and Dick Wilder, K3DI, are doing. [Jamie Windon photo]

Hamfests

Amateur Radio’s broader social world extends beyond making on-the-air acquaintances. Regular ham radio gatherings, usually called “hamfests,” offer opportunities to meet other hams in person — called “an eyeball contact” in ham parlance. Hams also enjoy buying, selling and trading ham radio equipment and accessories in the hamfest “flea market.” *Every* ham loves a bargain. Other hamfest visitors take advantage of classroom sessions or forums to learn more about particular aspects of the hobby.

Hamfests are great places to get good deals on gear — some vendors offer substantial hamfest discounts — and to expand your knowledge. Thousands of radio amateurs from the US and around the world gather each spring at Dayton Hamvention® in Ohio. This truly international event epitomizes the goodwill that exists among the world’s Amateur Radio enthusiasts.

The annual Dayton Hamvention attracts upward of 20,000 hams from around the world to meet and greet, learn, buy, sell and trade.

market, perhaps at a ham radio flea market or hamfest or through an Internet auction or classified ad site. An abundance of ham gear is readily available, and there's something out there to meet your needs within your budget. Used VHF or VHF-UHF (or "dual-band") handheld transceivers often are available for \$100 or so, and the entrance of Chinese manufacturers into the ham radio market has resulted in a significant reduction in the price of some types of brand new gear.

Those interested in HF work can get in on the ground floor with a used, but serviceable, transceiver in the \$200 to \$500 range, and an excellent selection of new transceivers is available in the \$500 to \$1500 range. "Flea-power" CW (Morse code) transceivers covering single bands sell new for less than \$100 in kit form; a new four-band CW transceiver manufactured in China and marketed by a US ham radio manufacturer is available for less than \$300. An HF antenna such as a simple backyard dipole suspended from available trees is both inexpensive and effective. You'll find some great equipment choices advertised in ARRL's monthly journal, *QST*. In addition to advertising new ham gear, *QST* includes comprehensive equipment reviews.

More elaborate antennas and various accessories can add appreciably to the cost of your station, but less-expensive alternatives are available, including building your own.

1.3.2 Computers and Ham Radio

The marriage of ham radio and computers is solid and longstanding. Radio amateurs have discovered that interconnecting their PCs with their ham stations not only makes

operating more convenient but can open the door to additional activities on the ham bands. Most radio amateurs now have a computer in the shack, often one that's dedicated to ham radio tasks. Software is available for many ham radio applications, from record keeping to antenna and circuit design.

Probably the most common use for a computer in the ham shack is logging — keeping a record of — contacts. This is especially true for contesters, where speed and accuracy are paramount. While there's no longer a legal requirement to maintain a detailed logbook of your on-the-air activities, many hams still keep one, even for casual operating, and computer logging can make the task less tedious (see sidebar "Keeping a Log").

Many computer logging applications also let you control many or most of your radio's functions, such as frequency or band selection, without having to leave your logging program. It's also possible to control various accessories, such as antenna rotators or selection switches, by computer.

Via your computer's soundcard, you can enjoy *digital modes* with nothing more than a couple of simple connections, operating software (often free) and an interface. RTTY (radioteletype) and PSK31 are two of the most popular HF "keyboard-to-keyboard" digital modes. PSK31 lets you communicate over great distances with a very modest ham station, typically at extremely low power levels.

Computers also can alert you to DX activity on the bands, help you practice taking Amateur Radio license examinations or improve your Morse code abilities. Many ham radio organizations, interest groups and even individuals maintain websites too.

Keeping a Log

Keeping a log — on paper or using your computer — of your on-air activity is optional, but there are some important reasons for doing so. These include:

Awards tracking — A log lets you track contacts required for DXCC, WAS and other awards. Some computer logging programs do this automatically, so you can see how well you are progressing toward your goal.

An operating diary — A log book is a good place to record general information about your station. For example, you may want to note comparisons between different antennas or pieces of equipment based on reports from other stations. Your log is also a logical place to record new acquisitions (complete with serial numbers in case your gear is ever stolen). You can track other events as well, including the names and call signs of visiting operators, license upgrades, contests, propagation and so forth.

Legal protection — Good record keeping can help you protect yourself if you are ever accused of intentional interference or ever have a problem with unauthorized use of your call sign.

Paper or Computer?

Many hams, even some with computers, keep "hard copy" log books. A paper log is low tech; it doesn't consume power, it's flexible and can never suffer a hard-drive crash! Preprinted log sheets are available, or you can create your own customized log sheets in no time using word processing or publishing software.

On the other hand, computer logging offers many advantages, especially for contesters, DXers and those chasing awards. For example, a computerized log can instantly indicate whether you need a particular station for DXCC or WAS. Contesters use computer logs to manage contact data during a contest and to weed out duplicate contacts in advance. Most major contest sponsors prefer to receive computer log files, and some do not accept paper logs at all. Computer logs can also tell you at a glance how far along you are toward certain awards and even print QSL labels. And of course computer logs make it easy to submit your contacts to ARRL's online Logbook of The World.

Several of the most popular computer logging programs (and regular updates) are available at no cost, while others are available for a small fee. You also can purchase logging software from commercial vendors. Some are general-purpose programs, while others are optimized for contesting, DXing or other activities. Check the ads in *QST* and compare capabilities and requirements before you choose.

Fig 1.13 — Ham radio contesting or "radiosport" attracts thousands of participants. Jeff Stai, WK6I, took advantage of modern computer technology to set a West Coast record score in the 2013 ARRL RTTY (radioteletype) Roundup event. RTTY (pronounced "ritty" by most hams) is a keyboard-to-keyboard mode. Computer software and displays have taken the place of old-fashioned electromechanical teleprinters as well as paper logbooks. A computer also controls his radio. [Tom Taormina, K5RC, photo]

1.4 Getting on the Air

Amateur Radio is a *social* activity as well as a technical pursuit. It's a way to make new friends and acquaintances on the air that you may later meet in person. Some ham radio relationships last a lifetime, even though the individuals sometimes never meet face to face. Ham radio can be the glue that keeps high school and college friends in touch through the years.

Amateur Radio also can cement relationships between radio amateurs of different nationalities and cultures, leading to greater international goodwill and understanding — something that's especially beneficial in this era of heightened cultural tensions and misperceptions. When you become an Amateur Radio operator, you become a “world citizen.” In return you can learn about the lives of the radio amateurs you contact in other countries.

“What do hams say to each other?” you might wonder. When they meet for the first time on the air, hams exchange the same sorts of pleasantries that anyone might when meeting face to face. Ham radio operators exchange name and location (abbreviated “QTH” by hams) and — specific to hamming — radio signal reports indicating how well they're hearing (or “copying”) each other over the air. This name/location/signal report pattern is typical, regardless of radio mode. With these preliminaries out of the way, ham radio conversations often focus on equipment or may extend to other interests.

Although English is arguably the most common language on the ham bands (even spoken by hams whose first language may be something other than English), English

Fig 1.14 — Nick McPherson, son of Greg McPherson, N2KUN, of New York, was an enthusiastic participant in Kids Day, which encourages veteran radio amateurs to invite interested youngsters into their ham shacks to experience ham radio firsthand. Kids Day events are held in January and June.

speakers can make a favorable impression on hams in foreign countries if they can speak a little of the other person's language — even if it's as simple as *danke*, *gracias* or *arigato*.

1.4.1 Voice Modes

We've mentioned the use of voice (or “phone,” short for “radiotelephone”) and Morse code (or CW) on the amateur bands. Although more hams are embracing digital modes every day, phone and CW by far remain the most popular Amateur Radio communication modes. Ham voice modes are amplitude modulation (AM), which includes the narrower-bandwidth single sideband (SSB), and frequency modulation (FM). For the most part, SSB is heard on HF, while FM is the typical voice mode employed on VHF, UHF and microwave bands.

The great majority of ham radio HF phone operators use SSB (subdivided further into upper sideband and lower sideband), but a few still enjoy and experiment with the heritage “full-carrier AM.” Once the primary ham radio voice mode, this type of AM still is heard on the standard broadcast band (530 to 1710 kHz). Today's AM buffs appreciate its warm, rich audio quality, and the simplicity of circuit design encourages restoring or modifying vintage radios or building from scratch. For more information about AM operation, visit www.arrl.org/am-phone-operating-and-activities.

1.4.2 Morse Code

Morse code was the very first radio transmission mode, although it wasn't long before early experimenters figured out how to transmit the human voice and even music over the airwaves. Morse is also the original digital mode; the message is transmitted by turning a radio signal on and off (a “1” and a “0” in digital terms) in a prescribed pattern to represent individual letters, numerals and characters. This pattern is the International Morse Code, sometimes called the “radio code,” which varies in many respects from the original Morse-Vail Code (or “American Morse”) used by 19th century railroad telegraphers. Leaning on longstanding tradition, hams often refer to Morse transmissions as “CW,” after an archaic definition for “continuous wave” which described the type of radio wave involved.

Federal regulations once required that prospective radio amateurs be proficient in sending and receiving Morse code in order to operate on “worldwide” (ie, shortwave or HF) ham bands. Although this is no longer the case for any class of Amateur Radio license

in the US, many hams still embrace CW as a favorite mode and use it routinely. Hams typically send Morse code signals by manipulating a manual telegraph key, a “semi-automatic” key (called a “bug”) or a CW “paddle” and an electronic keyer that forms the dots and dashes. Most hams decipher Morse code “by ear,” either writing down the letters, numerals and characters as they come through the receiver's headphones or speaker or simply reading it in their heads. Some use one of the available computer-based or stand-alone accessories that can translate CW into plain text without the need to learn the code.

Hams who enjoy CW cite its narrow bandwidth — a CW signal takes up very little of the radio spectrum — simpler equipment and the ability of a CW signal to “get through” noise and interference with minimal transmitting power. CW is a common low-power (QRP) mode.

1.4.3 FM Repeaters

Hams often make their first contacts on local voice repeaters, although in recent years the nearly ubiquitous cell phone has reduced the popularity of — and even the need for — repeaters for everyday ham communication. Repeaters can greatly extend the useful range of a typical handheld FM transceiver much in the same way a cell tower retransmits your voice or text messages, and they carry the vast majority of VHF/UHF traffic, making local and even regional mobile communication possible for many hams. Located on

Fig 1.15 — Max McCoy, KCØMAX, has combined his enthusiasm for Amateur Radio with spending time in the outdoors, hiking, canoeing and camping in remote spots.

hilltops, tall buildings or other high structures, repeaters strengthen signals and retransmit them. This provides communication over much farther distances than would be possible when operating point to point or “direct.” The wider coverage can be especially important if the repeater is ever pressed into service during an emergency.

Typically, hams use repeaters for brief contacts, although socializing and “ragchewing” are routine on some “machines,” as repeaters are often called. All repeater users give priority to emergency communications. Most repeaters are maintained by clubs or groups of hams. If you use a particular repeater frequently, you should join and support the repeater organization. Some hams set up their own repeaters as a service to the community.

The best way to learn the customs of a particular repeater is to listen for a while before transmitting. Most repeaters are *open*, meaning that any amateur may use the repeater, although repeaters typically require users to transmit an access tone (which you can select on any modern FM transceiver). A few repeaters are *closed*, meaning that usage is restricted to members of the club or group that own and operate the repeater. Some repeaters have *autopatch* capability that allows amateurs to make telephone calls through the repeater. The *ARRL Repeater Directory* shows repeater locations, frequencies, capabilities and whether the repeater is open or closed.

1.4.4 Digital Modes

Radioteletype (RTTY—often pronounced “Ritty”) is a venerable data communication mode that remains in wide use today among radio amateurs. While RTTY does not support the features of newer computer-based data modes, it is well suited for keyboard-to-keyboard chats with other stations. It also is the most popular mode for worldwide digital contests and remains in common use among DXers and DXpeditions. RTTY was originally designed for use with mechanical teleprinters, predating personal computers by

several decades. Today, Amateur Radio RTTY uses soundcard-equipped computers and dedicated RTTY software.

An HF digital mode for general domestic and DX contacts is PSK31, a keyboard-to-keyboard mode that’s especially effective for very low power (QRP) communication. It’s easy to transmit and receive PSK31 using a PC and software—typically free—that operates via a PC soundcard. Most digital modes use the same basic PC/soundcard setup and new modes are developed on a regular basis.

One of the more recent software-based, soundcard modes is JT65 by Nobel laureate and radio amateur Joe Taylor, K1JT, who developed the software for this mode as part of *WSJT (Weak Signal communications by K1JT)*. See www.arrl.org/files/file/18JT65.pdf. JT65 uses 64 audio tones to transmit information. Contacts in this mode, which often take place on the HF bands, are a bit different than typical two-way conversations. Stations take turns during synchronized 60-second transmissions cycles that alternate between odd and even minutes on the clock, until concluding the contact.

JT65 rivals Twitter in its brevity. Stations can transmit only about 13 characters each time, but the data are repeated each cycle to maximize information transfer. Successful JT65 contacts can take place under adverse radio conditions and using extremely low signal levels; a transmitter output power of 20 W is considered high power in the JT65 world.

Another digital mode, packet radio, is much less popular in today’s ham radio world than it was in the 1990s. Packet’s most important applications today include networking and *unattended* operation. The most common uses are the worldwide DX station spotting network, the Automatic Packet/Position Reporting System (APRS) and regional or local general-purpose networks.

APRS

Developed by Bob Bruninga, WB4APR, APRS or the Automatic Packet/Position Reporting System (www.aprs.org) is used

for tracking stations or objects in motion or in fixed positions and for exchanging data. It uses the *unconnected* packet radio mode to graphically indicate objects on maps displayed on a computer monitor. Using unconnected packets permits all stations to receive each transmitted APRS packet on a one-to-all basis rather than the one-to-one basis required by connected packets.

As with other packet transmissions, APRS data are relayed through stations called *digipeaters* (digital repeaters). Unlike standard packet radio, APRS stations use generic digipeater paths, so the operator needs no prior knowledge of the network. In addition, the Internet is an integral part of the system that is used for collecting and disseminating current APRS data in real time.

Virtually all VHF APRS activity occurs on 2 meters, specifically on 144.39 MHz, the recognized APRS operating channel in the US and Canada. On UHF, you’ll find APRS activity on 445.925 MHz.

Many groups and individuals that participate in public service and disaster communications find APRS a useful tool. Others use it to view real-time weather reports. APRS also is useful to track roving (i.e., mobile) operators in certain ham radio operating events and supports the exchange of short messages.

1.4.5 Image Communication

Users of current technology often enjoy sharing photos or even talking face-to-face. While not as sophisticated, several ham radio communication modes allow the exchange of still or moving images over the air. Advances in technology have brought the price of image transmission equipment within reach of the average ham’s budget. This has caused a surge of interest in image communication.

Amateur TV (ATV) is full-motion video over the air, sometimes called “fast-scan TV.” Amateur Radio communication takes on an exciting, new dimension when you can actually *see* the person you’re communicating with. In addition, ATV has proved to be very useful in emergency and disaster communication situations. Amateur groups in some areas have set up ATV repeaters, allowing lower-power stations to communicate over a fairly wide area. Since this is a wide-bandwidth mode, operation is limited to the UHF bands (70 cm and higher).

Digital ATV folds nicely into a newer Amateur Radio technological initiative called high-speed multimedia (HSMM) radio. The ham bands above 50 MHz can support computer-to-computer communication at speeds high enough to support multimedia applications—voice, data and image. One approach adapts IEEE 802 technologies, particularly

Fig 1.16 — APRS is a popular ham radio digital mode that allows tracking of mobile stations transmitting beacons via packet radio as they travel.

Fig 1.17 — Slow-scan television (SSTV) allows hams to exchange pictures over the air without wide-bandwidth live video equipment.

802.11b, operating on specific Amateur Radio frequencies in the 2400-2450 MHz band.

SSTV or “slow-scan TV” is an older, narrow-bandwidth image mode that remains popular in Amateur Radio. Instead of full-motion video, SSTV enthusiasts exchange photographs and other static images. Individual SSTV pictures take anywhere from 8 seconds to about 2 minutes to send, depending on the transmission method. These days most SSTV operation is done in color, using computers and soundcards in conjunction with software that’s often free. Images are converted into a series of audio tones representing brightness level and colors. Since SSTV is a narrow-band mode, it is popular on HF on the same frequencies used for voice operation.

1.5 Your Ham Radio “Lifestyle”

After some on-the-air experience, many Amateur Radio enthusiasts focus on a particular mode or operating style and may identify themselves primarily as contesters, DXers, CW operators or VHF-UHFers. Others center their operating on such activities as specialized or experimental modes, mobile ham radio, very low-power operating (known as “QRP”) and radio direction finding (RDF).

1.5.1 Ham Radio Contesting — Radiosport

Ham radio contesting, often called “radiosport,” continues to grow in worldwide popularity. Hardly a weekend goes by when there isn’t a ham radio contest of some sort. These on-the-air competitions range from regional operating events with a few hundred participants to national and worldwide competitions with thousands of stations on the air at the same time, attempting to communicate with one another for points.

Objectives vary from one event to another, but ham radio contests typically involve trying to contact — or “work” — as many *other* contest participants on the air within a specified period. In each contact, participants exchange certain information, often a signal report and a location, as the contest’s rules dictate. A lot of contest scoring schemes place a premium on two-way contacts with stations in certain countries, states or zones. Top scorers in the various entry categories usually get certificates, but a few events offer sponsored plaques and trophies. Competition can be fierce among individual contesters and among contest clubs.

There are contests for nearly every mode

and operating preference available to Amateur Radio — voice, Morse code and digital modes. Some members of the contesting community are earnest competitors who constantly tweak their stations and skills to better their scores. Others take a more casual approach. All have lots of fun.

In the ARRL International DX Contest, for example, participants try to contact as many DX (foreign) stations as possible over the course of a weekend. Experienced hams with top-notch stations easily contact 1000 or more stations in more than 100 different countries in a single weekend, but even operators with more modest stations can make lots of contacts.

Other popular contests include state QSO parties, where the goal is to contact stations in as many of the sponsoring state’s counties.

Fig 1.18 — Retired Oakland Athletics baseball All Star Joe Rudi, NK7U, enjoys contesting and DXing from his well-equipped station in Oregon.

ARRL November Sweepstakes (SS) is a high-energy US-and-Canadian contest that attracts thousands of operators each fall. One weekend is dedicated to CW, another to voice. VHF, UHF and microwave contests focus on making contacts using our highest-frequency bands. Digital-mode contests have gained in popularity in recent years, thanks to computer soundcards, radios that offer digital-mode capabilities, and often-free software.

You can find information on contests each month in ARRL’s monthly membership journal *QST*; the contest calendar on the ARRL website also provides up-to-date information on upcoming operating events. The ARRL’s bimonthly publication *National Contest Journal (NCJ)* focuses on topics of particular interest to contesting novices and veterans alike. For timely contest news and information, check “The ARRL Contest Update” e-newsletter at www.arrl.org/contest-update-issues, available every other week via e-mail and on the ARRL website.

ARRL FIELD DAY

An emergency communication training exercise with some elements of a contest, ARRL Field Day (FD) prompts thousands of participants outdoors the field on the fourth full weekend of June. Portable gear in tow, hams take to the hills, forests, campsites, parking lots and even emergency operations centers or vans to take part. Tracing its origins to the 1930s, Field Day started out as a way to publicly demonstrate ham radio’s ability to operate “in the field” and “off the grid.” The goal is not only to make lots of contacts but to operate successfully under

the sorts of conditions that could prevail in the aftermath of a disaster or emergency.

Most stations are set up outdoors and use emergency power sources, such as generators, solar panels, wind turbines and occasionally even water wheels. Creativity reigns when it comes to power sources! Over the years, Field Day's contest-like nature has led to plenty of good-natured competition among clubs and groups. Field Day stations range from simple to elaborate. If a real disaster were to strike, stations such as these could be set up quickly wherever needed, without having to rely on commercial power.

1.5.2 Chasing DX

People unfamiliar with ham radio often ask, "How far can you talk?" Well, "talking far" is what chasing "DX" is all about. DX stations are those in distant places around the world. Chasing DX is a time-honored ham radio tradition. Hams who focus on contacting stations in far-flung and rare locations are called "DXers." Ham radio pioneers a century ago often competed in terms of how far *they* could talk; spanning the Atlantic via ham radio in the early 1920s was a stupendous accomplishment in its day. DXers often have as a goal attaining DX Century Club (DXCC) membership, earning a place on the vaunted DXCC "Honor Roll" or entering the annual ARRL DX Challenge.

Working DX does not necessarily require an expensive radio and huge antenna system. It's possible to work a lot of DX all over the world with very low power and/or with modest

antennas, including wires hung from trees or mobile (ie, vehicle-mounted) antennas.

Some hams specialize in certain ham bands to work DX, such as 160 meters, where DXing can be challenging due to the low operating frequency involved as well as frequent noise and infrequent DX propagation. Others prefer "the high bands," such as 20, 15 and 10 meters, where DX typically is more common and, in fact, typically abounds in times of favorable propagation.

Fig 1.20 — Eric Hall, K9GY and T6MO, deployed with the US military in Afghanistan in 2012, spent some of his down time enjoying ham radio. [Eric Hall, K9GY/T6MO, photo]

DXPEDITIONS

DXers who have run out of new countries to work sometimes couple a love of ham radio and travel to *become* the DX! "DXpeditions" are journeys by hams to "rare" countries having few or no hams, where they set up a station (or stations), often making thousands of contacts in the space of a few days. They not only have a great time but can promote international goodwill.

Some DXpeditions are huge productions. Early in 2011, an international team activated Antarctica's South Orkney Islands, which have no indigenous population. South Orkney Islands count as a separate country (or "entity") for the DXCC award. In the space of about two weeks, the team completed nearly 64,000 two-way contacts with other hams around the world from their remote

Fig 1.19 — ARRL Field Day is the largest Amateur Radio event on the planet, with tens of thousands of hams participating in the 24-hour event each June. These members of the Cheshire County DX Club of Keene, New Hampshire, are enjoying the fun and camaraderie that this popular operating event evokes. [Heather Goodell, photo]

Fig 1.21 — Saraj Cory, KU6F, takes part in "The Day of YLs" contest. She made more than 325 contacts in 44 states and several countries. "YL" (for "young lady") is an old ham radio slang term for a female Amateur Radio operator. Its counterpart is "OM," which stands for "old man."

QSL Cards

Long before the Internet and e-mail, hams began the custom of exchanging postcards that became known as QSL cards or simply QSLs. “QSL” is another radiotelegraph, or Morse code, abbreviation that means “I confirm receipt of your transmission.” A QSL card contains information to verify that a two-way contact took place. Exchanging QSL cards can enhance your ham radio enjoyment and even lead to a regular correspondence.

Hams still take great pride in having distinctive QSL cards to exchange following a contact, although today, thanks to the Internet, electronic means exist, such as ARRL’s Logbook of The World (see sidebar, “Logbook of The World”) to confirm contacts.

DX stations, especially those in very rare places, are often inundated with QSL cards and requests from US hams. To ease the cost and administrative burden, most DX QSLs travel via QSL bureaus, which ship cards in bulk, then sort and distribute them on the receiving end. The Outgoing QSL Service is available to ARRL members at nominal cost. The incoming QSL bureaus are available to all amateurs. Bureau instructions and addresses are on the ARRL website.

encampment. Members of the worldwide Amateur Radio community dig deep into their pockets to fund DXpeditions such as this one, which cost upward of \$350,000. The 2012 HKØNA Malpelo Island DXpedition off the coast of Colombia logged more than 195,000 contacts on 160 through 6 meters, breaking the record for a “non-hotel, non-fly-in” DXpedition!

Most DXpeditions are smaller affairs in which one or two operators may combine a vacation with some on-air fun. Activity often peaks in conjunction with major DX contests. If you don’t want to drag your radio and antennas along, fully equipped DX stations sometimes are available to rent in more-frequented locations, such as Hawaii and the Caribbean islands.

DX SPOTS AND NETS

The beginning DXer can get a good jump on DXCC by frequenting the DX spotting sites on the Internet. A DX spotting website is essentially an Internet clearing house of reports — or “spots” — posted by other DXers of stations actually heard or worked. The DX Summit website, www.dxsummit.fi, hosted in Finland is a popular one. Users around the world post spots in real time. Each lists the call sign and frequency of the DX station as well as the call sign of the station

Logbook of The World

Instead of exchanging and collecting QSL cards, more and more radio amateurs are taking advantage of the ARRL’s Logbook of The World to confirm contacts for award credit. LoTW is a world repository of individual radio contact records submitted by users. When both participants in a radio contact submit matching QSO records to LoTW, the result is a virtual QSL that each ham can apply toward ARRL award credit. Uploading contact data costs nothing; users only pay to “redeem” their QSO credits for an award, such as ARRL’s DXCC, VUCC, WAS and the WPX Award sponsored by CQ Communications.

Once signed up as a Logbook user, you can submit new contact records whenever you wish. Your submissions are matched against those of other Logbook users. Whenever a match occurs, you receive instant credit for the contact.

To minimize the chance of fraudulent submissions, all LoTW QSO records are digitally “signed” by the licensee, who must hold an LoTW certificate. LoTW began operation in 2003 and in 2014 had more than 65,000 users and more than half a billion QSO records in the system. Visit the Logbook of The World website, www.arrl.org/logbook-of-the-world, to learn more.

that posted the spot. Knowing where the DX station is being heard can tell you if you’re likely to hear the DX station at *your* location.

DX nets offer another DX gateway. On DX nets, a net control station tracks which DX stations have checked into the net, then allows individual operators on frequency to try working one of the DX stations. This permits weaker stations to be heard instead of their signals being covered up by stations calling in a “pileup.”

1.5.3 Operating Awards

Earning awards that reflect Amateur Radio operating accomplishments is a time-honored tradition. Literally hundreds of operating awards are available to suit your level of activity and sense of accomplishment.

WORKED ALL CONTINENTS

The Worked All Continents (WAC) certificate is a good starting point for newcomers. Sponsored by the International Amateur Radio Union (IARU), earning WAC requires working and confirming contacts with one station on each of six continents (excluding Antarctica).

WORKED ALL STATES

Hams who can confirm two-way ham radio contacts with stations in each of the 50 United States can apply for the popular ARRL’s Worked All States (WAS) award. Those who enjoy operating different bands and a seek a greater challenge may attempt the ARRL’s 5-Band WAS (5BWAS) award by confirming contacts with all 50 US states on each of the 80, 40, 20, 15 and 10 meter bands.

A twist on the WAS award is the ARRL’s Triple Play Award. Introduced in 2009, it was an instant hit. To earn the Triple Play Award,

Fig 1.22 — The ARRL Worked All States (WAS) certificate is awarded for confirming contacts with hams in all 50 states. Confirmations may be made by traditional paper QSL cards, or electronically through ARRL’s Logbook of The World online database.

an amateur must contact other amateurs in each of the 50 US states using voice, Morse code and a digital mode, such as RTTY or PSK31. All qualifying contacts must be confirmed via the ARRL’s Logbook of the World (LoTW — see sidebar, “Logbook of The World”). The Triple Play Award is available to hams worldwide.

DX CENTURY CLUB

The most prestigious and popular DX award is the DX Century Club (DXCC), sponsored by the ARRL. Earning DXCC is quite a challenge. You must confirm two-way contact with stations in 100 countries (or “entities,” as they’re known in the DXCC program). Hams with very simple stations have earned DXCC. Operating in various DX contests when stations all over the world are looking for contact is a good way to combine

DXing and contesting and to get a leg up on earning DXCC. There's also a 5-Band DXCC (5BDXCC) for earning DXCC on each of five bands, 80, 40, 20, 15 and 10 meters.

Top-rung DX enthusiasts have been challenging themselves and each other through the ARRL DXCC Challenge. This ongoing activity involves confirming contacts with DXCC entities on all bands from 160 through 6 meters.

VHF/UHF CENTURY CLUB

Hams who operate on the VHF and UHF bands have a "century club" of their own, the VHF/UHF Century Club. Instead of working 100 DXCC entities, participants earn awards for making two-way contacts with a specified number of Maidenhead $2^\circ \times 1^\circ$ grid locators or "grid squares," as they're more commonly known. Grid squares are designated by a combination of two letters and two numbers and represent a specific area on the globe. For operations on 6 meters, 2 meters and satellite, operators must contact 100 individual grid squares. More information is on the ARRL website, www.arrl.org/awards/vucc.

1.5.4 Satellite Communication

Amateur Radio established its initial foothold in space in 1961, with the launch of the OSCAR 1 satellite (OSCAR is an acronym for Orbiting Satellite Carrying Amateur Radio). Since then, amateurs have launched dozens of satellites, most of the low-earth orbit (LEO) variety and a small number in the high-earth orbit category. The history of Amateur Radio satellites and information on

Fig 1.23 — Hams can use simple antennas and hand-held radios to contact amateur satellites, even the International Space Station. Sean Kutzko, KX9X took his satellite gear along during a vacation to Puerto Rico, making contacts via the AO-27 orbiting "bird." [Ward Silver, (NØAX, photo)]

Fig 1.24 — Tiny Amateur Radio "CubeSats" are deployed into orbit from a robotically controlled launcher on the International Space Station, after traveling into space on a cargo rocket. The advent of CubeSats and the availability of launches from the ISS have made it easier and cheaper to put all sorts of satellites into orbit. [NASA photo]

which ones are in operation is available on the AMSAT website, www.amsat.org.

Amateurs have pioneered several developments in the satellite industry, including low-earth orbit communication "birds" and PACSATs — orbiting packet-radio bulletin board systems — and CubeSats which are standard-sized miniature satellites constructed by student teams around the world. Operating awards, are available from ARRL and other organizations specifically for satellite operation.

Satellite operation is neither complex nor difficult; it's possible to work through some satellites with nothing more than a dual-band (VHF/UHF) handheld radio and perhaps a small portable antenna. More serious satellite work requires some specialized equipment. You may be able to work several Amateur Radio satellites (OSCARs) with the equipment that's now in your shack!

AMATEUR RADIO IN SPACE

In 1983, ham-astronaut Owen Garriott, W5LFL, operated the first ham radio station in space, communicating with earthbound hams from the space shuttle *Columbia*. NASA subsequently made Amateur Radio a part of many shuttle missions and later a permanent presence aboard the International Space Station. The Russian *Mir* space station also was equipped with ham radio, and since those early days, dozens of astronauts and cosmonauts from several countries have communicated from their orbital perches with hams on earth. NASA has promoted ham activity aboard spacecraft because of its proven educational and public relations value — and because ham radio could be used for backup communication in a pinch.

The Amateur Radio on the International Space Station (ARISS) program, www.arrl.org/amateur-radio-on-the-international-space-station and www.ariss.rac.ca, is the

international organization for ham radio in space. ARISS is a consortium of the ARRL, AMSAT and NASA. The all-volunteer program seeks to inspire students worldwide to pursue careers in science, technology, engineering and math by making available opportunities to speak with on-orbit ISS crew members via ham radio. The ARISS International Working Group includes representatives of nine countries, including the US, several European nations and Japan, Russia and Canada. ARISS-provided ham gear on two ISS modules makes possible analog voice and digital communication between earthbound hams and the ISS crew as well as with the onboard ISS digipeater packet radio mailbox and APRS digipeater.

Most ISS crew members are Amateur Radio licensees. During scheduled contacts with demonstration stations set up in schools around the world, students are able to ask the astronauts questions about their time in space and life aboard the space station. These voice contacts typically take place using VHF FM (2 meter) equipment. Some Amateur Radio satellites have been launched from the ISS.

1.5.5 QRP: Low-Power Operating

A very active segment of the Amateur Radio community enjoys operating with minimal transmitting power. They call themselves "QRP operators" or "QRPs" after the Morse code abbreviation for "I shall decrease transmitter power." According to the FCC rules regulating Amateur Radio, "An amateur station must use the minimum transmitter power necessary to carry out the desired communications." The FCC allows most hams to transmit or "run" up to 1500 W (watts), and many hams run 100 W. QRPs, however, typically use 5 W or less — sometimes *far* less (one ham achieved

Fig 1.25 — Some hams enjoy building their own equipment to learn more about radio and electronics. This photo shows one of the winning entries in a recent ARRL “homebrew” competition — a complete transceiver for the 6, 10 and 12 meter amateur bands designed and built by Jim Veatch, WA2EJJ.

Fig 1.26 — Portable or “mountaintopping” operation is very popular on the VHF and UHF bands. In this photo Bob Witte, KØNR has set up a station atop Mt Herman, near Monument, Colorado. [Joyce Witte, KØJJW. photo]

WAS while running 2 milliwatts — that’s two-thousandths of a watt!).

Operating QRP can be challenging. Other stations may not hear your signal as easily, so patience becomes a real virtue, both for the low-power enthusiast and the station on the other end of the contact. What their stations lack in transmitting power QRPers make up for with effective antennas and skillful operating, and they make contacts around the world. This operating style has become so popular that many contests now include an entry category for stations running 5 W or less output power.

One of the best reasons to operate QRP is that low-power equipment typically is lightweight and less expensive. Many QRP operators enjoy designing and building their own “flea-power” transceivers, and various organizations support low-power operating by offering kits, circuits and advice. A few commercial manufacturers also market QRP equipment and kits. The QRP Amateur Radio Club International (www.qrparci.org) is perhaps the oldest organization to advance and promote QRP as a ham radio way of life. In addition to sponsoring various operating events throughout the year, QRP ARCI publishes *QRP Quarterly*, which includes articles of interest to both QRP operators and the broader ham radio community.

1.5.6 Operating Mobile

Many hams enjoy operating on the fly — usually from a car or truck but sometimes from a boat, a motorcycle, a bicycle and even while on foot (sometimes called “pedestrian

mobile” or “manpack radio”)! Operating radio gear installed in a motor vehicle is the most common form of “mobile,” and manufacturers today offer a wide range of ham radio gear, including antennas, designed for such work. A mobile station can be as simple as a basic VHF or dual-band VHF/UHF radio and a little antenna attached magnetically to the roof, or as complex as an HF station and a more substantial antenna system. Some mobile stations are very sophisticated, with capabilities that rival those of many fixed stations.

While most hams who operate mobile use FM or SSB, a significant number operate CW while on the road. It takes a bit of practice, in part because the operator must learn to understand (or “copy”) Morse code without having to write it down.

Hams on bicycle treks or hikes carry along lightweight radio gear. A lot of cyclists or hikers pack a small ham radio transceiver and wire antenna along with their sleeping bag, food and water.

1.5.7 VHF, UHF and Microwave Operating

Hams use many modes and techniques to extend the range of their line-of-sight VHF, UHF and microwave signals. Those who explore the potential of VHF/UHF communication often are called “weak-signal” operators to differentiate them from FM operators who communicate locally — although the signals involved often are not really *weak*.

These enthusiasts and experimenters probe the limits of propagation in the upper reaches

of the Amateur Radio spectrum, often with the goal of discovering just how far they can communicate. They use directional antennas (beams or parabolic dishes) and very sensitive receivers. In some instances, they also employ considerable transmitter output power. As a result of their efforts, distance records are broken almost yearly. On 2 meters, for example, conversations between stations hundreds and even thousands of miles apart are not uncommon even though the stations are far beyond “line of sight” separation. Maximum distances decrease as frequencies increase, but communication regularly can span several hundred miles, even at microwave frequencies.

Weak-signal operators for many years depended on SSB and CW, but computer/sound card-based digital modes are now part of their arsenal. These modes use state-of-the-art digital signal processing (DSP) software for transmitting and receiving very weak signals that can be well below levels that the human ear can detect.

MOONBOUNCE (EME)

EME (Earth-Moon-Earth) communication, commonly called “moonbounce,” fascinates many amateurs. The concept is simple: Use the Moon as a passive reflector of VHF and UHF signals. Considering the total path of some 500,000 miles, EME is the ultimate DX — at least to date. The first two-way amateur EME contacts took place in 1952.

In its earliest days EME was a CW mode activity requiring large antennas and high power. Advances in technology, such as low-noise receivers and digital signal processing

Fig 1.27 — Justin De Vuyst, N2ZBH, enjoyed some great views as a “rover” during the 2013 ARRL January VHF Contest. He operated on mountaintop locations in several New Jersey grid squares to hand out contacts. [Justin De Vuyst, N2ZBH, photo]

(DSP) tools, have made EME contacts possible for more and more amateurs with modest stations.

METEOR SCATTER

Years ago hams discovered they could bounce signals off the ionized trails of vaporized matter that follow meteors entering Earth’s atmosphere. Such trails often can reflect VHF radio signals for several seconds, during which stations can exchange extremely brief reports. During meteor showers, the ionized region becomes large enough — and lasts long enough — to sustain short contacts. It’s exciting to hear a signal from hundreds of miles away pop out of the noise for a brief period!

Amateurs experimenting with meteor-scatter propagation use transmitter powers of 100 W or more and beam antennas. Most contacts are made using SSB, CW or digital modes. Although most SSB and CW QSOs are made during annual meteor showers, digital mode contacts are possible any day of the year.

Nobel laureate astrophysicist and radio amateur Joe Taylor, K1JT, has developed open-source *Windows* and *Linux* software (under the *WSJT* umbrella) for weak-signal digital communication via meteor scatter, moonbounce and similar techniques on VHF and UHF, as well as for HF skywave propagation. Taylor says on his *WSJT* home page (physics.princeton.edu/pulsar/K1JT) that his program “can

decode fraction-of-a-second signals reflected from ionized meteor trails and steady signals 10 dB below the audible threshold.”

1.5.8 Vintage Radio

Many, if not most, veteran radio amateurs have a nostalgic streak, and this extends toward vintage radio gear. Present-day commercial Amateur Radio equipment has reached a level of complexity that often requires specialized test and troubleshooting equipment to repair or align. Modern component manufacturing technology such as surface-mount devices (SMDs) has become so commonplace that a modular approach to equipment repair is commonplace; rather than troubleshoot and replace a defective component, many manufacturers now prefer to swap out an entire module.

Yet many amateurs still would rather repair and adjust their own equipment and covet the days when this was simpler and easier. This is but one reason behind the surge in vintage radio collecting and operating. Others enjoy vintage gear for its lower cost and wider availability, the novelty of operating older gear on today’s ham bands, and for its rarity and antique value. Many of these radios are affectionately called “boat anchors” by vintage radio aficionados, since early radio gear tends to be relatively large and heavy.

Some enthusiasts enjoy the challenge of collecting and restoring older radios, sometimes striving to bring the equipment back to

Fig 1.28 — Hams enjoy restoring and using old radio equipment. Rod Bunn, KA6ROD restored his Heathkit transceiver and station monitor to use during the annual ARRL Straight Key Night special operating event.

Fig 1.29 — Vintage vacuum tubes such as these were among the wares on sale in the Dayton Hamvention 2012 flea market, helping to satisfy the ham radio community’s appetite for nostalgia. Flea markets are good sources for parts needed to refurbish older ham gear that many enjoy collecting. [Rick Lindquist, WW1ME, photo]

its original factory condition. Other vintage radio enthusiasts may have a parallel interest in conventional AM voice transmission. These activities take vintage radio fans back to an era when it was much more common for amateurs to build their own station equipment.

1.5.9 Radio Direction Finding (DF)

DFing is the art of locating a signal or noise source by tracking it with portable receivers and directional antennas. Direction finding is not only fun, it has a practical side.

Hams who are proficient at DFing have been instrumental in hunting down signals from illegal jammers and malfunctioning transmitters in addition to locating noise (interference) sources. Because DFing only involves receiving, it does not require a ham ticket, however.

“Fox hunting” — also called “T-hunting,” “radio-orienteeing” or “bunny hunting” — is ham radio’s answer to hide-and-peek. One player is designated the fox; he or she hides a transmitter, and the other players attempt to find it. Rules vary, but the fox must generally place the transmitter within certain

boundaries and transmit at specific intervals.

Fox hunts differ around the world. American fox hunts often employ teams of fox hunters cruising in vehicles over a wide area. European and other fox hunters restrict their events to smaller areas and conduct fox hunts on foot. *Radiosport* competitions typically follow the European model and attract hundreds or more competitors.

DF techniques can come into play when tracking down sources of interference on the ham bands — intentional or inadvertent — or when there’s a suspected “pirate” (unlicensed ham station) in the area.

1.6 Public Service

Providing communication in support of public service at no cost forms part of the Basis and Purpose of the Amateur Radio Service and has been a traditional responsibility of Amateur Radio from the start. Today, this most often involves ham radio’s volunteer efforts during disasters and emergencies.

When Hurricane Sandy struck New York City and the Middle Atlantic States in the fall of 2012, the Amateur Radio community from Maine to the Carolinas responded to requests for assistance, activated local nets and supported the operations of the Hurricane Watch Net and the VoIP Hurricane Net. Hams volunteered around the clock to bridge the gap in the wake of downed utility lines to provide communication for evacuation efforts, as well as to link hospitals experiencing communications breakdowns, shelters, emergency operations centers and non-government relief agencies, such as The American Red Cross and The Salvation Army, which has its own Amateur Radio contingent, The Salvation Army Team Emergency Radio Network (SATERN). Radio amateurs also assisted after the storm by helping officials to assess damage. Many hams also are part of SKYWARN, which helps to identify and track severe weather activity via ham radio and coordinates its efforts with the National Weather Service.

Public service can take less dramatic forms: Hams also step forward to provide communication for walkathons, marathons, bike races, parades and other community events. The Boston and New York City marathons are two major events that welcome Amateur Radio assistance.

1.6.1 Public Service Communication

The ability to provide communication during disasters is a major justification for Amateur Radio’s existence. Government officials on all levels and the general public

have come to recognize that Amateur Radio works when other communications networks are unavailable. Despite the proliferation of cell phones and other personal communication devices, Amateur Radio continues to prove its value, since it can operate without an existing infrastructure. Ham radio doesn’t need the mobile telephone network or the Internet.

Battery-powered equipment allows hams to provide essential communication even when power is knocked out. If need be, hams can make and install antennas on the spot from available materials. In the wake of hurricanes, forest fires, earthquakes and other natural disasters that cripple or compromise normal communications, hams may be called upon to handle thousands of messages in and out of the stricken region. The work that hams do during crisis situations cultivates good relations with neighbors and with local governments.

Amateur Radio operators have a long tradition of operating from back-up power sources. Through events such as Field Day, hams cultivate the ability to set up communication posts wherever they are needed. Moreover, Amateur Radio can provide computer networks (with over-the-air links as needed) and other services, such as video, that no other service can deploy on the fly, even on a wide scale.

1.6.2 Public Service Communication Organizations

Should a disaster or emergency arise, volunteer teams of amateurs from disaster response organizations cooperate with first responders such as police and fire personnel, and with the Red Cross and medical personnel to provide or supplement communication. Hams sometimes are called upon to fill

Fig 1.30 — At the 2014 Boston Marathon ARES volunteer Marek Kozubal, KB1NCG, deployed in an indoor command center to support communication for the annual event. [Courtesy of Paul Topolski, W1SEX]

the communication gap between agencies whose radio systems are incompatible with one another.

ARES AND RACES

Ham radio disaster response activities typically take place under the umbrella of the Amateur Radio Emergency Service (ARES®), sponsored by the ARRL, and the Radio Amateur Civil Emergency Service (RACES), administered by the Federal Emergency Management Agency (FEMA). RACES works with government agencies to maintain civil preparedness and provide communication in times of civil emergency. RACES is activated at the request of a local, state or federal official. To remain at the ready, hams affiliated with emergency communication teams assess their systems and themselves through regularly scheduled nets and simulated emergency tests (SETS).

ARES and RACES organizations frequently work hand-in-hand. Amateurs serious about disaster response communication typically are active in both groups or may carry dual ARES/RACES membership. FCC rules make it possible for ARES and RACES to use many of the same frequencies, so an ARES group also enrolled in RACES can work within either organization as circumstances dictate.

MILITARY AUXILIARY RADIO SYSTEM (MARS)

MARS is administered by the US armed forces. Its primary mission is to provide adjunct communication support to military and federal government homeland defense

operations on a local, national and international basis. MARS volunteers joined Amateur Radio organizations to assist medical and humanitarian relief efforts in the wake of the devastating 2010 earthquake in Haiti. MARS has existed in one form or another since 1925.

There are three branches of MARS: Army MARS, Navy/Marine Corps MARS and Air Force MARS. Each branch has its own membership requirements, although all three branches require members to hold a valid US Amateur Radio license and to be at least 18 years old (in some cases, amateurs who are 17 years old may join with the signature of a parent or legal guardian).

MARS operation takes place on frequencies adjacent to the amateur bands and usually consists of nets scheduled to handle traffic or to handle administrative tasks. Various MARS branches also maintain repeaters or packet radio networks.

1.6.3 Public Service and Traffic Nets

The ARRL came into existence to coordinate and promote the formation of message-handling nets, so public service and traffic nets are part of a tradition that dates back almost to the dawn of Amateur Radio. In those early days, nets were needed to communicate over distances greater than a few miles. From their origination point, messages (also called “traffic”) leapfrogged from amateur station to amateur station to their destination — thus the word “relay” in American Radio Relay League. It still works that way

today, although individual stations typically have a much greater range.

Some nets and stations are typically only active in emergencies. These include Amateur Radio station WX4NHC at the National Hurricane Center, the Hurricane Watch Net, SKYWARN (weather observers), The Salvation Army Team Emergency Radio Network (SATERN), The Waterway Net and the VoIP (voice over Internet protocol) SKYWARN/Hurricane Net.

THE NATIONAL TRAFFIC SYSTEM (NTS)

The National Traffic System (NTS) exists to pass formal written messages from any point in the US to any other point. Messages, which follow a standard format called a “Radiogram,” are relayed from one ham to another, using a variety of modes, including voice, Morse code, RTTY or packet. An NTS operator who lives near the recipient typically delivers the message by telephone.

During disasters or emergencies, radiograms communicate information critical to saving lives or property or to inquire about the health or welfare of disaster victims. At such times, the NTS works in concert with the Amateur Radio Emergency Service (ARES) and other emergency and disaster-relief organizations, such as the American Red Cross and The Salvation Army.

The NTS oversees many existing traffic nets, which meet daily. Most nets are local or regional. Handling routine message traffic such as birthday and holiday greetings keeps NTS participants prepared for emergencies.

1.7 Ham Radio in the Classroom

Amateur Radio is a terrific teaching tool! Many individuals began their path towards careers in electronics and wireless communication thanks to their experiences with Amateur Radio as children and teenagers.

Amateur Radio complements any school curriculum and gives students a chance to make a direct and immediate connection with their studies. For example, the math and science used in Amateur Radio apply equally in the classroom. Even geography takes on a new meaning when students are able to contact other countries around the globe and even to speak with the people who live in them!

Local volunteers are important to establishing an active Amateur Radio presence in schools. An HF or satellite station or even a VHF or UHF handheld transceiver tuned to the local repeater can prove an exciting and educational experience for pupils and volunteers alike.

Fig 1.31 — Canadian Radio Amateur Peter West, VE3HG, enjoys contesting and low-power (QRP) operating. His station is tucked into the back of his family's main-floor home office and shared with his wife Marion, VE3HEN. [Mike Goldstein, VE3GFN, photo]

Fig 1.32 — Sixth-grade teacher Kaci Heins, KF7RCV (left in flight suit) stands by while one of her students in Flagstaff, Arizona, speaks with astronaut Joe Acaba, KE5DAR aboard the ISS during an Amateur Radio on the International Space Station (ARIS) school contact. Heins got her own ham ticket while preparing her class for the event. (Courtesy Kacy Heins, KF7RCV)

Fig 1.33 — At Eisenhower Middle School in Lawton, Oklahoma, Jada, KF5TAT (left) and Kerson, KF5TAQ sit at the Viking Radio Club station in the classroom of teacher Clifton Harper, KE5YZB. The school received a ham radio equipment grant through the ARRL Foundation and in 2012 Harper attended an ARRL Education & Technology Program Teacher's Institute on Wireless Technology at ARRL Headquarters. [Pamely Harper, KF5JXO, photo]

Thanks to the Amateur Radio on the International Space Station (ARIS) program, amateurs all over the nation have made it possible for students to speak directly with astronauts in space via ham radio.

1.7.1 ARRL Amateur Radio Education & Technology Program

Through the ARRL Amateur Radio Education & Technology Program (ETP), Amateur Radio can become a valuable resource for the classroom teacher. The goal of the ETP is “to build a foundation of wireless technology literacy to US teachers and students.” Launched in 2000 the program continues to offer resources to schools, including

ham radio equipment, at no cost, thanks to the support of donors in the Amateur Radio community. The ETP emphasizes the integration of technology, math, science, geography, writing, speaking and social responsibility within a global society. Applying Amateur Radio as part of the class curriculum offers students a new dimension to learning. Each summer the ETP sponsors Teachers Institute on Wireless Technology sessions for educators, to enable them to make the most effective use of the ETP in their schools.

Amateur Radio emphasizes self-challenge, the value of lifelong learning and the importance of public service. From a more practical standpoint, future employers will be looking for candidates who are familiar not only with computers but with the sorts of

wireless communication concepts used in Amateur Radio.

The ETP offers a range of resources to encourage educators. These include publications related to the use of technology in wireless communications; workshops, tips and ideas for teaching wireless technology in schools, community groups and clubs; and lesson plans and projects to help provide authentic, hands-on technological experiences for students.

Schools interested in incorporating Amateur Radio into their curricula, using it as an enrichment program or as a club activity may apply to become Project schools. See www.arrrl.org/education-technology-program for more information on the ARRL Education & Technology Program.

1.8 Resources

ARRL—the National Association for Amateur Radio

225 Main St
Newington, CT 06111-1494
860-594-0200
Fax: 860-594-0259
e-mail: hq@arrl.org
Prospective hams call 1-800-32 NEW HAM (1-800-326-3942)

www.arrl.org

Membership organization of US ham radio operators and those interested in ham radio. Publishes study guides for all Amateur Radio license classes, a monthly journal, *QST*, and many books on Amateur Radio and electronics.

Amateur Radio Service Rules & Regulations — FCC Part 97

Available on the ARRL website: www.arrl.org/part-97-amateur-radio
Available as a PDF file on the FCC website: www.fcc.gov/Bureaus/Engineering_Technology/Documents/cfr/1998/47cfr97.pdf

AMSAT NA (The Radio Amateur Satellite Corporation Inc)

10605 Concord St #304
Kensington, MD 20895
888-322-6728 or 301-822-4376
www.amsat.org

Membership organization for those interested in Amateur Radio satellites.

Courage Handi-Ham System

3915 Golden Valley Rd
Golden Valley, MN 55422
763-520-0512 or 866-426-3442
www.handiham.org

Provides assistance to persons with disabilities who want to earn a ham radio license or set up a station.

OMIK Amateur Radio Association

www.omikradio.org

OMIK, an ARRL affiliated club, is the largest predominately African-American Amateur Radio organization in the US. It promotes fellowship and Amateur Radio advancement and offers scholarships and other financial assistance for college-bound youth.

The ARRL Ham Radio License Manual

www.arrl.org/ham-radio-license-manual

Complete introduction to ham radio, including the exam question pool, complete explanations of the subjects on the exams. Tips on buying equipment, setting up a station and more.

The ARRL's Tech Q&A

www.arrl.org/shop/

Contains all of the questions in the Technician Class question pool, with correct answers highlighted and explained in plain English. Includes many helpful diagrams.

General Information and Other Study Material

The ARRL website (www.arrl.org) carries a wealth of information for anyone interested in getting started in Amateur Radio. For complete information on all options available for study material, check out the “Welcome to the World of Ham Radio” page, www.arrl.org/what-is-ham-radio and its associated links. You can also use the ARRL website to search for clubs, classes and Amateur Radio exam sessions near you.

1.9 Glossary

AM (Amplitude modulation) — The oldest voice operating mode still found on the amateur bands. The most common HF voice mode, SSB, is actually a narrower-bandwidth variation of AM.

Amateur Radio — A radiocommunication service for the purpose of self-training, intercommunication and technical investigation carried out by licensed individuals interested in radio technique solely with a personal aim and without pecuniary interest. (*Pecuniary* means payment of any type, whether money or goods.) Also called “ham radio.”

Amateur Radio operator — A person holding an FCC license to operate a radio station in the Amateur Radio Service.

Amateur Radio station — A station licensed by the FCC in the Amateur Radio Service, including necessary equipment.

Amateur (Radio) Service — A radiocommunication service for the purpose of self-training, intercommunication and technical investigations carried out by licensed individuals interested in radio technique solely with a personal aim and without pecuniary interest.

AMSAT (Radio Amateur Satellite Corporation)

— An international membership organization that designs, builds and promotes the use of Amateur Radio satellites, which are called “OSCARs.”

APRS—Automatic Packet/Position Reporting System, a marriage of an application of the Global Positioning System and Amateur Radio to relay position and tracking information.

ARES (Amateur Radio Emergency Service) — An ARRL program for radio amateurs who participate in emergency communication.

ARISS — An acronym for Amateur Radio on the International Space Station. NASA, ARRL and AMSAT cooperate in managing the ARISS Program.

ARRL — The national association for Amateur Radio in the US; the US membership society in the *IARU* (International Amateur Radio Union).

ATV (Amateur television) — An Amateur Radio operating mode for sharing real-time video.

Band — A range of frequencies in the radio spectrum, usually designated by approximate wavelength in meters. For

example, 7.0 to 7.3 MHz (megahertz) is the 40 meter amateur band. Hams are authorized to transmit on many different bands.

Bandwidth — In general, the width of a transmitted signal in terms of occupied spectrum. FCC definition: “The width of a frequency band outside of which the mean power of the transmitted signal is attenuated at least 26 dB below the mean power of the transmitted signal within the band.”

Beacon — An amateur station transmitting communication for the purposes of observation of propagation and reception or other related experimental activities.

Beam antenna — A ham radio antenna having directional characteristics to enhance the transmitted signal in one direction at the expense of others. A “rotary beam” can be pointed in any direction.

Broadcasting — Transmissions intended for reception by the general public, either direct or relayed. Amateur Radio licensees are not permitted to engage in broadcasting.

Call sign — A series of unique letters and

- numerals that the FCC assigns to an individual who has earned an Amateur Radio license.
- Contact** — A two-way communication between Amateur Radio operators.
- Contest** — A competitive Amateur Radio operating activity in which hams use their stations to contact the most stations within a designated time period.
- Courage Handi-Ham System** — Membership organization for ham radio enthusiasts with various physical disabilities and abilities.
- CW** — A synonym for radiotelegraphy (ie, Morse code by radio). CW is an abbreviation for “continuous wave,” a term used in the early years of wireless.
- Digital communication** — Computer-based communication modes such as RTTY, PSK31, packet and other radio transmissions that employ an accepted digital code to convey intelligence or data.
- Dipole antenna** — Typically, a wire antenna with a feed line connected to its center and having two legs. Dipoles most often are used on the high-frequency (HF) amateur bands.
- DSP (digital signal processing)** — Technology that allows software to replace electronic circuitry.
- DX** — A ham radio abbreviation that refers to distant stations, typically those in other countries.
- DXCC** — DX Century Club, a popular ARRL award earned for contacting Amateur Radio operators in 100 different countries or “entities.”
- DXpedition** — A trip to a location — perhaps an uninhabited island or other geographical or political entity — which has few, if any, Amateur Radio operators, thus making a contact rare.
- Elmer** — A traditional term for a person who enjoys helping newcomers get started in ham radio; a mentor.
- Emergency communication** — Amateur Radio communication during a disaster or emergency that support or supplants traditional means of telecommunication.
- FCC (Federal Communications Commission)** — The government agency that regulates Amateur Radio in the US.
- Field Day** — A popular, annual Amateur Radio activity sponsored by the ARRL during which hams set up radio stations, often outdoors, using emergency power sources to simulate emergency operation.
- Field Organization** — A cadre of ARRL volunteers who perform various services for the Amateur Radio community at the state and local level.
- FM (Frequency modulation)** — A method of transmitting voice and the mode commonly used on ham radio repeaters.
- Fox hunt** — A competitive radio direction-finding activity in which participants track down the source of a transmitted signal.
- Fast-scan television** — A mode of operation that Amateur Radio operators can use to exchange live TV images from their stations. Also called *ATV (Amateur Television)*.
- Ham band** — A range of frequencies in the radio spectrum on which ham radio communication is authorized.
- Ham radio** — Another name for Amateur Radio.
- Ham radio operator** — A radio operator holding a license granted by the FCC to operate on Amateur Radio frequencies.
- HF (high frequency)** — The radio frequencies from 3 to 30 MHz.
- HSM (high-speed multimedia)** — A digital radio communication technique using spread spectrum modes primarily on UHF to simultaneously send and receive video, voice, text, and data.
- IARU (International Amateur Radio Union)** — The international organization made up of national Amateur Radio organizations or societies such as the ARRL.
- Image** — Facsimile and television signals.
- International Morse Code** — A digital code in which alphanumeric characters are represented by a defined set of short and long transmission elements — called “dots and dashes” or “dits and dahs” — that many Amateur Radio operators use to communicate.
- ITU (International Telecommunication Union)** — An agency of the United Nations that allocates the radio spectrum among the various radio services.
- MARS** — Military Auxiliary Radio System, a volunteer auxiliary communication program that supports the US Department of Defense and federal government homeland defense activities. Most MARS operators are Amateur Radio operators.
- Mode** — A type of ham radio communication, such as frequency modulation (FM voice), slow-scan television (SSTV), SSB (single sideband voice), CW (Morse code), or digital (eg, PSK-31 or JT65).
- Morse code** — A communication mode characterized by on/off keying of a radio signal to convey intelligence. Hams use the International Morse Code.
- Net** — An on-the-air meeting of hams at a set time, day and radio frequency, usually for a specific purpose.
- Packet radio** — A computer-to-computer radio communication mode in which information is encapsulated in short groups of data called packets. These packets contain addressing and error-detection information.
- Phone** — Emissions carrying speech or other sound information, such as FM, SSB or AM.
- Public service** — Activities involving Amateur Radio that hams perform to benefit their communities.
- QRP** — An abbreviation for low power.
- QSL bureau** — A system for sending and receiving Amateur Radio verification or “QSL” cards.
- QSL cards** — Cards that provide written confirmation of a communication between two hams.
- QST** — The monthly journal of the ARRL. *QST* means “calling all radio amateurs.”
- RACES (Radio Amateur Civil Emergency Service)** — A radio service that uses amateur stations for civil defense communication during periods of local, regional or national civil emergencies.
- RF (Radio frequency)** — Electromagnetic radiation in the form of radio waves.
- Radio (or Ham) shack** — The room where Amateur Radio operators keep their station.
- Radiotelegraphy** — See **Morse code**.
- Receiver** — A device that converts radio signals into a form that can be heard or viewed.
- Repeater** — A typically unattended amateur station, usually located on a mountaintop, hilltop or tall building, that automatically and simultaneously receives and retransmits the signals of other stations on a different channel or channels for greater range.
- RTTY (radio teletype)** — Narrow-band direct-printing radioteletype that uses a digital code.
- Space station** — An amateur station located more than 50 km above Earth’s surface.
- SSB (Single sideband)** — A common mode of voice of Amateur Radio voice transmission.
- SSTV (Slow-scan television)** — An operating mode ham radio operators use to exchange still pictures from their stations.
- SWL (Shortwave listener)** — A person who enjoys listening to shortwave radio broadcasts or Amateur Radio conversations. (A *BCL* is someone who listens for distant AM broadcast stations. Some SWLs also are BCLs.)
- TIS (Technical Information Service)** — A service of the ARRL that helps hams solve technical problems (www.arrl.org/tis).

Transceiver — A radio transmitter and receiver combined in one unit.

Transmitter — A device that produces radio-frequency (RF) signals.

UHF (Ultra-high frequency) — The radio frequencies from 300 to 3000 MHz.

VE (Volunteer Examiner) — An Amateur

Radio operator who is qualified to administer Amateur Radio licensing examinations.

VHF (Very-high frequency) — The radio frequency range from 30 to 300 MHz.

WAS (Worked All States) — An ARRL award that is earned when an Amateur

Radio operator confirms two-way radio contact with other stations in all 50 US states.

Wavelength — A means of designating a frequency band, such as the 80 meter band.

Work — To contact another ham.

Electrical Fundamentals

Building on the work of numerous earlier contributors (most recently Roger Taylor, K9ALD's section on DC Circuits and Resistance), this chapter has been updated by Ward Silver, NØAX. Kai Siwiak, KE4PT, updated the material on Q and on resonant circuits. Look for the section "Radio Mathematics," available on the *Handbook* CD-ROM for a list of online math resources and sections on some of the mathematical techniques used in radio and electronics. Glossaries follow the sections on dc and ac theory, as well.

Chapter 2 — CD-ROM Content

- "Thermistor Based Temperature Controller" by Bill Sabin, WØIYH

2.1 Introduction to Electricity

The *atom* is the primary building block of matter and is made up of a *nucleus*, containing *protons* and *neutrons*, surrounded by *electrons*. Protons have a positive electrical charge, electrons a negative charge, and neutrons have no electrical charge. An *element* (or *chemical element*) is a type of atom that has a specific number of protons, the element's *atomic number*. Each different element, such as iron, oxygen, silicon, or bromine has a distinct chemical and physical identity determined primarily by the number of protons. A *molecule* is two or more atoms bonded together and acting as a single particle.

Unless modified by chemical, mechanical, or electrical processes, all atoms are electrically neutral because they have the same number of electrons as protons. If an atom loses electrons, it has more protons than electrons and thus has a net positive charge. If an atom gains electrons, it has more electrons than protons and a net negative charge. Atoms or molecules with a positive or negative charge are called *ions*. Electrons not bound to any atom, or *free electrons*, can also be considered as ions because they have a negative charge.

2.1.1 Electric Charge, Voltage and Current

Any piece of matter that has a net positive or negative electrical charge is said to be *electrically charged*. An electrical force exists between electrically charged particles, pushing charges of the same type apart (like charges repel each other) and pulling opposite charges together (opposite charges attract). This is the *electromotive force* (or EMF), also referred to as *voltage* or *potential*. The higher the EMF's voltage, the stronger is its force on an electrical charge.

Under most conditions, the number of positive and negative charges in any volume of space is very close to balanced and so the region has no net charge. When there are extra positive ions in one region and extra negative ions (or electrons) in another region, the resulting EMF attracts the charges toward each other. The direction of the force, from the positive region to the negative region, is called its *polarity*. Because EMF results from an imbalance of charge between two regions, its voltage is always measured between two points, with positive voltage defined as being in the direction from the positively-charged to the negatively-charged region.

If there is no path by which electric charge can move in response to an EMF (called a *conducting path*), the charges cannot move together and so remain separated. If a conducting path is available, then the electrons or ions will flow along the path, neutralizing the net imbalance of charge. The movement of electrical charge is called *electric current*. Materials through which current flows easily are called *conductors*. Most metals, such as copper or aluminum are good conductors. Materials in which it is difficult for current to flow are *insulators*. *Semiconductors*, such as silicon or germanium, are materials with much poorer conductivity than metals. Semiconductors can be chemically altered to acquire properties that make them useful in solid-state devices such as diodes, transistors and integrated circuits.

Voltage differences can be created in a variety of ways. For example, chemical ions can be physically separated to form a battery. The resulting charge imbalance creates a voltage difference at the battery terminals so that if a conductor is connected to both terminals at once, electrons flow between the terminals and gradually eliminate the charge imbalance, discharging the battery's stored energy. Mechanical means such as friction (static electricity, lightning) and moving conductors in a magnetic field (generators) can also produce voltages. Devices or systems that produce voltage are called *voltage sources*.

2.1.2 Electronic and Conventional Current

Electrons move in the direction of positive voltage — this is called *electronic current*. *Conventional current* takes the other point of view — of positive charges moving in the direction of negative voltage. Conventional current was the original model for electricity and results from an arbitrary decision made by Benjamin Franklin in the 18th century when the nature of electricity and atoms was still unknown. It can be imagined as electrons flowing “backward” and is completely equivalent to electronic current.

Conventional current is used in nearly all electronic literature and is the standard used in this book. The direction of conventional current direction establishes the polarity for most electronics calculations and circuit diagrams. The arrows in the drawing symbols for transistors point in the direction of conventional current, for example.

2.1.3 Units of Measurement

To measure electrical quantities, certain definitions have been adopted. Charge is measured in *coulombs* (C) and represented by q in equations. One coulomb is equal to 6.25×10^{18} electrons (or protons). Current, the flow of charge, is measured in *amperes* (A) and represented by i or I in equations. One ampere represents one coulomb of charge flowing past a point in one second and so amperes can also be expressed as coulombs per second. Electromotive force is measured in *volts* (V) and represented by e , E , v , or V in equations. One volt is defined as the electromotive force between two points required to cause one ampere of current to do one *joule* (measure of energy) of work in flowing between the points. Voltage can also be expressed as joules per coulomb.

2.1.4 Series and Parallel Circuits

A *circuit* is any conducting path through which current can flow between two points of that have different voltages. An *open circuit* is a circuit in which a desired conducting path is interrupted, such as by a broken wire or a switch. A *short circuit* is a circuit in which a conducting path allows current to flow directly between the two points at different voltages.

The two fundamental types of circuits are shown in **Fig 2.1**. Part A shows a *series circuit* in which there is only one current path. The current in this circuit flows from the voltage source's positive terminal (the symbol for a battery is shown with its voltage polarity shown as + and -) in the direction shown by the arrow through three *resistors* (electronic components discussed below) and back to

Schematic Diagrams

The drawing in Fig 2.1 is a *schematic diagram*. Schematics are used to show the electrical connections in a circuit without requiring a drawing of the actual components or wires, called a *pictorial diagram*. Pictorials are fine for very simple circuits like these, but quickly become too detailed and complex for everyday circuits. Schematics use lines and dots to represent the conducting paths and connections between them. Individual electrical devices and electronic components are represented by *schematic symbols* such as the resistors shown here. A set of the most common schematic symbols is provided in the **Component Data and References** chapter. You will find additional information on reading and drawing schematic diagrams in the ARRL Web site Technology section at www.arrl.org/circuit-construction.

Fig 2.1 — A series circuit (A) has the same current through all components. Parallel circuits (B) apply the same voltage to all components.

the battery's negative terminal. Current is the same at every point in a series circuit.

Part B shows a *parallel circuit* in which there are multiple paths for the current to take. One terminal of both resistors is connected to the battery's positive terminal. The other terminal of both resistors is connected to the

battery's negative terminal. Current flowing out of the battery's positive terminal divides into smaller currents that flow through the individual resistors and then recombine at the battery's negative terminal. All of the components in a parallel circuit experience the same voltage. All circuits are made up of series and parallel combinations of components and sources of voltage and current.

2.1.5 Glossary — DC and Basic Electricity

Alternating current (ac) — A flow of charged particles through a conductor, first in one direction, then in the other direction.

Ampere — A measure of flow of charged particles per unit of time. One ampere (A) represents one coulomb of charge flowing past a point in one second.

Atom — The smallest particle of matter that makes up a distinct chemical element. Atoms consist of protons and neutrons in the central region called the nucleus, with electrons surrounding the nucleus.

Circuit — Conducting path between two points of different voltage. In a *series circuit*, there is only one current path. In a *parallel circuit*, there are multiple current paths.

Conductance (G) — The reciprocal of resistance, measured in siemens (S).

Conductor — Material in which electrons or ions can move easily.

Conventional Current — Current defined as the flow of positive charges in the direction of positive to negative voltage. Conventional current flows in the opposite direction of electronic current,

When Is E a V and V an E?

Beginners in electronics are often confused about the interchange of V and E to refer to voltage in a circuit. When should each be used? In ham radio E or e is usually used in equations that refer to an electric field or the electromotive force around a circuit. E is also commonly used to state Ohm's Law: $I = E / R$. V or v is used in equations describing the difference in voltage between two points in a circuit or the terminal voltage of a power supply or battery. V is always used when referring to units of volts.

the flow of negative charges (electrons) from negative to positive voltage.

Coulomb — A unit of measure of a quantity of electrically charged particles. One coulomb (C) is equal to 6.25×10^{18} electrons.

Current (I) — The movement of electrical charge, measured in amperes and represented by *i* in equations.

Direct current (dc) — A flow of charged particles through a conductor in one direction only.

Electronic current — see **Conventional Current**

EMF — Electromotive Force is the term used to define the force of attraction or repulsion between electrically-charged

regions. Also called *voltage* or *potential*.

Energy — Capability of doing work. It is usually measured in electrical terms as the number of watts of power consumed during a specific period of time, such as watt-seconds or kilowatt-hours.

Insulator — Material in which it is difficult for electrons or ions to move.

Ion — Atom or molecule with a positive or negative electrical charge.

Joule — Measure of a quantity of energy. One joule is defined as one newton (a measure of force) acting over a distance of one meter.

Ohm — Unit of resistance. One ohm is defined as the resistance that will allow

one ampere of current when one volt of EMF is impressed across the resistance.

Polarity — The direction of EMF or voltage, from positive to negative.

Potential — See **EMF**.

Power — Power is the rate at which work is done. One watt of power is equal to one volt of EMF causing a current of one ampere through a resistor.

Resistance (R) — Opposition to current by conversion into other forms of energy, such as heat, measured in ohms (Ω).

Volt, voltage — See **EMF**.

Voltage source — Device or system that creates a voltage difference at its terminals.

2.2 Resistance and Conductance

2.2.1 Resistance

Any conductor connected to points at different voltages will allow current to pass between the points. No conductor is perfect or lossless, however, at least not at normal temperatures. The moving electrons collide with the atoms making up the conductor and lose some of their energy by causing the atoms to vibrate, which is observed externally as heat. The property of energy loss due to interactions between moving charges and the atoms of the conductor is called *resistance*. The amount of resistance to current is measured in *ohms* (Ω) and is represented by *r* or *R* in equations.

Suppose we have two conductors of the same size and shape, but of different materials. Because all materials have different internal structures, the amount of energy lost by current flowing through the material is also different. The material's ability to impede current flow is its *resistivity*. Numerically, the resistivity of a material is given by the resistance, in ohms, of a cube of the material measuring one centimeter on each edge. The symbol for resistivity is the Greek letter rho, ρ .

The longer a conductor's physical path, the higher the resistance of that conductor. For direct current and low-frequency alternating currents (up to a few thousand hertz) the conductor's resistance is inversely proportional to the cross-sectional area of the conductor. Given two conductors of the same material and having the same length, but differing in cross-sectional area, the one with the larger area (for example, a thicker wire or sheet) will have the lower resistance.

One of the best conductors is copper, and it is frequently convenient to compare the resistance of a material under consideration with that of a copper conductor of the same size and shape. **Table 2.1** gives the ratio of the resistivity of various conductors to the resistivity of copper.

2.2.2 Conductance

The reciprocal of resistance ($1/R$) is *conductance*. It is usually represented by the symbol *G*. A circuit having high conductance has low resistance, and vice versa. In radio work, the term is used chiefly in connection with electron-tube and field-effect transistor characteristics. The units of conductance are siemens (S). A resistance of 1Ω has a conductance of 1 S , a resistance of 1000Ω has a conductance of 0.001 S , and so on. A unit frequently used in regards to vacuum tubes and the field-effect transistor is the μS or one millionth of a siemens. It is the conductance of a $1\text{-M}\Omega$ resistance. Siemens have replaced the obsolete unit *mho* (abbreviated as an upside-down Ω symbol).

2.2.3 Ohm's Law

The amount of current that will flow through a conductor when a given EMF is

Table 2.1
Relative Resistivity of Metals

Material	Resistivity Compared to Copper
Aluminum (pure)	1.60
Brass	3.7-4.90
Cadmium	4.40
Chromium	8.10
Copper (hard-drawn)	1.03
Copper (annealed)	1.00
Gold	1.40
Iron (pure)	5.68
Lead	12.80
Nickel	5.10
Phosphor bronze	2.8-5.40
Silver	0.94
Steel	7.6-12.70
Tin	6.70
Zinc	3.40

The Origin of Unit Names

Many units of measure carry names that honor scientists who made important discoveries in or advanced the state of scientific knowledge of electrical and radio phenomena. For example, Georg Ohm (1787-1854) discovered the relationship between current, voltage and resistance that now bears his name as Ohm's Law and as the unit of resistance, the ohm. The following table lists the most common electrical units and the scientists for whom they are named. You can find more information on these and other notable scientists in encyclopedia entries on the units that bear their names.

Electrical Units and Their Namesakes

Unit	Measures	Named for
Ampere	Current	Andree Ampere 1775 -1836
Coulomb	Charge	Charles Coulomb 1736-1806
Farad	Capacitance	Michael Faraday 1791-1867
Henry	Inductance	Joseph Henry 1797-1878
Hertz	Frequency	Heinrich Hertz 1857-1894
Ohm	Resistance	Georg Simon Ohm 1787-1854
Watt	Power	James Watt 1736-1819
Volt	Voltage	Alessandro Volta 1745-1827

applied will vary with the resistance of the conductor. The lower the resistance, the greater the current for a given EMF. One ohm is defined as the amount of resistance that allows one ampere of current to flow between two points that have a potential difference of one volt. This proportional relationship is known as *Ohm's Law*:

$$R = \frac{E}{I} \quad (1)$$

where

- R = resistance in ohms,
- E = potential or EMF in volts and
- I = current in amperes.

Transposing the equation gives the other common expressions of Ohm's Law as:

$$E = I \times R \quad (2)$$

and

$$I = \frac{E}{R} \quad (3)$$

All three forms of the equation are used often in electronics and radio work. You must remember that the quantities are in volts, ohms and amperes; other units cannot be used in the equations without first being converted. For example, if the current is in milliamperes you must first change it to the equivalent fraction of an ampere before substituting the value into the equations.

The following examples illustrate the use of Ohm's Law in the simple circuit of Fig 2.2. If 150 V is applied to a circuit and the current is measured as 2.5 A, what is the resistance of the circuit? In this case R is the unknown, so we will use equation 1:

$$R = \frac{E}{I} = \frac{150 \text{ V}}{2.5 \text{ A}} = 60 \Omega$$

No conversion of units was necessary because the voltage and current were given in volts and amperes.

If the current through a 20,000-Ω resistance is 150 mA, what is the voltage? To find voltage, use equation 2. Convert the current from milliamperes to amperes by dividing by 1000 mA / A (or multiplying by 10⁻³ A / mA) so that 150 mA becomes 0.150 A. (Notice the conversion factor of 1000 does not limit the number of significant figures in the calculated answer.)

Fig 2.2 — A simple circuit consisting of a battery and a resistor.

Ohm's Law Timesaver

This simple diagram presents the mathematical equations relating voltage, current, and resistance. Cover the unknown quantity (E, I, or R) and the remaining symbols are shown as in the equation. For example, covering I shows E over R, as they would be written in the equation $I = E/R$.

When the current is small enough to be expressed in milliamperes, calculations are simplified if the resistance is expressed in kilohms rather than in ohms. With voltage in volts, if resistance in kilohms is substituted directly in Ohm's Law, the current will be milliamperes. Expressed as an equation: $V = \text{mA} \times \text{k}\Omega$.

$$I = \frac{150 \text{ mA}}{1000 \frac{\text{mA}}{\text{A}}} = 0.150 \text{ A}$$

Then:

$$E = 0.150 \text{ A} \times 20,000 \Omega = 3000 \text{ V}$$

In a final example, how much current will flow if 250 V is applied to a 5000-Ω resistor? Since I is unknown,

$$I = \frac{E}{R} = \frac{250 \text{ V}}{5000 \Omega} = 0.05 \text{ A}$$

Component Tolerance

Resistors are manufactured with a specific *nominal* value of resistance. This is the value printed on the body of the resistor or marked with stripes of colored paint. The *actual* value of resistance varies from the nominal value because of random variations in the manufacturing process. The maximum allowable amount of variation is called the *tolerance* and it is expressed in percent. For example, a 1000 Ω resistor with a tolerance of 5% could have any value of resistance between 95% and 105% of 1000 Ω; 950 to 1050 Ω. In most circuits, this small variation doesn't have much effect, but it is important to be aware of tolerance and choose the correct value (10%, 5%, 1%, or even tighter tolerance values are available for *precision components*) of tolerance for the circuit to operate properly, no matter what the actual value of resistance. All components have this same nominal-to-actual value relationship.

It is more convenient to express the current in mA, and $0.05 \text{ A} \times 1000 \text{ mA} / \text{A} = 50 \text{ mA}$.

It is important to note that Ohm's Law applies in any portion of a circuit as well as to the circuit as a whole. No matter how many resistors are connected together or how they are connected together, the relationship between the resistor's value, the voltage across the resistor, and the current through the resistor still follows Ohm's Law.

2.2.4 Resistance of Wires

The problem of determining the resistance of a round wire of given diameter and length — or the converse, finding a suitable size and length of wire to provide a desired amount of resistance — can easily be solved with the help of the copper wire table given in the chapter on **Component Data and References**. This table gives the resistance, in ohms per 1000 ft, of each standard wire size. For example, suppose you need a resistance of 3.5 Ω, and some #28 AWG wire is on hand. The wire table shows that #28 AWG wire has a resistance of 65.31 Ω / 1000 ft. Since the desired resistance is 3.5 Ω, the required length of wire is:

$$\text{Length} = \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} = \frac{3.5 \Omega}{\frac{65.31 \Omega}{1000 \text{ ft}}} \quad (4)$$

$$= \frac{3.5 \Omega \times 1000 \text{ ft}}{65.31 \Omega} = 55 \text{ ft}$$

As another example, suppose that the resistance of wire in a radio's power cable must not exceed 0.05 Ω and that the length of wire required for making the connections totals 14 ft. Then:

$$\frac{R_{\text{WIRE}}}{1000 \text{ ft}} < \frac{R_{\text{MAXIMUM}}}{\text{Length}} = \frac{0.05 \Omega}{14.0 \text{ ft}} \quad (5)$$

$$= 3.57 \times 10^{-3} \frac{\Omega}{\text{ft}} \times \frac{1000 \text{ ft}}{1000 \text{ ft}}$$

$$\frac{R_{\text{WIRE}}}{1000 \text{ ft}} < \frac{3.57 \Omega}{1000 \text{ ft}}$$

Find the value of $R_{\text{WIRE}} / 1000 \text{ ft}$ that is less than the calculated value. The wire table shows that #15 AWG is the smallest size having a resistance less than this value. (The resistance of #15 AWG wire is given as 3.1810 Ω/1000 ft.) Select any wire size larger than this for the connections in your circuit, to ensure that the total wire resistance will be less than 0.05 Ω.

When the wire in question is not made of copper, the resistance values in the wire table should be multiplied by the ratios shown in Table 2.1 to obtain the resulting resistance. If

the wire in the first example were made from nickel instead of copper, the length required for 3.5 Ω would be:

$$\begin{aligned} \text{Length} &= \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} \\ &= \frac{3.5 \Omega}{\frac{65.31 \Omega}{1000 \text{ ft}}} = \frac{3.5 \Omega \times 1000 \text{ ft}}{65.31 \Omega} \\ &= 53.76 \text{ ft} \end{aligned} \quad (6)$$

$$\text{Length} = \frac{3500 \text{ ft}}{337.5} = 10.5 \text{ ft}$$

2.2.5 Temperature Effects

The resistance of a conductor changes with its temperature. The resistance of practically every metallic conductor increases with increasing temperature. Carbon, however, acts in the opposite way; its resistance decreases when its temperature rises. It is seldom necessary to consider temperature in making resistance calculations for amateur work. The temperature effect is important when it is necessary to maintain a constant resistance under all conditions, however. Special materials that have little or no change in resistance over a wide temperature range are used in that case.

2.2.6 Resistors

A package of material exhibiting a certain amount of resistance and made into a single unit is called a *resistor*. (See the **Component Data and References** chapter for information on resistor value marking conventions.) The size and construction of resistors having the same value of resistance in ohms may vary

considerably based on how much power they are intended to dissipate, how much voltage is expected to be applied to them, and so forth (see **Fig 2.3**).

TYPES OF RESISTORS

Resistors are made in several different ways: carbon composition, metal oxide, carbon film, metal film and wirewound. In some circuits, the resistor value may be critical. In this case, precision resistors are used. These are typically wirewound or carbon-film devices whose values are carefully controlled during manufacture. In addition, special material or construction techniques may be used to provide temperature compensation, so the value does not change (or changes in a precise manner) as the resistor temperature changes.

Carbon composition resistors are simply small cylinders of carbon mixed with various binding agents to produce any desired resistance. The most common sizes of “carbon comp” resistors are ½- and ¼-W resistors. They are moderately stable from 0 to 60 °C (their resistance increases above and below this temperature range). They can absorb short overloads better than film-type resistors, but they are relatively noisy, and have relatively wide tolerances. Because carbon composition resistors tend to be affected by humidity and other environmental factors and because they are difficult to manufacture in surface-mount packages, they have largely been replaced by film-type resistors.

Metal-oxide resistors are similar to carbon composition resistors in that the resistance is supplied by a cylinder of metal oxide. Metal-oxide resistors have replaced carbon composition resistors in higher power applications

because they are more stable and can operate at higher temperatures.

Wirewound resistors are made from wire, which is cut to the proper length and wound on a coil form (usually ceramic). They are capable of handling high power; their values are very stable, and they are manufactured to close tolerances.

Metal-film resistors are made by depositing a thin film of aluminum, tungsten or other metal on an insulating substrate. Their resistances are controlled by careful adjustments of the width, length and depth of the film. As a result, they have very tight tolerances. They are used extensively in surface-mount technology. As might be expected, their power handling capability is somewhat limited. They also produce very little electrical noise.

Carbon-film resistors use a film of carbon mixed with other materials instead of metal. They are not quite as stable as other film resistors and have wider tolerances than metal-film resistors, but they are still as good as (or better than) carbon composition resistors.

THERMAL CONSIDERATIONS FOR RESISTORS

Current through a resistance causes the conductor to become heated; the higher the resistance and the larger the current, the greater the amount of heat developed. Resistors intended for carrying large currents must be physically large so the heat can be radiated quickly to the surrounding air or some type of heat sinking material. If the resistor does not dissipate the heat quickly, it may get hot enough to melt or burn.

The amount of heat a resistor can safely dissipate depends on the material, surface area and design. Typical resistors used in amateur electronics (½ to 2-W resistors) dissipate heat primarily through the surface area of the case, with some heat also being carried away through the connecting leads. Wirewound resistors are usually used for higher power levels. Some have finned cases for better convection cooling and/or metal cases for better conductive cooling.

The major departure of resistors from ideal behavior at low-frequencies is their *temperature coefficient* (TC). (See the chapter on **RF Techniques** for a discussion of the behavior of

Fig 2.3 — Examples of various resistors. At the top left is a small 10-W wirewound resistor. A single in-line package (SIP) of resistors is at the top right. At the top center is a small PC-board-mount variable resistor. A tiny surface-mount (chip) resistor is also shown

at the top. Below the variable resistor is a 1-W carbon composition resistor and then a ½-W composition unit. The dog-bone-shaped resistors at the bottom are ½-W and ¼-W film resistors. The ¼-inch-ruled graph paper background provides a size comparison. The inset photo shows the chip resistor with a penny for size comparison.

Table 2.2
Temperature Coefficients for Various Resistor Compositions

Type	TC (PPM/°C)
Wire wound	±(30 - 50)
Metal Film	±(100 - 200)
Carbon Film	+350 to -800
Carbon composition	±800

resistors at high frequencies.) The resistivity of most materials changes with temperature, and typical TC values for resistor materials are given in **Table 2.2**. TC values are usually expressed in parts-per-million (PPM) for each degree (centigrade) change from some nominal temperature, usually room temperature (77 °F or 27 °C). A positive TC indicates an increase in resistance with increasing temperature while a negative TC indicates a decreasing resistance. For example, if a 1000-Ω resistor with a TC of +300 PPM/°C is heated to 50 °C, the *change* in resistance is $300 \times (50 - 27) = 6900$ PPM, yielding a new resistance of

$$1000 \left(1 + \frac{6900}{1,000,000} \right) = 1006.9 \Omega$$

Carbon-film resistors are unique among the major resistor families because they alone have a negative temperature coefficient. They are often used to “offset” the thermal effects of the other components.

If the temperature increase is small (less than 30-40 °C), the resistance change with temperature is nondestructive — the resistor will return to normal when the temperature returns to its nominal value. Resistors that get too hot to touch, however, may be permanently damaged even if they appear normal. For this reason, be conservative when specifying power ratings for resistors. It’s common to specify a resistor rated at 200% to 400% of the expected dissipation.

POTENTIOMETERS

Potentiometer (pronounced po-ten-tchee-AH-meh-tur) is a formal name for a variable resistor and the common name for these components is “pots.” A typical potentiometer consists of a circular pattern of resistive material, usually a carbon compound similar to that used in carbon composition resistors, with a wiper contact on a shaft moving across the material. For higher power applications, the resistive material may be wire, wound around a core, like a wirewound resistor.

As the wiper moves along the material, more resistance is introduced between the wiper and one of the fixed contacts on the material. A potentiometer may be used to control current, voltage or resistance in a circuit. **Fig 2.4** shows several different types of potentiometers. **Fig 2.5** shows the schematic symbol for a potentiometer and how changing the position of the shaft changes the resistance between its three terminals. The figure shows a *panel pot*, designed to be

Fig 2.4 — This photo shows examples of different styles of potentiometers. The ¼-inch-ruled graph paper background provides a size comparison.

Fig 2.5 — Typical potentiometer construction and schematic symbol. Rotation on the shaft moves the wiper along the element, changing the resistance between the wiper terminal and the element terminals. Moving the wiper closer to an element terminal

mounted on an equipment panel and adjusted by an operator. The small rectangular *trimmer* potentiometers in Fig 2.5 are adjusted with a screwdriver and have wire terminals.

Typical specifications for a potentiometer include element resistance, power dissipation, voltage and current ratings, number of turns (or degrees) the shaft can rotate, type and size of shaft, mounting arrangements and resistance “taper.”

Not all potentiometers have a *linear* taper. That is, the change in resistance may not be the same for a given number of degrees of shaft rotation along different portions of the resistive material. These are called *nonlinear tapers*

A typical use of a potentiometer with a nonlinear taper is as a volume control in an audio amplifier. Since the human ear has a logarithmic response to sound, a volume control must change the amplifier output much more near one end of the potentiometer than the other (for a given amount of rotation) so that the “perceived” change in volume is about the same for a similar change in the control’s position. This is commonly called an *audio taper* or *log taper* as the change in resistance per degree of rotation attempts to match the response of the human ear. Tapers can be designed to match almost any desired control function for a given application. Linear and audio tapers are the most common tapers.

2.3 Basic Circuit Principles

Circuits are composed of *nodes* and *branches*. A node is any point in the circuit at which current can divide between conducting paths. For example, in the parallel circuit of **Fig 2.6**, the node is represented by the schematic dot. A branch is any unique conducting path between nodes. A series of branches that make a complete current path, such as the series circuit of Fig 2.1A, is called a *loop*.

Very few actual circuits are as simple as those shown in Fig 2.1. However, all circuits, no matter how complex, are constructed of combinations of these series and parallel circuits. We will now use these simple circuits of resistors and batteries to illustrate two fundamental rules for voltage and current, known as *Kirchoff's Laws*.

2.3.1 Kirchoff's Current Law

Kirchoff's Current Law (KCL) states, "The sum of all currents flowing into a node and all currents flowing out of a node is equal to zero." KCL is stated mathematically as:

$$(I_{in1} + I_{in2} + \dots) - (I_{out1} + I_{out2} + \dots) = 0 \quad (7A)$$

The dots indicate that as many currents as necessary may be added.

Another way of stating KCL is that the sum of all currents flowing into a node must balance the sum of all currents flowing out of a node as shown in equation 7B:

$$(I_{in1} + I_{in2} + \dots) = (I_{out1} + I_{out2} + \dots) \quad (7B)$$

Equations 7A and 7B are mathematically equivalent.

KCL is illustrated by the following example. Suppose three resistors (5.0 kΩ, 20.0 kΩ and 8.0 kΩ) are connected in parallel as shown in Fig 2.6. The same voltage, 250 V, is applied to all three resistors. The current through R1 is I1, I2 is the current through R2 and I3 is the current through R3.

The current in each can be found from Ohm's Law, as shown below. For convenience, we can use resistance in kΩ, which gives current in milliamperes.

$$I_1 = \frac{E}{R_1} = \frac{250 \text{ V}}{5.0 \text{ k}\Omega} = 50.0 \text{ mA}$$

$$I_2 = \frac{E}{R_2} = \frac{250 \text{ V}}{20.0 \text{ k}\Omega} = 12.5 \text{ mA}$$

$$I_3 = \frac{E}{R_3} = \frac{250 \text{ V}}{8.0 \text{ k}\Omega} = 31.2 \text{ mA}$$

Notice that the branch currents are inversely proportional to the resistances. The 20,000-Ω resistor has a value four times larger than the 5000-Ω resistor, and has a current

Fig 2.6 — An example of resistors in parallel.

one-quarter as large. If a resistor has a value twice as large as another, it will have half as much current through it when they are connected in parallel.

Using the balancing form of KCL (equation 7B) the current that must be supplied by the battery is therefore:

$$I_{BATT} = I_1 + I_2 + I_3$$

$$I_{BATT} = 50.0 \text{ mA} + 12.5 \text{ mA} + 31.2 \text{ mA}$$

$$I_{BATT} = 93.7 \text{ mA}$$

2.3.2 Resistors in Parallel

In a circuit made up of resistances in parallel, the resistors can be represented as a single *equivalent* resistance that has the same value as the parallel combination of resistors. In a parallel circuit, the equivalent resistance is less than that of the lowest resistance value present. This is because the total current is always greater than the current in any individual resistor. The formula for finding the equivalent resistance of resistances in parallel is:

$$R_{EQUIV} = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} \dots} \quad (8)$$

where the dots indicate that any number of parallel resistors can be combined by the same method. In the example of the previous section, the equivalent resistance is:

$$R = \frac{1}{\frac{1}{5000 \Omega} + \frac{1}{20 \text{ k}\Omega} + \frac{1}{8000 \Omega}} = 2.67 \text{ k}\Omega$$

The notation “//” (two slashes) is frequently used to indicate “in parallel with.” Using that notation, the preceding example would be given as “5000 Ω // 20 kΩ // 8000 Ω.”

For only two resistances in parallel (a very common case) the formula can be reduced to the much simpler (and easier to remember):

$$R_{EQUIV} = \frac{R_1 \times R_2}{R_1 + R_2} \quad (9)$$

Example: If a 500-Ω resistor is connected in parallel with one of 1200 Ω, what is the total resistance?

$$R = \frac{R_1 \times R_2}{R_1 + R_2} = \frac{500 \Omega \times 1200 \Omega}{500 \Omega + 1200 \Omega}$$

$$R = \frac{600,000 \Omega^2}{1700 \Omega} = 353 \Omega$$

Any number of parallel resistors can be combined two at a time by using equation 9 until all have been combined into a single equivalent. This is a bit easier than using equation 8 to do the conversion in a single step.

CURRENT DIVIDERS

Resistors connected in parallel form a circuit called a *resistive current divider*. For any number of resistors connected in parallel (R1, R2, R3, ... R4), the current through one of the resistors, R_n, is equal to the sum of all resistor currents multiplied by the ratio of the equivalent of all parallel resistors *except* R_n to the sum of R_n and the equivalent value.

$$I_n = I_{TOT} (R_{EQ}/R_n + R_{EQ})$$

For example, in a circuit with three parallel resistors; R1, R2, and R3, the current through R2 is equal to:

$$I_2 = I \frac{R1 // R3}{R2 + R1 // R3}$$

where I is the total current through all the resistors and // indicates the equivalent parallel value. If I = 100 mA, R1 = 100 Ω, R2 = 50 Ω, and R3 = 200 Ω:

$$100 \text{ mA} \frac{(100 // 200)}{(50 + 100 // 200)} = 100 \frac{66.7}{116.7} = 57.2 \text{ mA}$$

2.3.3 Kirchoff's Voltage Law

Kirchoff's Voltage Law (KVL) states, "The sum of the voltages around a closed current loop is zero." Where KCL is somewhat intuitive, KVL is not as easy to visualize. In the circuit of **Fig 2.7**, KVL requires that the battery's voltage must be balanced exactly by the voltages that appear across the three resistors in the circuit. If it were not, the “extra” voltage would create an infinite current with no limiting resistance, just as KCL prevents

Fig 2.7 — An example of resistors in series.

charge from “building up” at a circuit node. KVL is stated mathematically as:

$$E_1 + E_2 + E_3 + \dots = 0 \quad (10)$$

where each E represents a voltage encountered by current as it flows around the circuit loop.

This is best illustrated with an example. Although the current is the same in all three of the resistances in the example of Fig 2.7, the total voltage divides between them, just as current divides between resistors connected in parallel. The voltage appearing across each resistor (the *voltage drop*) can be found from Ohm’s Law. (Voltage across a resistance is often referred to as a “drop” or “I-R drop” because the value of the voltage “drops” by the amount $E = I \times R$.)

For the purpose of KVL, it is common to assume that if current flows *into* the more positive terminal of a component the voltage is treated as positive in the KVL equation. If the current flows *out* of a positive terminal, the voltage is treated as negative in the KVL. Positive voltages represent components that consume or “sink” power, such as resistors. Negative voltages represent components that produce or “source” power, such as batteries. This allows the KVL equation to be written in a balancing form, as well:

$$(E_{\text{source}1} + E_{\text{source}2} + \dots) =$$

$$(E_{\text{sink}1} + E_{\text{sink}2} + \dots)$$

All of the voltages are treated as positive in this form, with the power sources (current flowing *out* of the more positive terminal) on one side and the power sinks (current flowing *into* the more positive terminal) on the other side.

Note that it doesn’t matter what a component terminal’s *absolute* voltage is with respect to ground, only which terminal of the component is more positive than the other. If one side of a resistor is at +1000 V and the other at +998 V, current flowing into the first terminal and out of the second experiences a +2 V voltage drop. Similarly, current supplied by a 9 V battery with its positive terminal at –100 V and its negative terminal at –108.5 V still counts for KVL as an 8.5 V power source. Also note that current can flow *into* a battery’s positive terminal, such as during recharging, making the battery a power sink, just like a resistor.

Here’s an example showing how KVL works: In Fig 2.7, if the voltage across R1 is E1, that across R2 is E2 and that across R3 is E3, then:

$$-250 + I \times R1 + I \times R2 + I \times R3 = 0$$

This equation can be simplified to:

$$-250 + I (R1 + R2 + R3) =$$

$$-250 + I (33,000 \Omega) = 0$$

Solving for I gives $I = 250 / 33000 = 0.00758$ A = 7.58 mA. This allows us to calculate the value of the voltage across each resistor:

$$E1 = I \times R1 = 0.00758 \text{ A} \times 5000 \Omega = 37.9 \text{ V}$$

$$E2 = I \times R2 = 0.00758 \text{ A} \times 20,000 \Omega = 152 \text{ V}$$

$$E3 = I \times R3 = 0.00758 \text{ A} \times 8000 \Omega = 60.6 \text{ V}$$

Verifying that the sum of E1, E2, and E3 does indeed equal the battery voltage of 250 V ignoring rounding errors.

$$E_{\text{TOTAL}} = E1 + E2 + E3$$

$$E_{\text{TOTAL}} = 37.9 \text{ V} + 152 \text{ V} + 60.6 \text{ V}$$

$$E_{\text{TOTAL}} = 250 \text{ V}$$

2.3.4 Resistors in Series

The previous example illustrated that in a circuit with a number of resistances connected in series, the equivalent resistance of the circuit is the sum of the individual resistances. If these are numbered R1, R2, R3 and so on, then:

$$R_{\text{EQUIV}} = R1 + R2 + R3 + R4... \quad (11)$$

Example: Suppose that three resistors are connected to a source of voltage as shown in Fig 2.7. The voltage is 250 V, R1 is 5.0 kΩ, R2 is 20.0 kΩ and R3 is 8.0 kΩ. The total resistance is then

$$R_{\text{EQUIV}} = R1 + R2 + R3$$

$$R_{\text{EQUIV}} = 5.0 \text{ k}\Omega + 20.0 \text{ k}\Omega + 8.0 \text{ k}\Omega$$

$$R_{\text{EQUIV}} = 33.0 \text{ k}\Omega$$

The current in the circuit is then

$$I = \frac{E}{R} = \frac{250 \text{ V}}{33.0 \text{ k}\Omega} = 7.58 \text{ mA}$$

VOLTAGE DIVIDERS

Notice that the voltage drop across each resistor in the KVL example is directly proportional to the resistance. The value of the 20,000 Ω resistor is four times larger than the 5000 Ω resistor, and the voltage drop across the 20,000 Ω resistor is four times larger. A resistor that has a value twice as large as another will have twice the voltage drop across it when they are connected in series.

Resistors in series without any other connections form a *resistive voltage divider*. (Other types of components can form voltage dividers, too.) The voltage across any specific resistor in the divider, R_n , is equal to the voltage across the entire string of resistors multiplied by the ratio of R_n to the sum of all resistors in the string.

For example, in the circuit of Fig 2.7, the voltage across the 5000 Ω resistor is:

$$E1 = 250 \frac{5000}{5000 + 20,000 + 8000} = 37.9 \text{ V}$$

This is a more convenient method than calculating the current through the resistor and using Ohm’s Law.

Voltage dividers can be used as a source of voltage. As long as the device connected to the output of the divider has a much higher resistance than the resistors in the divider, there will be little effect on the divider output voltage. For example, for a voltage divider with a voltage of $E = 15 \text{ V}$ and two resistors of $R1 = 5 \text{ k}\Omega$ and $R2 = 10 \text{ k}\Omega$, the voltage across R2 will be 10 V measured on a high-impedance voltmeter because the measurement draws very little current from the divider. However, if the measuring device or load across R2 draws significant current, it will increase the amount of current drawn through the divider and change the output voltage.

A good rule of thumb is that the load across a voltage divider’s output should be at least ten times the value of the highest resistor in the divider to stay reasonably close to the required voltage. As the load resistance gets closer to the value of the divider resistors, the current drawn by the load affects the voltage division and causes changes from the desired value.

Potentiometers (variable resistors described previously) are often used as adjustable voltage dividers and this is how they got their name. Potential is an older name for voltage and a “potential-meter” is a device that can “meter” or adjust potential, thus potentiometer.

2.3.5 Conductances in Series and Parallel

Since conductance is the reciprocal of resistance, $G = 1/R$, the formulas for combining resistors in series and in parallel can be converted to use conductance by substituting $1/G$ for R. Substituting $1/G$ into equation 11 shows that conductances in series are combined this way:

$$G = \frac{1}{\frac{1}{G1} + \frac{1}{G2} + \frac{1}{G3} + \frac{1}{G4} \dots}$$

and two conductances in series may be combined in a manner similar to equation 9:

$$G_{\text{EQUIV}} = \frac{G1 \times G2}{G1 + G2}$$

Substituting $1/G$ into equation 8 shows that conductances in parallel are combined this way:

$$G_{\text{TOTAL}} = G1 + G2 + G3 + G4...$$

This also shows that when faced with a large number of parallel resistances, converting

them to conductances may make the math a little easier to deal with.

2.3.6 Equivalent Circuits

A circuit may have resistances both in parallel and in series, as shown in Fig 2.8A. In order to analyze the behavior of such a circuit, *equivalent circuits* are created and combined by using the equations for combining resistors in series and resistors in parallel. Each separate combination of resistors, series or parallel, can be reduced to a single equivalent resistor. The resulting combinations can be reduced still further until only a single resistor remains.

The method for analyzing the circuit of Fig 2.8A is as follows: Combine R2 and R3 to create the equivalent single resistor, R_{EQ} whose value is equal to R2 and R3 in parallel.

$$R_{EQ} = \frac{R_2 \times R_3}{R_2 + R_3} = \frac{20,000 \Omega \times 8000 \Omega}{20,000 \Omega + 8000 \Omega}$$

$$= \frac{1.60 \times 10^8 \Omega^2}{28,000 \Omega} = 5710 \Omega = 5.71 \text{ k}\Omega$$

This resistance in series with R1 then forms a simple series circuit, as shown in Fig 2.8B. These two resistances can then be combined into a single equivalent resistance, R_{TOTAL}, for the entire circuit:

$$R_{TOTAL} = R_1 + R_{EQ} = 5.0 \text{ k}\Omega + 5.71 \text{ k}\Omega$$

$$R_{TOTAL} = 10.71 \text{ k}\Omega$$

The battery current is then:

$$I = \frac{E}{R} = \frac{250 \text{ V}}{10.71 \text{ k}\Omega} = 23.3 \text{ mA}$$

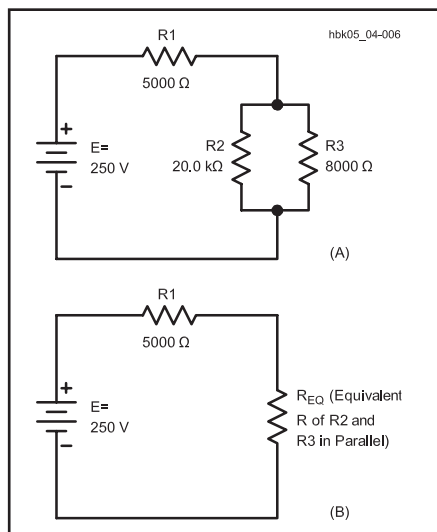

Fig 2.8 — At A, an example of resistors in series-parallel. The equivalent circuit is shown at B.

The voltage drops across R1 and R_{EQ} are:

$$E_1 = I \times R_1 = 23.3 \text{ mA} \times 5.0 \text{ k}\Omega = 117 \text{ V}$$

$$E_2 = I \times R_{EQ} = 23.3 \text{ mA} \times 5.71 \text{ k}\Omega = 133 \text{ V}$$

These two voltage drops total 250 V, as described by Kirchhoff's Voltage Law. E2 appears across both R2 and R3 so,

$$I_2 = \frac{E_2}{R_2} = \frac{133 \text{ V}}{20.0 \text{ k}\Omega} = 6.65 \text{ mA}$$

$$I_3 = \frac{E_3}{R_3} = \frac{133 \text{ V}}{8.0 \text{ k}\Omega} = 16.6 \text{ mA}$$

where

I2 = current through R2 and

I3 = current through R3.

The sum of I2 and I3 is equal to 23.3 mA, conforming to Kirchhoff's Current Law.

2.3.7 Voltage and Current Sources

In designing circuits and describing the behavior of electronic components, it is often useful to use *ideal sources*. The two most common types of ideal sources are the *voltage source* and the *current source*, symbols for which are shown in Fig 2.9. These sources are considered ideal because no matter what circuit is connected to their terminals, they continue to supply the specified amount of voltage or current. Practical voltage and current sources can approximate the behavior of an ideal source over certain ranges, but are limited in the amount of power they can supply and so under excessive load, their output will drop.

Voltage sources are defined as having zero *internal impedance*, where impedance is a more general form of resistance as described in the sections of this chapter dealing with alternating current. A short circuit across an ideal voltage source would result in the source providing an infinite amount of current. Practical voltage sources have non-zero internal impedance and this also limits the amount of power they can supply. For example, placing a

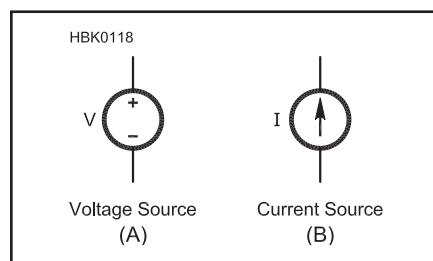

Fig 2.9 — Voltage sources (A) and current sources (B) are examples of ideal energy sources.

short circuit across the terminals of a practical voltage source such as 1.5 V dry-cell battery may produce a current of several amperes, but the battery's internal impedance acts to limit the amount of current produced in accordance with Ohm's Law — as if the resistor in Fig 2.2 was inside of or internal to the battery.

Current sources are defined to have infinite internal impedance. This means that no matter what is connected to the terminals of an ideal current source, it will supply the same amount of current. An open circuit across the terminal of an ideal current source will result in the source generating an infinite voltage at its terminals. Practical current sources will raise their voltage until the internal power supply limits are reached and then reduce output current.

2.3.8 Thevenin's Theorem and Thevenin Equivalents

Thevenin's Voltage Theorem (usually just referred to as "Thevenin's Theorem") is a useful tool for simplifying electrical circuits or *networks* (the formal name for circuits) by allowing circuit designers to replace a circuit with a simpler equivalent circuit. Thevenin's Theorem states, "Any two-terminal network made up of resistors and voltage or current sources can be replaced by an equivalent network made up of a single voltage source and a series resistor."

Thevenin's Theorem can be readily applied to the circuit of Fig 2.8A, to find the current through R3. In this example, illustrated in Fig 2.10, the circuit is redrawn to show R1 and R2 forming a voltage divider, with R3 as the load (Fig 2.10A). The current drawn by the load (R3) is simply the voltage across R3, divided by its resistance. Unfortunately, the value of R2 affects the voltage across R3, just as the presence of R3 affects the voltage appearing across R2. Some means of separating the two is needed; hence the *Thevenin-equivalent circuit* is constructed, replacing everything connected to terminals A and B with a single voltage source (the *Thevenin-equivalent voltage*, E_{THEV}) and series resistor (the *Thevenin-equivalent resistance*, R_{TH}).

The first step of creating the Thevenin-equivalent of the circuit is to determine its *open-circuit voltage*, measured when there is no load current drawn from either terminal A or B. Without a load connected between A and B, the total current through the circuit is (from Ohm's Law):

$$I = \frac{E}{R_1 + R_2} \quad (12)$$

and the voltage between terminals A and B (E_{AB}) is:

$$E_{AB} = I \times R_2 \quad (13)$$

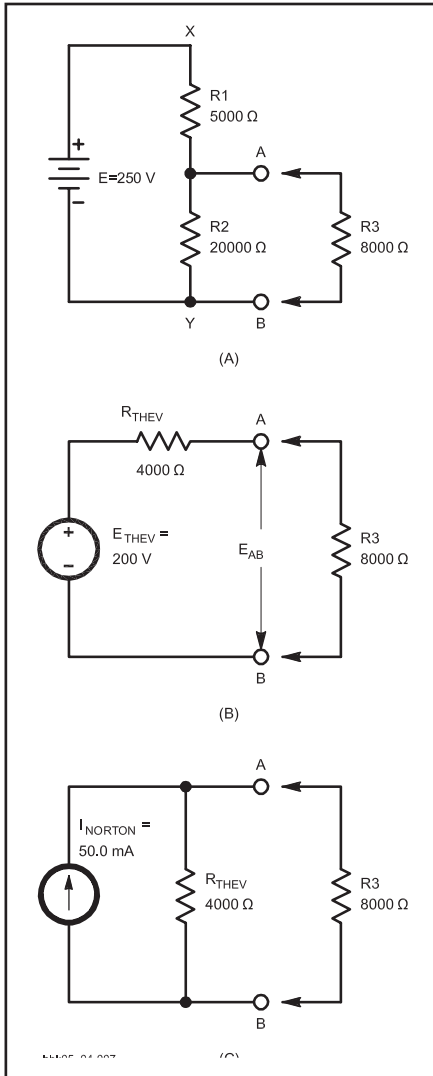

Fig 2.10 — Equivalent circuits for the circuit shown in Fig 2.8. A shows the circuit to be replaced by an equivalent circuit from the perspective of the resistor (R3 load). B shows the Thevenin-equivalent circuit, with a resistor and a voltage source in series. C shows the Norton-equivalent circuit, with a resistor and current source in parallel.

By substituting equation 12 into equation 13, we have an expression for E_{AB} in which all values are known:

$$E_{AB} = \frac{R_2}{R_1 + R_2} \times E \quad (14)$$

Using the values in our example, this becomes:

$$E_{AB} = \frac{20.0 \text{ k}\Omega}{25.0 \text{ k}\Omega} \times 250 \text{ V} = 200 \text{ V}$$

when nothing is connected to terminals A or B.

E_{THEV} is equal to E_{AB} with no current drawn.

The equivalent resistance between terminals A and B is R_{THEV} . R_{THEV} is calculated as the equivalent circuit at terminals A and B with all sources, voltage or current, replaced by their internal impedances. The ideal voltage source, by definition, has zero internal resistance and is replaced by a short circuit. The ideal current source has infinite internal impedance and is replaced by an open circuit.

Assuming the battery to be a close approximation of an ideal source, replace it with a short circuit between points X and Y in the circuit of Fig 2.10A. R1 and R2 are then effectively placed in parallel, as viewed from terminals A and B. R_{THEV} is then:

$$R_{THEV} = \frac{R_1 \times R_2}{R_1 + R_2} \quad (15)$$

$$R_{THEV} = \frac{5000 \Omega \times 20,000 \Omega}{5000 \Omega + 20,000 \Omega}$$

$$R_{THEV} = \frac{1.0 \times 10^8 \Omega^2}{25,000 \Omega} = 4000 \Omega$$

This gives the Thevenin-equivalent circuit as shown in Fig 2.10B. The circuits of Figs 2.10A and 2.10B are completely equivalent from the perspective of R3, so the circuit becomes a simple series circuit.

Once R3 is connected to terminals A and B, there will be current through R_{THEV} , causing a voltage drop across R_{THEV} and reducing E_{AB} . The current through R3 is equal to

$$I_3 = \frac{E_{THEV}}{R_{TOTAL}} = \frac{E_{THEV}}{R_{THEV} + R_3} \quad (16)$$

Substituting the values from our example:

$$I_3 = \frac{200 \text{ V}}{4000 \Omega + 8000 \Omega} = 16.7 \text{ mA}$$

This agrees with the value calculated earlier.

The Thevenin-equivalent circuit of an ideal voltage source in series with a resistance is a good model for a real voltage source with non-zero internal resistance. Using this more realistic model, the maximum current that a real voltage source can deliver is seen to be

$$I_{sc} = \frac{E_{THEV}}{R_{THEV}}$$

and the maximum output voltage is $V_{oc} = E_{THEV}$.

Sinusoidal voltage or current sources can be modeled in much the same way, keeping in mind that the internal impedance, Z_{THEV} ,

for such a source may not be purely resistive, but may have a reactive component that varies with frequency.

2.3.9 Norton's Theorem and Norton Equivalents

Norton's Theorem is another method of creating an equivalent circuit. Norton's Theorem states, "Any two-terminal network made up of resistors and current or voltage sources can be replaced by an equivalent network made up of a single current source and a parallel resistor." Norton's Theorem is to current sources what Thevenin's Theorem is to voltage sources. In fact, the Thevenin-resistance calculated previously is also the *Norton-equivalent resistance*.

The circuit just analyzed by means of Thevenin's Theorem can be analyzed just as easily by Norton's Theorem. The equivalent Norton circuit is shown in Fig 2.10C. The short circuit current of the equivalent circuit's current source, I_{NORTON} , is the current through terminals A and B with the load (R3) replaced by a short circuit. In the case of the voltage divider shown in Fig 2.10A, the short circuit completely bypasses R2 and the current is:

$$I_{AB} = \frac{E}{R_1} \quad (17)$$

Substituting the values from our example, we have:

$$I_{AB} = \frac{E}{R_1} = \frac{250 \text{ V}}{5000 \Omega} = 50.0 \text{ mA}$$

The resulting Norton-equivalent circuit consists of a 50.0-mA current source placed in parallel with a 4000-Ω resistor. When R3 is connected to terminals A and B, one-third of the supply current flows through R3 and the remainder through R_{THEV} . This gives a current through R3 of 16.7 mA, again agreeing with previous conclusions.

A Norton-equivalent circuit can be transformed into a Thevenin-equivalent circuit and vice versa. The equivalent resistor, R_{THEV} , is the same in both cases; it is placed in series with the voltage source in the case of a Thevenin-equivalent circuit and in parallel with the current source in the case of a Norton-equivalent circuit. The voltage for the Thevenin-equivalent source is equal to the open-circuit voltage appearing across the resistor in the Norton-equivalent circuit. The current for a Norton-equivalent source is equal to the short circuit current provided by the Thevenin source. A Norton-equivalent circuit is a good model for a real current source that has a less-than infinite internal impedance.

2.4 Power and Energy

Regardless of how voltage is generated, energy must be supplied if current is drawn from the voltage source. The energy supplied may be in the form of chemical energy or mechanical energy. This energy is measured in joules (J). One joule is defined from classical physics as the amount of energy or *work* done when a force of one newton (a measure of force) is applied to an object that is moved one meter in the direction of the force.

Power is another important concept and measures the rate at which energy is generated or used. One *watt* (W) of power is defined as the generation (or use) of one joule of energy (or work) per second.

One watt is also defined as one volt of EMF causing one ampere of current to flow through a resistance. Thus,

$$P = I \times E \quad (18)$$

where

P = power in watts

I = current in amperes

E = EMF in volts.

(This discussion pertains only to direct current in resistive circuits. See the AC Theory and Reactance section of this chapter for a discussion about power in ac circuits, including reactive circuits.)

Common fractional and multiple units for power are the milliwatt (mW, one thousandth of a watt) and the kilowatt (kW, 1000 W).

Example: The plate voltage on a transmitting vacuum tube is 2000 V and the plate current is 350 mA. (The current must be changed to amperes before substitution in the formula, and so is 0.350 A.) Then:

$$P = I \times E = 2000 \text{ V} \times 0.350 \text{ A} = 700 \text{ W}$$

Power may be expressed in *horsepower* (hp) instead of watts, using the following conversion factor:

$$1 \text{ horsepower} = 746 \text{ W}$$

This conversion factor is especially useful if you are working with a system that converts electrical energy into mechanical energy, and vice versa, since mechanical power is often expressed in horsepower in the US. In metric countries, mechanical power is usually expressed in watts. All countries use the metric power unit of watts in electrical systems, however. The value 746 W/hp assumes lossless conversion between mechanical and electrical power; practical efficiency is taken up shortly.

2.4.1 Energy

When you buy electricity from a power company, you pay for electrical energy, not

power. What you pay for is the work that the electrical energy does for you, not the rate at which that work is done. Like energy, work is equal to power multiplied by time. The common unit for measuring electrical energy is the *watt-hour* (Wh), which means that a power of one watt has been used for one hour. That is:

$$\text{Wh} = P t \quad (19)$$

where

Wh = energy in watt-hours

P = power in watts

t = time in hours.

Actually, the watt-hour is a fairly small energy unit, so the power company bills you for *kilowatt-hours* (kWh) of energy used. Another energy unit that is sometimes useful is the *watt-second* (Ws), which is equal to joules.

It is important to realize, both for calculation purposes and for efficient use of power resources, a small amount of power used for a long time can eventually result in a power bill that is just as large as if a large amount of power had been used for a very short time.

A common use of energy units in radio is in specifying the energy content of a battery. Battery energy is rated in *ampere-hours* (Ah) or *milliampere-hours* (mAh). While the multiplication of amperes and hours does not result in units of energy, the calculation assumes the result is multiplied by a specified (and constant) battery voltage. For example, a rechargeable NiMH battery rated to store 2000 mAh of energy is assumed to supply that energy at a terminal voltage of 1.5 V. Thus, after converting 2000 mA to 2 A, the actual energy stored is:

$$\text{Energy} = 1.5 \text{ V} \times 2 \text{ A} \times 1 \text{ hour} = 3 \text{ Wh}$$

Another common energy unit associated with batteries is *energy density*, with units of Ah per unit of volume or weight.

One practical application of energy units is to estimate how long a radio (such as a hand-held unit) will operate from a certain battery. For example, suppose a fully charged battery stores 900 mAh of energy and that the radio draws 30 mA on receive. A simple calculation indicates that the radio will be able receive 900 mAh / 30 mA = 30 hours with this battery, assuming 100% efficiency. You shouldn't expect to get the full 900 mAh out of the battery because the battery's voltage will drop as it is discharged, usually causing the equipment it powers to shut down before the last fraction of charge is used. Any time spent transmitting will also reduce the time the battery will last. The **Power Sources** chapter includes additional

information about batteries and their charge/discharge cycles.

2.4.2 Generalized Definition of Resistance

Electrical energy is not always turned into heat. The energy used in running a motor, for example, is converted to mechanical motion. The energy supplied to a radio transmitter is largely converted into radio waves. Energy applied to a loudspeaker is changed into sound waves. In each case, the energy is converted to other forms and can be completely accounted for. None of the energy just disappears! These are examples of the Law of Conservation of Energy. When a device converts energy from one form to another, we often say it *dissipates* the energy, or power. (Power is energy divided by time.) Of course the device doesn't really "use up" the energy, or make it disappear, it just converts it to another form. Proper operation of electrical devices often requires that the power be supplied at a specific ratio of voltage to current. These features are characteristics of resistance, so it can be said that any device that "dissipates power" has a definite value of resistance.

This concept of resistance as something that absorbs power at a definite voltage-to-current ratio is very useful; it permits substituting a simple resistance for the load or power-consuming part of the device receiving power, often with considerable simplification of calculations. Of course, every electrical device has some resistance of its own in the more narrow sense, so a part of the energy supplied to it is converted to heat in that resistance even though the major part of the energy may be converted to another form.

2.4.3 Efficiency

In devices such as motors and transmitters, the objective is to convert the supplied energy (or power) into some form other than heat. In such cases, power converted to heat is considered to be a loss because it is not useful power. The efficiency of a device is the useful power output (in its converted form) divided by the power input to the device. In a transmitter, for example, the objective is to convert power from a dc source into ac power at some radio frequency. The ratio of the RF power output to the dc input is the *efficiency* (*Eff* or η) of the transmitter. That is:

$$\text{Eff} = \frac{P_O}{P_I} \quad (20)$$

where

Eff = efficiency (as a decimal)

P_O = power output (W)

P_I = power input (W).

Example: If the dc input to the transmitter is 100 W, and the RF power output is 60 W, the efficiency is:

$$\text{Eff} = \frac{P_O}{P_I} = \frac{60 \text{ W}}{100 \text{ W}} = 0.6$$

Efficiency is usually expressed as a percentage — that is, it expresses what percent of the input power will be available as useful output. To calculate percent efficiency, multiply the value from equation 20 by 100%. The efficiency in the example above is 60%.

Suppose a mobile transmitter has an RF power output of 100 W with 52% efficiency at 13.8 V. The vehicle's alternator system charges the battery at a rate of 5.0 A at this voltage. Assuming an alternator efficiency of 68%, how much horsepower must the engine produce to operate the transmitter and charge the battery? Solution: To charge the battery, the alternator must produce $13.8 \text{ V} \times 5.0 \text{ A} = 69 \text{ W}$. The transmitter dc input power is $100 \text{ W} / 0.52 = 190 \text{ W}$. Therefore, the total electrical power required from the alternator is $190 + 69 = 259 \text{ W}$. The engine load then is:

$$P_I = \frac{P_O}{\text{Eff}} = \frac{259 \text{ W}}{0.68} = 381 \text{ W}$$

We can convert this to horsepower using the conversion factor given earlier to convert between horsepower and watts:

$$\frac{381 \text{ W}}{746 \text{ W/hp}} = 0.51 \text{ horsepower (hp)}$$

2.4.4 Ohm's Law and Power Formulas

Electrical power in a resistance is turned into heat. The greater the power, the more rapidly the heat is generated. By substituting the Ohm's Law equivalent for E and I, the following formulas are obtained for power:

$$P = \frac{E^2}{R} \quad (21)$$

and

Ohm's Law and Power Circle

During the first semester of my *Electrical Power Technology* program, one of the first challenges issued by our dedicated instructor — Roger Cerie — to his new freshman students was to identify and develop 12 equations or formulas that could be used to determine voltage, current, resistance and power. Ohm's Law is expressed as $R = E / I$ and it provided three of these equation forms while the basic equation relating power to current and voltage ($P = I \times E$) accounted for another three. With six known equations, it was just a matter of applying mathematical substitution for his students to develop the remaining six. Together, these 12 equations compose the *circle* or *wheel* of voltage (E), current (I), resistance (R) and power (P) shown in Fig 2.A1. Just as Roger's previous students had learned at the Worcester Industrial Technical Institute (Worcester, Massachusetts), our Class of '82 now held the basic electrical formulas needed to proceed in our studies or professions. As can be seen in Fig 2.A1, we can determine any one of these four electrical quantities by knowing the value of any two others. You may want to keep this page bookmarked for your reference. You'll probably be using many of these formulas as the years go by — this has certainly been my experience. — Dana G. Reed, W1LC

Figure 2.A1 — Electrical formulas.

$$P = I^2 \times R \quad (22)$$

These formulas are useful in power calculations when the resistance and either the current or voltage (but not both) are known.

Example: How much power will be converted to heat in a 4000-Ω resistor if the potential applied to it is 200 V? From equation 21,

$$P = \frac{E^2}{R} = \frac{40,000 \text{ V}^2}{4000 \Omega} = 10.0 \text{ W}$$

As another example, suppose a current of 20 mA flows through a 300-Ω resistor. Then:

$$P = I^2 \times R = 0.020^2 \text{ A}^2 \times 300 \Omega$$

$$P = 0.00040 \text{ A}^2 \times 300 \Omega$$

$$P = 0.12 \text{ W}$$

Note that the current was changed from milliamperes to amperes before substitution in the formula.

Resistors for radio work are made in many sizes, the smallest being rated to safely operate at power levels of about $\frac{1}{16}$ W. The largest resistors commonly used in amateur equipment are rated at about 100 W. Large resistors, such as those used in dummy-load antennas, are often cooled with oil to increase their power-handling capability.

2.5 Circuit Control Components

2.5.1 Switches

Switches are used to allow or interrupt a current flowing in a particular circuit. Most switches are mechanical devices, although the same effect may be achieved with solid-state devices.

Switches come in many different forms and a wide variety of ratings. The most important ratings are the *voltage-handling* and *current-handling* capabilities. The voltage rating usually includes both the *breakdown voltage rating* and the *interrupt voltage rating*.

ing. The breakdown rating is the maximum voltage that the switch can withstand when it is open before the voltage will arc between the switch's terminals. The interrupt voltage rating is the maximum amount of voltage that the switch can interrupt without arcing. Normally, the interrupt voltage rating is the lower value, and therefore the one given for (and printed on) the switch.

Switches typically found in the home are usually rated for 125 V ac and 15 to 20 A. Switches in cars are usually rated for 12 V dc

and several amperes. The breakdown voltage rating of a switch primarily depends on the insulating material surrounding the contacts and the separation between the contacts. Plastic or phenolic material normally provides both structural support and insulation. Ceramic material may be used to provide better insulation, particularly in rotary (wafer) switches.

A switch's current rating includes both the *current-carrying capacity* and the *interrupt capability*. The current-carrying capacity of the switch depends on the contact material

and size, and on the pressure exerted to keep the contacts closed. It is primarily determined from the allowable contact temperature rise. On larger ac switches and most dc switches, the interrupt capability is usually lower than the current carrying value.

Most power switches are rated for alternating current use. Because ac current goes through zero twice in each cycle, switches can successfully interrupt much higher alternating currents than direct currents without arcing. A switch that has a 10-A ac current rating may arc and damage the contacts if used to turn off more than an ampere or two of dc.

Switches are normally designated by the number of *poles* (circuits controlled) and *throws* or *positions* (circuit path choices). The simplest switch is the on-off switch, which is a single-pole, single-throw (SPST) switch as shown in Fig 2.11A. The off position does not direct the current to another circuit. The next step would be to change the current path to another path. This would be a single-pole, double-throw (SPDT) switch as shown in Fig 2.11B. Adding an off position would give a single-pole, double-throw, center-off switch as shown in Fig 2.11C.

Several such switches can be “ganged” to or actuated by the same mechanical activator to provide double-pole, triple-pole or even more, separate control paths all activated at once. Switches can be activated in a variety of ways. The most common methods include lever or toggle, push-button and rotary switches. Samples of these are shown in Fig 2.12. Most switches stay in position once set, but some are spring-loaded so they only stay in the desired position while held there. These are called *momentary* switches.

Rotary/wafer switches can provide very complex switching patterns. Several poles (separate circuits) can be included on each wafer. Many wafers may be stacked on the same shaft. Not only may many different circuits be controlled at once, but by wiring different poles/positions on different wafers together, a high degree of circuit switching logic can be developed. Such switches can select different paths as they are turned and

Fig 2.11 — Schematic diagrams of various types of switches. A is an SPST, B is an SPDT, and C is an SPDT switch with a center-off position.

can also “short” together successive contacts to connect numbers of components or paths.

Rotary switches can also be designed to either break one contact before making another (*break-before-make*), or to short two contacts together before disconnecting the first one (*make-before-break*) to eliminate arcing or perform certain logic functions. The two types of switches are generally not interchangeable and may cause damage if inappropriately substituted for one another during circuit construction or repair. When buying rotary switches from a surplus or flea-market vendor, check to be sure the type of switch is correct.

Microswitches are designed to be actuated by the operation of machine components, opening or closing of a door, or some other mechanical movement. Instead of a handle or button-type actuator that would be used by a human, microswitches have levers or buttons more suitable for being actuated as part of an enclosure or machine.

In choosing a switch for a particular task, consideration should be given to function, voltage and current ratings, ease of use, availability and cost. If a switch is to be operated

frequently, a better-quality switch is usually less costly over the long run. If signal noise or contact corrosion is a potential problem (usually in low-current signal applications), it is best to get gold-plated contacts. Gold does not oxidize or corrode, thus providing surer contact, which can be particularly important at very low signal levels. Gold plating will not hold up under high-current-interrupt applications, however.

2.5.2 Fuses and Circuit Breakers

Fuses self-destruct to protect circuit wiring or equipment. The fuse *element* that melts or *blows* is a carefully shaped piece of soft metal, usually mounted in a cartridge of some kind. The element is designed to safely carry a given amount of current and to melt at a current value that is a certain percentage above the rated value.

The most important fuse rating is the *nominal current rating* that it will safely carry for an indefinite period without blowing. A fuse’s melting current depends on the type of material, the shape of the element and the

Fig 2.12 — This photo shows examples of various styles of switches. The ¼-inch-ruled graph paper background provides for size comparison.

Fig 2.13 — These photos show examples of various styles of fuses. Cartridge-type fuses (A, top) can use glass or ceramic construction. The center fuse is a slow-blow type. Automotive blade-type fuses (A, bottom) are common for low-voltage dc use. A typical home circuit breaker for ac wiring is shown at B.

heat dissipation capability of the cartridge and holder, among other factors.

Next most important are the timing characteristics, or how quickly the fuse element blows under a given current overload. Some fuses (*slow-blow*) are designed to carry an overload for a short period of time. They typically are used in motor-starting and power-supply circuits that have a large inrush current when first started. Other fuses are designed to blow very quickly to protect delicate instruments and solid-state circuits.

A fuse also has a voltage rating, both a value in volts and whether it is expected to be used in ac or dc circuits. The voltage rating is the amount of voltage an open fuse can withstand without arcing. While you should never substitute a fuse with a higher current rating than the one it replaces, you may use a fuse with a higher voltage rating.

Fig 2.13A shows typical cartridge-style cylindrical fuses likely to be encountered in ac-powered radio and test equipment. Automotive style fuses, shown in the lower half of Fig 2.13A, have become widely used in low-voltage dc power wiring of amateur stations. These are called “blade” fuses. Rated for vehicle-level voltages, automotive blade fuses should never be used in ac line-powered circuits.

Circuit breakers perform the same function as fuses — they open a circuit and interrupt current flow when an overload occurs. Instead of a melting element, circuit breakers use spring-loaded magnetic mechanisms to open a switch when excessive current is present. Once the overload has been corrected, the circuit-breaker can be reset. Circuit breakers are generally used by amateurs in home ac wiring (a typical ac circuit breaker is shown in Fig 2.13B) and in dc power supplies.

A replacement fuse or circuit breaker should have the same current rating and the same characteristics as the fuse it replaces. Never substitute a fuse with a larger current rating. You may cause permanent damage (maybe even a fire) to wiring or circuit elements by allowing larger currents to flow when there is an internal problem in equipment. (Additional discussion of fuses and circuit breakers is provided in the chapter on **Safety**.)

Fuses blow and circuit breakers open for several reasons. The most obvious reason is that a problem develops in the circuit, causing too much current to flow. In this case, the circuit problem needs to be fixed. A fuse can fail from being cycled on and off near its current rating. The repeated thermal stress causes metal fatigue and eventually the fuse blows. A fuse can also blow because of a momentary power surge, or even by rapidly turning equipment with a large inrush current on and off several times. In these cases it is only necessary to replace the fuse with

the same type and value.

Panel-mount fuse holders should be wired with the hot lead of an ac power circuit (the black wire of an ac power cord) connected to the end terminal, and the ring terminal is connected to the power switch or circuit inside the chassis. This removes voltage from the fuse as it is removed from the fuse holder. This also locates the line connection at the far end of the fuse holder where it is not easily accessible.

2.5.3 Relays And Solenoids

Relays are switches controlled by an electrical signal. *Electromechanical relays* consist of an electromagnetic *coil* and a moving *armature* attracted by the coil’s magnetic field when energized by current flowing in the coil. Movement of the armature pushes the switch contacts together or apart. Many sets of contacts can be connected to the same armature, allowing many circuits to be controlled by a single signal. In this manner, the signal voltage that energizes the coil can control circuits carrying large voltages and/or currents.

Relays have two positions or *states* — *energized* and *de-energized*. Sets of contacts called *normally-closed* (NC) are closed when the relay is de-energized and open when it is energized. *Normally-open* contact sets are closed when the relay is energized.

Like switches, relay contacts have breakdown voltage, interrupting, and current-carrying ratings. These are not the same as the voltage and current requirements for energizing the relay’s coil. Relay contacts (and housings) may be designed for ac, dc or RF signals. The most common control voltages for relays used in amateur equipment are 12 V dc or 120 V ac. Relays with 6, 24, and 28 V dc, and 24 V ac coils are also common. **Fig 2.14** shows some typical relays found in amateur equipment.

A relay’s *pull-in voltage* is the minimum voltage at which the coil is guaranteed to cause the armature to move and change the relay’s state. *Hold-in voltage* is the minimum voltage at which the relay is guaranteed to hold the armature in the energized position after the relay is activated. A relay’s pull-in voltage is higher than its hold-in voltage due to magnetic hysteresis of the coil (see the section on magnetic materials below). *Current-sensing relays* activate when the current through the coil exceeds a specific value, regardless of the voltage applied to the coil. They are used when the control signal is a current rather than a voltage.

Latching relays have two coils; each moves the armature to a different position where it remains until the other coil is energized. These relays are often used in portable and low-power equipment so that the contact configuration can be maintained without the need to continuously supply power to the relay.

Reed relays have no armature. The contacts are attached to magnetic strips or “reeds” in a glass or plastic tube, surrounded by a coil. The reeds move together or apart when current is applied to the coil, opening or closing contacts. Reed relays can open and close very quickly and are often used in transmit-receive switching circuits.

Solid-state relays (SSR) use transistors in-

(A)

(C)

Fig 2.14 — These photos show examples of various styles and sizes of relays. Photo A shows a large reed relay, and a small reed relay in a package the size of a DIP IC. The contacts and coil can clearly be seen in the open-frame relay. Photo B shows a relay inside a plastic case. Photo C shows a four-position coaxial relay-switch combination with SMA connectors. The ¼-inch-ruled graph paper background provides a size comparison.

stead of mechanical contacts and electronic circuits instead of magnetic coils. They are designed as substitutes for electromechanical relays in power and control circuits and are not used in low-level ac or dc circuits.

Coaxial relays have an armature and contacts designed to handle RF signals. The sig-

nal path in coaxial relays maintains a specific characteristic impedance for use in RF systems. Coaxial connectors are used for the RF circuits. Coaxial relays are typically used to control antenna system configurations or to switch a transceiver between a linear amplifier and an antenna.

A *solenoid* is very similar to a relay, except that instead of the moving armature actuating switch contacts, the solenoid moves a lever or rod to actuate some mechanical device. Solenoids are not commonly used in radio equipment, but may be encountered in related systems or devices.

2.6 AC Theory and Waveforms

2.6.1 AC in Circuits

A circuit is a complete conductive path for current to flow from a source, through a load and back to the source. If the source permits the current to flow in only one direction, the current is *dc* or *direct current*. If the source permits the current to change direction, the current is *ac* or *alternating current*. **Fig 2.15** illustrates the two types of circuits. Circuit A shows the source as a battery, a typical dc source. Circuit B shows the more abstract voltage source symbol to indicate ac. In an ac circuit, both the current and the voltage reverse direction. For nearly all ac signals in electronics and radio, the reversal is *periodic*, meaning that the change in direction occurs on a regular basis. The rate of reversal may range from a few times per second to many billions per second.

Graphs of current or voltage, such as **Fig 2.15**, begin with a horizontal axis that represents time. The vertical axis represents the amplitude of the current or the voltage, whichever is graphed. Distance above the zero line indicates larger positive amplitude; distance below the zero line means larger negative amplitude. Positive and negative only designate the opposing directions in which current may flow in an alternating current circuit or the opposing *polarities* of an ac voltage.

If the current and voltage never change direction, then from one perspective, we have a dc circuit, even if the level of dc constantly changes. **Fig 2.16** shows a current that is always positive with respect to 0. It varies periodically in amplitude, however. Whatever the shape of the variations, the current can be called *pulsating dc*. If the current periodically reaches 0, it can be called *intermittent dc*. From another perspective, we may look at intermittent and pulsating dc as a combination of an ac and a dc current. Special circuits can separate the two currents into ac and dc *components* for separate analysis or use. There are circuits that combine ac and dc currents and voltages, as well.

2.6.2 AC Waveforms

A *waveform* is the pattern of amplitudes reached by an ac voltage or current as measured over time. The combination of ac and dc voltages and currents results in *complex*

waveforms. **Fig 2.17** shows two ac waveforms fairly close in frequency and their combination. **Fig 2.18** shows two ac waveforms dissimilar in both frequency and wavelength, along with the resultant combined waveform. Note the similarities (and the differences) between the resultant waveform in **Fig 2.18** and the combined ac-dc waveform in **Fig 2.16**.

Alternating currents may take on many useful waveforms. **Fig 2.19** shows a few that are commonly used in electronic and radio circuits. The *sine wave* is both mathematically and practically the foundation of all other forms of ac; the other forms can usually be reduced to (and even constructed from) a particular collection of sine waves. The *square wave* is vital to digital electronics. The *triangular* and *ramp waves* — the latter sometimes called a *sawtooth* waveform — are especially

useful in timing circuits. The individual repeating patterns that make up these *periodic waveforms* are called *cycles*. Waveforms that do not consist of repetitive patterns are called *aperiodic* or *irregular* waveforms. Speech is

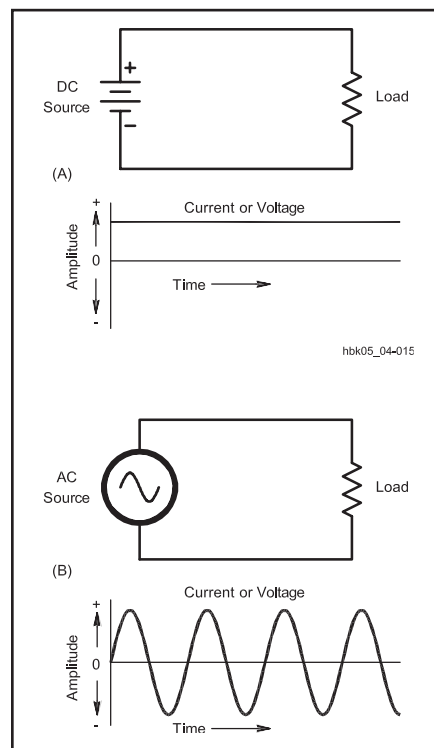

Fig 2.15 — Basic circuits for direct and alternating currents. With each circuit is a graph of the current, constant for the dc circuit, but periodically changing direction in the ac circuit.

Fig 2.16 — A pulsating dc current (A) and its resolution into an ac component (B) and a dc component (C).

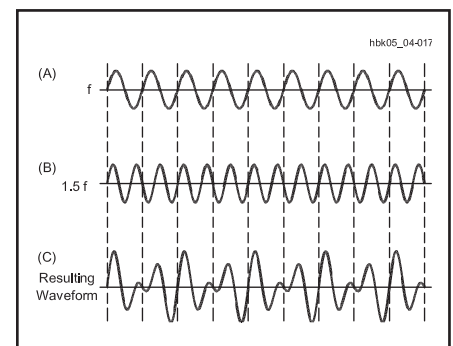

Fig 2.17 — Two ac waveforms of similar frequencies ($f_1 = 1.5 f_2$) and amplitudes form a composite wave. Note the points where the positive peaks of the two waves combine to create high composite peaks at a frequency that is the difference between f_1 and f_2 . The beat note frequency is $1.5f - f = 0.5f$ and is visible in the drawing.

FREQUENCY AND PERIOD

With a continuously rotating generator, alternating current or voltage will pass through many equal cycles over time. This is a *periodic waveform*, composed of many identical cycles. An arbitrary point on any one cycle can be used as a marker of position on a periodic waveform. For this discussion, the positive peak of the waveform will work as an unambiguous marker. The number of times per second that the current (or voltage) reaches this positive peak in any one second is called the *frequency* of the waveform. In other words, frequency expresses the *rate* at which current (or voltage) cycles occur. The unit of frequency is *cycles per second*, or *hertz*—abbreviated Hz (after the 19th century radio-phenomena pioneer, Heinrich Hertz).

The length of any cycle in units of time is the *period* of the cycle, as measured between equivalent points on succeeding cycles. Mathematically, the period is the inverse of frequency. That is,

$$\text{Frequency (f) in Hz} = \frac{1}{\text{Period (T) in seconds}} \quad (23)$$

and

$$\text{Period (T) in seconds} = \frac{1}{\text{Frequency (f) in Hz}} \quad (24)$$

Example: What is the period of a 400-hertz ac current?

$$T = \frac{1}{f} = \frac{1}{400 \text{ Hz}} = 0.00250 \text{ s} = 2.5 \text{ ms}$$

The frequency of alternating currents used in radio circuits varies from a few hertz, or cycles per second, to thousands of millions of hertz. Likewise, the period of alternating currents amateurs use ranges from significant fractions of a second down to nanoseconds or smaller. In order to express compactly the units of frequency, time and almost everything else in electronics, a standard system of prefixes is used. In magnitudes of 1000 or 10^3 , frequency is measurable in hertz, in kilohertz (1000 hertz or kHz), in megahertz (1 million hertz or MHz), gigahertz (1 billion hertz or GHz — pronounced “gee-gah” with a hard ‘g’ as in ‘golf’) and even in terahertz (1 trillion hertz or THz). For units smaller than unity, as in the measurement of period, the basic unit can be milliseconds (1 thousandth of a second or ms), microseconds (1 millionth of a second or μs), nanoseconds (1 billionth of a second or ns) and picoseconds (1 trillionth of a second or ps).

It is common for complex ac signals to contain a series of sine waves with frequencies related by integer multiples of some lowest or *fundamental* frequency. Sine waves with the higher frequency are called harmonics and are

Fig 2.18 — Two ac waveforms of widely different frequencies and amplitudes form a composite wave in which one wave appears to ride upon the other.

Fig 2.19 — Some common ac waveforms: square, triangle, ramp and sine.

a good example of an irregular waveform, as is noise or static.

There are numerous ways to generate alternating currents: with an ac power generator (an *alternator*), with a *transducer* (for example, a microphone) or with an electronic circuit (for example, an RF oscillator). The basis of the sine wave is circular or cyclical motion, which underlies the most usual methods of generating alternating current. The circular motion of the ac generator may be physical or mechanical, as in an alternator. Currents in the resonant circuit of an oscillator may also produce sine waves as repetitive electrical cycles without mechanical motion.

SINE WAVES AND CYCLICAL MOTION

The relationship between circular motion and the sine wave is illustrated in **Fig 2.20** as the correlation between the amplitude of an ac current (or voltage) and the relative positions of a point making circular rotations through one complete revolution of 360° . Following the height of the point above the horizontal

axis, its height is zero at point 1. It rises to a maximum at a position 90° from position 1, which is position 3. At position 4, 180° from position 1, the point’s height falls back to zero. Then the point’s height begins to increase again, but below the horizontal axis, where it reaches a maximum at position 5.

An alternative way of visualizing the relationship between circular motion and sine waves is to use a yardstick and a light source, such as a video projector. Hold the yardstick horizontally between the light source and the wall so that it points directly at the light source. This is defined as the 0° position and the length of the yardstick’s shadow is zero. Now rotate the yardstick, keeping the end farthest from the projector stationary, until the yardstick is vertical. This is the 90° position and the shadow’s length is a maximum in the direction defined as positive. Continue to rotate the yardstick until it reaches horizontal again. This is the 180° position and the shadow once again has zero length. Keep rotating the yardstick in the same direction until it is vertical and the shadow is at maximum, but now below the stationary end of the yardstick. This is the 270° position and the direction of the shadow is defined to be negative. Another 90° of rotation brings the pointer back to its original position at 0° and the shadow’s length to zero. If the length of the shadow is plotted against the amount of rotation of the yardstick, the result is a sine wave.

The corresponding rise and fall of a *sinusoidal* or sine wave current (or voltage) along a linear time line produces the curve accompanying the circle in **Fig 2.20**. The curve is sinusoidal because its amplitude varies as the sine of the angle made by the circular movement with respect to the zero position. This is often referred to as the *sine function*, written $\sin(\text{angle})$. The sine of 90° is 1, and 90° is also the position of maximum current (along with 270° , but with the opposite polarity). The sine of 45° (point 2) is 0.707, and the value of current at point 2, the 45° position of rotation, is 0.707 times the maximum current. Both ac current and voltage sine waves vary in the same way.

Fig 2.20 — The relationship of circular motion and the resultant graph of ac current or voltage. The curve is sinusoidal, a sine wave.

said to be *harmonically related* to the fundamental. For example, if a complex waveform is made up of sine waves with frequencies of 10, 20 and 30 kHz, 10 kHz is the fundamental and the other two are harmonics.

The uses of ac in radio circuits are many and varied. Most can be cataloged by reference to ac frequency ranges used in circuits. For example, the frequency of ac power used in the home, office and factory is ordinarily 60 Hz in the United States and Canada. In Great Britain and much of Europe, ac power is 50 Hz. Sonic and ultrasonic applications of ac run from about 20 Hz (audio) up to several MHz.

Radio circuits include both power- and sonic-frequency-range applications. Radio communication and other electronics work, however, require ac circuits capable of operation with frequencies up to the GHz range. Some of the applications include signal sources for transmitters (and for circuits inside receivers); industrial induction heating; diathermy; microwaves for cooking, radar and communication; remote control of appliances, lighting, model planes and boats and other equipment; and radio direction finding and guidance.

PHASE

When drawing the sine-wave curve of an ac voltage or current, the horizontal axis represents time. This type of drawing in which the amplitude of a waveform is shown compared to time is called the *time domain*. Events to the right take place later; events to the left occur earlier. Although time is measurable in parts of a second, it is more convenient to treat each cycle as a complete time unit divided into 360° . The conventional starting point for counting degrees in a sinusoidal waveform such as ac is the *zero point* at which the voltage or current begins the positive *half cycle*. The essential elements of an ac cycle appear in Fig 2.21.

The advantage of treating the ac cycle in this way is that many calculations and measurements can be taken and recorded in a manner that is independent of frequency. The positive peak voltage or current occurs at 90° into the cycle. Relative to the starting point, 90° is the *phase* of the ac at that point. Phase is the position within an ac cycle expressed in degrees or *radians*. Thus, a complete description of an ac voltage or current involves reference to three properties: frequency, amplitude and phase.

Phase relationships also permit the comparison of two ac voltages or currents at the same frequency. If the zero point of two signals with the frequency occur at the same time, there is zero phase difference between the signals and they are said to be *in phase*.

Fig 2.22 illustrates two waveforms with a constant phase difference. Since B crosses

Fig 2.21 — An ac cycle is divided into 360° that are used as a measure of time or phase.

Fig 2.22 — When two waves of the same frequency start their cycles at slightly different times, the time difference or phase difference is measured in degrees. In this drawing, wave B starts 45° (one-eighth cycle) later than wave A, and so lags 45° behind A.

the zero point in the positive direction after A has already done so, there is a *phase difference* between the two waves. In the example, B lags A by 45° , or A leads B by 45° . If A and B occur in the same circuit, their composite waveform will also be a sine wave at an intermediate phase angle relative to each. Adding any number of sine waves of the same frequency always results in a sine wave at that frequency. Adding sine waves of different frequencies, as in Fig 2.17, creates a complex waveform with a *beat frequency* that is the difference between the two sine waves.

Fig 2.22 might equally apply to a voltage and a current measured in the same ac circuit. Either A or B might represent the voltage; that is, in some instances voltage will lead the current and in others voltage will lag the current.

Two important special cases appear in Fig 2.23. In Part A, line B lags 90° behind line A. Its cycle begins exactly one quarter cycle later than the A cycle. When one wave is passing through zero, the other just reaches its maximum value. In this example, the two sine waves are said to be *in quadrature*.

In Part B, lines A and B are 180° out of phase, sometimes called *anti-phase*. In this case, it does not matter which one is considered to lead or lag. Line B is always positive

Fig 2.23 — Two important special cases of phase difference: In the upper drawing, the phase difference between A and B is 90° ; in the lower drawing, the phase difference is 180° .

while line A is negative, and vice versa. If the two waveforms are of two voltages or two currents in the same circuit and if they have the same amplitude, they will cancel each other completely.

Phase also has other meanings. It is important to distinguish between *polarity*, meaning the sense in which positive and negative voltage or current relate to circuit operation, and phase, which is a function of time or position in a waveform. It is quite possible for two signals to have opposite polarities, but still be in phase, for example. In a multi-phase ac power system, “phase” refers to one of the distinct voltage waveforms generated by the utility.

Degrees and Radians

While most electronic and radio mathematics use degrees as a measure of phase, you will occasionally encounter *radians*. Radians are used because they are more convenient mathematically in certain equations and computations. Radians are used for angular measurements when the *angular frequency* (ω) is being used. There are 2π radians in a circle, just as there are 360° , so one radian = $360/2\pi \approx 57.3^\circ$. Angular frequency is measured in radians/second (not revolutions/second or cycles/second) so $\omega = 2\pi f$. In this *Handbook*, unless specifically noted otherwise, the convention will be to use degrees in all calculations that require an angle.

2.6.3 Electromagnetic Energy

Alternating currents are often loosely classified as audio frequency (AF) and radio frequency (RF). Although these designations are handy, they actually represent something other than electrical energy: They designate special forms of energy that we find useful.

Audio or *sonic* energy is the energy imparted by the mechanical movement of a medium, which can be air, metal, water or even the human body. Sound that humans can hear normally requires the movement of air between 20 Hz and 20 kHz, although the human ear loses its ability to detect the extremes of this range as we age. Some animals, such as elephants, can detect air vibrations well below 20 Hz, while others, such as dogs and cats, can detect air vibrations well above 20 kHz.

Electrical circuits do not directly produce air vibrations. Sound production requires a *transducer*, a device to transform one form of energy into another form of energy; in this case electrical energy into sonic energy. The speaker and the microphone are the most common audio transducers. There are numerous ultrasonic transducers for various applications.

RF energy occurs at frequencies for which it is practical to generate and detect *electromagnetic* or *RF waves* that exist independently of the movement of electrical charge, such as a radio signal. Like sonic energy, a transducer — an antenna — is required to convert the electrical energy in a circuit to electromagnetic waves. In a physical circuit, such as a wire, electromagnetic energy exists as both electromagnetic waves and the physical movement of electrical charge.

Electromagnetic waves have been generated and detected in many forms with frequencies from below 1 Hz to above 10^{12} GHz, including at the higher frequencies infrared, visible, and ultraviolet light, and a number of energy forms of greatest interest to physicists and astronomers. **Table 2.3** provides a brief glimpse at the total spectrum of electromagnetic energy. The *radio spectrum* is generally considered to begin around 3 kHz and end at infrared light.

Despite the close relationship between

electromagnetic energy and waves, it remains important to distinguish the two. To a circuit producing or amplifying a 15-kHz alternating current, the ultimate transformation and use of the electrical energy may make no difference to the circuit's operation. By choosing the right transducer, one can produce either a sonic wave or an electromagnetic wave — or both. Such is a common problem of video monitors and switching power supplies; forces created by the ac currents cause electronic parts both to vibrate audibly *and* to radiate electromagnetic energy.

All electromagnetic energy has one thing in common: it travels, or *propagates*, at the speed of light, abbreviated *c*. This speed is approximately 300,000,000 (or 3×10^8) meters per second in a vacuum. Electromagnetic-energy waves have a length uniquely associated with each possible frequency. The *wavelength* (λ) is the speed of propagation divided by the frequency (*f*) in hertz.

$$f \text{ (Hz)} = \frac{3.0 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{\lambda \text{ (m)}} \quad (25)$$

and

$$\lambda \text{ (m)} = \frac{3.0 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{f \text{ (Hz)}} \quad (26)$$

Example: What is the frequency of an RF wave with wavelength of 80 meters?

$$f \text{ (Hz)} = \frac{3.0 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{\lambda \text{ (m)}}$$

$$= \frac{3.0 \times 10^8 \left(\frac{\text{m}}{\text{s}} \right)}{80.0 \text{ m}}$$

$$= 3.75 \times 10^6 \text{ Hz}$$

This is 3.750 MHz or 3750 kHz, a frequency in the middle of the ham band known as “80 meters.”

A similar equation is used to calculate the wavelength of a sound wave in air, substituting the speed of sound instead of the speed of light in the numerator. The speed of propagation of the mechanical movement of air that we call sound varies considerably with air temperature and altitude. The speed of sound at sea level is about 331 m/s at 0 °C and 344 m/s at 20 °C.

To calculate the frequency of an electromagnetic wave directly in kilohertz, change the speed constant to 300,000 (3×10^5) km/s.

$$f \text{ (kHz)} = \frac{3.0 \times 10^5 \left(\frac{\text{km}}{\text{s}} \right)}{\lambda \text{ (m)}} \quad (27)$$

and

$$\lambda \text{ (m)} = \frac{3.0 \times 10^5 \left(\frac{\text{km}}{\text{s}} \right)}{f \text{ (kHz)}} \quad (28)$$

For frequencies in megahertz, change the speed constant to 300 (3×10^2) Mm/s.

$$f \text{ (MHz)} = \frac{300 \left(\frac{\text{Mm}}{\text{s}} \right)}{\lambda \text{ (m)}} \quad (29)$$

and

$$\lambda \text{ (m)} = \frac{300 \left(\frac{\text{Mm}}{\text{s}} \right)}{f \text{ (MHz)}} \quad (30)$$

Stated as it is usually remembered and used, “wavelength in meters equals 300 divided by frequency in megahertz.” Assuming the proper units for the speed of light constant simplify the equation.

Example: What is the wavelength of an RF wave whose frequency is 4.0 MHz?

$$\lambda \text{ (m)} = \frac{300}{f \text{ (MHz)}} = \frac{300}{4.0} = 75 \text{ m}$$

At higher frequencies, circuit elements with lengths that are a significant fraction of a wavelength can act like transducers. This property can be useful, but it can also cause problems for circuit operations. Therefore, wavelength calculations are of some importance in designing ac circuits for those frequencies.

Within the part of the electromagnetic-energy spectrum of most interest to radio applications, frequencies have been classified into groups and given names. **Table 2.4** provides a reference list of these classifications. To a significant degree, the frequencies within each group exhibit similar properties, both in circuits and as RF waves. For example, HF or high frequency waves, with frequencies from

Table 2.3

Key Regions of the Electromagnetic Energy Spectrum

Region Name	Frequency Range	
Radio frequencies	3.0×10^3 Hz	to 3.0×10^{11} Hz
Infrared	3.0×10^{11} Hz	to 4.3×10^{14} Hz
Visible light	4.3×10^{14} Hz	to 7.5×10^{14} Hz
Ultraviolet	7.5×10^{14} Hz	to 6.0×10^{16} Hz
X-rays	6.0×10^{16} Hz	to 3.0×10^{19} Hz
Gamma rays	3.0×10^{19} Hz	to 5.0×10^{20} Hz
Cosmic rays	5.0×10^{20} Hz	to 8.0×10^{21} Hz

Note: The range of radio frequencies can also be written as 3 kHz to 300 GHz

Table 2.4

Classification of the Radio Frequency Spectrum

Abbreviation	Classification	Frequency Range
VLF	Very low frequencies	3 to 30 kHz
LF	Low frequencies	30 to 300 kHz
MF	Medium frequencies	300 to 3000 kHz
HF	High frequencies	3 to 30 MHz
VHF	Very high frequencies	30 to 300 MHz
UHF	Ultrahigh frequencies	300 to 3000 MHz
SHF	Superhigh frequencies	3 to 30 GHz
EHF	Extremely high frequencies	30 to 300 GHz

3 to 30 MHz, all exhibit *skip* or ionospheric refraction that permits regular long-range radio communications. This property also applies occasionally both to MF (medium frequency) and to VHF (very high frequency) waves, as well.

2.6.4 Measuring AC Voltage, Current and Power

Measuring the voltage or current in a dc circuit is straightforward, as Fig 2.24A demonstrates. Since the current flows in only one direction, the voltage and current have constant values until the resistor values are changed.

Fig 2.24B illustrates a perplexing problem encountered when measuring voltages and currents in ac circuits — the current and voltage continuously change direction and value. Which values are meaningful? How are measurements performed? In fact, there are several methods of measuring sine-wave voltage and current in ac circuits with each method providing different information about the waveform.

INSTANTANEOUS VOLTAGE AND CURRENT

By far, the most common waveform associated with ac of any frequency is the sine wave. Unless otherwise noted, it is safe to assume that measurements of ac voltage or current are of a sinusoidal waveform. Fig 2.25 shows a sine wave representing a voltage or current of some arbitrary frequency and amplitude. The *instantaneous* voltage (or current) is the value at one instant in time. If a series of instantaneous values are plotted against time, the resulting graph will show the waveform.

In the sine wave of Fig 2.25, the instantaneous value of the waveform at any point in time is a function of three factors: the maximum value of voltage (or current) along the curve (point B, E_{max}), the frequency of the wave (f), and the time elapsed from the preceding positive-going zero crossing (t) in seconds or fractions of a second. Thus,

$$E_{inst} = E_{max} \sin(ft) \tag{31}$$

assuming all sine calculations are done in degrees. (See the sidebar “Degrees and Radians”.) If the sine calculation is done in radians, substitute $2\pi ft$ for ft in equation 31.

If the point’s phase is known — the position along the waveform — the instantaneous voltage at that point can be calculated directly as:

$$E_{inst} = E_{max} \sin \theta \tag{32}$$

where θ is the number of degrees of phase difference from the beginning of the cycle.

Example: What is the instantaneous value of voltage at point D in Fig 2.25, if the maximum voltage value is 120 V and point D’s phase is 60.0° ?

$$E_{inst} = 120 \text{ V} \times \sin 60^\circ$$

$$= 120 \times 0.866 = 104 \text{ V}$$

PEAK AND PEAK-TO-PEAK VOLTAGE AND CURRENT

The most important of an ac waveform’s instantaneous values are the maximum or *peak values* reached on each positive and negative half cycle. In Fig 2.25, points B and C represent the positive and negative peaks. Peak values (indicated by a “pk” or “p” subscript) are especially important with respect to component ratings, which the voltage or current in a circuit must not exceed without danger of component failure.

The *peak power* in an ac circuit is the

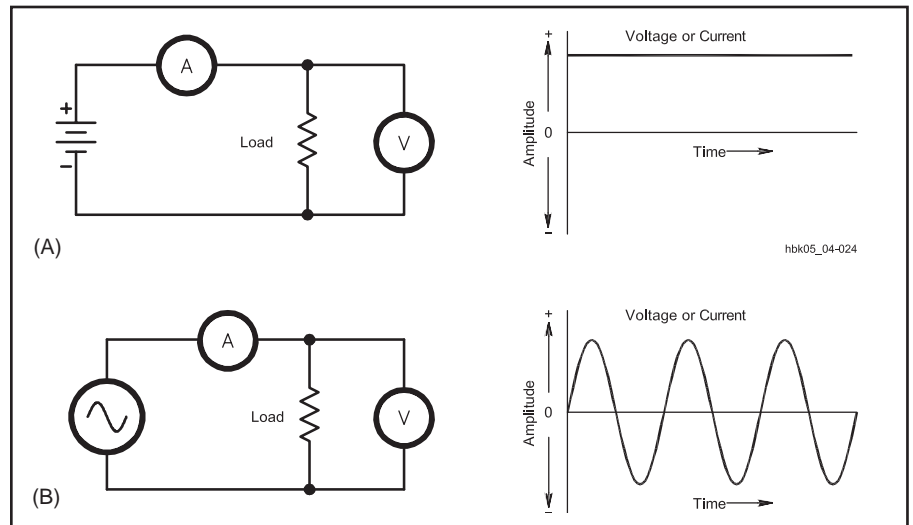

Fig 2.24 — Voltage and current measurements in dc and ac circuits.

Fig 2.25 — Two cycles of a sine wave to illustrate instantaneous, peak, and peak-to-peak ac voltage and current values.

product of the peak voltage and the peak current, or

$$P_{pk} = E_{pk} \times I_{pk} \quad (33)$$

The span from points B to C in Fig 2.25 represents the largest difference in value of the sine wave. Designated the *peak-to-peak* value (indicated by a “P-P” subscript), this span is equal to twice the peak value of the waveform. Thus, peak-to-peak voltage is:

$$E_{P-P} = 2 E_{pk} \quad (34)$$

Amplifying devices often specify their input limits in terms of peak-to-peak voltages. Operational amplifiers, which have almost unlimited gain, often require input-level limiting to prevent the output signals from distorting if they exceed the peak-to-peak output rating of the devices.

RMS VALUES OF VOLTAGES AND CURRENTS

The *root mean square* or *RMS* values of voltage and current are the most common values encountered in electronics. Sometimes called *effective* values, the RMS value of an ac voltage or current is the value of a dc voltage or current that would cause a resistor to dissipate the same average amount of power as the ac waveform. This measurement became widely used in the early days of electrification when both ac and dc power utility power were in use. Even today, the values of the ac line voltage available from an electrical power outlet are given as RMS values. Unless otherwise specified, unlabeled ac voltage and current values found in most electronics literature are normally RMS values.

The RMS values of voltage and current get their name from the mathematical method used to derive their value relative to peak voltage and current. Start by *squaring* the in-

dividual values of all the instantaneous values of voltage or current during an entire single cycle of ac. Take the average (*mean*) of these squares (this is done by computing an integral of the waveform) and then find the square *root* of that average. This procedure produces the RMS value of voltage or current for all waveforms, sinusoidal or not. (The waveform is assumed to be periodic.)

For the remainder of this discussion, remember that we are assuming that the waveform in question is a sine wave. The simple formulas and conversion factors in this section are generally *not* true for non-sinusoidal waveforms such as square or triangle waves (see the sidebar, “Measuring Non-Sinusoidal Waveforms”). The following formulas are true *only* if the waveform is a sine wave and the circuit is *linear*—that is, raising or lowering the voltage will raise or lower the current proportionally. If those conditions are true, the following conversion factors have been computed and can be used without any additional mathematics.

For a sine wave to produce heat equivalent to a dc waveform the peak ac power required is twice the dc power. Therefore, the average ac power equivalent to a corresponding dc power is half the peak ac power.

$$P_{ave} = \frac{P_{pk}}{2} \quad (35)$$

A sine wave’s RMS voltage and current values needed to arrive at average ac power are related to their peak values by the conversion factors:

$$E_{RMS} = \frac{E_{pk}}{\sqrt{2}} = \frac{E_{pk}}{1.414} = E_{pk} \times 0.707 \quad (36)$$

$$I_{RMS} = \frac{I_{pk}}{\sqrt{2}} = \frac{I_{pk}}{1.414} = I_{pk} \times 0.707 \quad (37)$$

RMS voltages and currents are what is displayed by most volt and ammeters.

If the RMS voltage is the peak voltage divided by $\sqrt{2}$, then the peak voltage must be the RMS voltage multiplied by $\sqrt{2}$, or

$$E_{pk} = E_{RMS} \times 1.414 \quad (38)$$

$$I_{pk} = I_{RMS} \times 1.414 \quad (39)$$

Example: What is the peak voltage and the peak-to-peak voltage at the usual household ac outlet, if the RMS voltage is 120 V?

$$E_{pk} = 120 \text{ V} \times 1.414 = 170 \text{ V}$$

$$E_{P-P} = 2 \times 170 \text{ V} = 340 \text{ V}$$

In the time domain of a sine wave, the instantaneous values of voltage and current correspond to the RMS values at the 45°, 135°, 225° and 315° points along the cycle shown in Fig 2.26. (The sine of 45° is approximately 0.707.) The instantaneous value of voltage or current is greater than the RMS value for half the cycle and less than the RMS value for half the cycle.

Since circuit specifications will most commonly list only RMS voltage and current values, these relationships are important in finding the peak voltages or currents that will stress components.

Example: What is the peak voltage on a capacitor if the RMS voltage of a sinusoidal waveform signal across it is 300 V ac?

$$E_{pk} = 300 \text{ V} \times 1.414 = 424 \text{ V}$$

The capacitor must be able to withstand this higher voltage, plus a safety margin. (The capacitor must also be rated for ac use because of the continually reversing polarity and ac current flow.) In power supplies that convert ac to dc and use capacitive input filters, the output voltage will approach the peak value of the ac voltage rather than the RMS value. (See the **Power Sources** chapter for more information on specifying components in this application.)

AVERAGE VALUES OF AC VOLTAGE AND CURRENT

Certain kinds of circuits respond to the *average* voltage or current (not power) of an ac waveform. Among these circuits are electrodynamic meter movements and power supplies that convert ac to dc and use heavily inductive (“choke”) input filters, both of which work with the pulsating dc output of a full-wave rectifier. The average value of each ac half cycle is the *mean* of all the instantaneous values in that half cycle. (The average value of a sine wave or any symmetric ac waveform over an entire cycle is zero!) Related to the peak values of voltage and current, average values for each half-cycle

Fig 2.26 — The relationships between RMS, average, peak, and peak-to-peak values of ac voltage and current.

Measuring Nonsinusoidal Waveforms

Making measurements of ac waveforms is covered in more detail in the **Test Equipment and Measurements** chapter. However, this is a good point in the discussion to reinforce the dependence of RMS and values on the nature of the waveform being measured.

Analog meters and other types of instrumentation that display RMS values may only be calibrated for sine waves, those being the most common type of ac waveform. Using that instrumentation to accurately measure waveforms other than sine waves — such as speech, intermittent sine waves (such as CW from a transmitter), square waves, triangle waves or noise — requires the use of *calibration factors* or the measurement may not be valid.

To make calibrated, reliable measurements of the RMS or value of these waveforms requires the use of *true-RMS* instruments. These devices may use a balancing approach to a known dc value or if they are microprocessor-based, may actually perform the full root-mean-square calculation on the waveform. Be sure you know the characteristics of your test instruments if an accurate RMS value is important.

of a sine wave are $2/\pi$ (or 0.6366) times the peak value.

$$E_{\text{ave}} = 0.6366 E_{\text{pk}} \quad (40)$$

$$I_{\text{ave}} = 0.6366 I_{\text{pk}} \quad (41)$$

For convenience, **Table 2.5** summarizes the relationships between all of the common ac values. All of these relationships apply only to sine waves.

COMPLEX WAVEFORMS AND PEAK-ENVELOPE VALUES

Complex waveforms, as shown earlier in Fig 2.18, differ from sine waves. The amplitude of the peak voltage may vary significantly

Fig 2.27 — The peak envelope voltage (PEV) for a composite waveform.

cantly from one cycle to the next, for example. Therefore, other amplitude measures are required, especially for accurate measurement of voltage and power with transmitted speech or data waveforms.

An SSB waveform (either speech or data) contains an RF ac waveform with a frequency many times that of the audio-frequency ac waveform with which it is combined. Therefore, the resultant *composite* waveform appears as an amplitude envelope superimposed upon the RF waveform as illustrated by **Fig 2.27**. For a complex waveform such as this, the *peak envelope voltage* (PEV) is the maximum or peak value of voltage anywhere in the waveform.

Peak envelope voltage is used in the calculation of *peak envelope power* (PEP). The Federal Communications Commission (FCC) sets the maximum power levels for amateur transmitters in terms of peak envelope power. PEP is the *average* power supplied to the antenna transmission line by the transmitter during one RF cycle at the crest of the modulation envelope, taken under normal operating conditions. That is, the average power for the RF cycle during which PEV occurs.

Since calculation of PEP requires the average power of the cycle, and the deviation of the modulated RF waveform from a sine wave is very small, the error incurred by using the conversion factors for sine waves is insignificant. Multiply PEV by 0.707 to obtain an RMS value. Then calculate PEP by using the square of the voltage divided by the load resistance.

$$\text{PEP} = \frac{(\text{PEV} \times 0.707)^2}{R} \quad (42)$$

Example: What is the PEP of a transmitter's

output with a PEV of 100 V into a 50-ohm load?

$$\text{PEP} = \frac{(100 \times 0.707)^2}{R} = \frac{(70.7)^2}{50} = 100 \text{ W}$$

2.6.5 – Glossary — AC Theory and Reactance

Admittance (Y) — The reciprocal of impedance, measured in siemens (S).

Capacitance (C) — The ability to store electrical energy in an electrostatic field, measured in farads (F). A device with capacitance is a capacitor.

Flux density (B) — The number of magnetic-force lines per unit area, measured in gauss.

Frequency (f) — The rate of change of an ac voltage or current, measured in cycles per second, or hertz (Hz).

Fundamental — The lowest frequency in a series of sine waves whose frequencies have an integer relationship.

Harmonic — A sine wave whose frequency is an integer multiple of a fundamental frequency.

Impedance (Z) — The complex combination of resistance and reactance, measured in ohms (Ω).

Inductance (L) — The ability to store electrical energy in a magnetic field, measured in henrys (H). A device, such as a coil of wire, with inductance is an inductor.

Peak (voltage or current) — The maximum value relative to zero that an ac voltage or current attains during any cycle.

Peak-to-peak (voltage or current) — The value of the total swing of an ac voltage

Table 2.5

Conversion Factors for Sinusoidal AC Voltage or Current

From	To	Multiply By
Peak	Peak-to-Peak	2
Peak-to-Peak	Peak	0.5
Peak	RMS	$1/\sqrt{2}$ or 0.707
RMS	Peak	$\sqrt{2}$ or 1.414
Peak-to-Peak	RMS	$1/(2 \times \sqrt{2})$ or 0.35355
RMS	Peak-to-Peak	$2 \times \sqrt{2}$ or 2.828
Peak	Average	$2/\pi$ or 0.6366
Average	Peak	$\pi/2$ or 1.5708
RMS	Average	$(2 \times \sqrt{2})/\pi$ or 0.90
Average	RMS	$\pi/(2 \times \sqrt{2})$ or 1.11

Note: These conversion factors apply only to continuous pure sine waves.

or current from its peak negative value to its peak positive value, ordinarily twice the value of the peak voltage or current.

Period (T) — The duration of one ac voltage or current cycle, measured in seconds (s).

Permeability (μ) — The ratio of the magnetic flux density of an iron, ferrite, or similar core in an electromagnet compared to the magnetic flux density of an air core, when the current through the electromagnet is held constant.

Power (P) — The rate of electrical-energy use, measured in watts (W).

Q (quality factor) — The ratio of energy stored in a reactive component (capacitor or inductor) to the energy dissipated, equal to the reactance divided by the resistance.

Reactance (X) — Opposition to alternating current by storage in an electrical field (by a capacitor) or in a magnetic field (by an inductor), measured in ohms (Ω).

Resonance — Ordinarily, the condition in an ac circuit containing both capacitive and inductive reactance in which the reactances are equal.

RMS (voltage or current) — Literally, “root mean square,” the square root of the average of the squares of the instantaneous values for one cycle of a waveform. A dc voltage or current that will produce the same heating effect as the waveform. For a sine wave, the RMS value is equal to 0.707 times the peak value of ac voltage or current.

Susceptance (B) — The reciprocal of reactance, measured in siemens (S).

Time constant (τ) — The time required for the voltage in an RC circuit or the current in an RL circuit to rise from zero to approximately 63.2% of its maximum value or to fall from its maximum value 63.2% toward zero.

Toroid — Literally, any donut-shaped solid; most commonly referring to ferrite or powdered-iron cores supporting inductors and transformers.

Transducer — Any device that converts one form of energy to another; for example an antenna, which converts electrical energy to electromagnetic energy or a speaker, which converts electrical energy to sonic energy.

Transformer — A device consisting of at least two coupled inductors capable of transferring energy through mutual inductance.

2.7 Capacitance and Capacitors

It is possible to build up and hold an electrical charge in an *electrostatic field*. This phenomenon is called *capacitance*, and the devices that exhibit capacitance are called *capacitors*. (Old articles and texts use the obsolete term *condenser*.) Fig 2.28 shows several schematic symbols for capacitors. Part A shows a fixed capacitor; one that has a single value of capacitance. Part B shows the symbol for variable capacitors; these are adjustable over a range of values. If the capacitor is of a type that is *polarized*, meaning that dc voltages must be applied with a specific polarity, the straight line in the symbol should be connected to the most positive voltage, while the curved line goes to the more negative voltage, which is often ground. For clarity,

the positive terminal of a polarized capacitor symbol is usually marked with a + symbol. The symbol for *non-polarized* capacitors may be two straight lines or the + symbol may be omitted. When in doubt, consult the capacitor’s specifications or the circuits parts list.

2.7.1 Electrostatic Fields and Energy

An *electrostatic field* is created wherever a voltage exists between two points, such as two opposite electric charges or regions that contain different amounts of charge. The field causes electric charges (such as electrons or ions) in the field to feel a force in the direction of the field. If the charges are not free to move, as in an insulator, they store the field’s energy as *potential energy*, just as a weight held in place by a surface stores gravitational energy. If the charges are free to move, the field’s stored energy is converted to *kinetic energy* of motion just as if the weight is released to fall in a gravitational field.

The field is represented by *lines of force* that show the direction of the force felt by the electric charge. Each electric charge is surrounded by an electric field. The lines of force of the field begin on the charge and extend away from charge into space. The lines of force can terminate on another charge (such as lines of force between a proton and an electron) or they can extend to infinity.

The strength of the electrostatic field is measured in *volts per meter* (V/m). Stronger fields cause the moving charges to accelerate more strongly (just as stronger gravity causes weights to fall faster) and stores more energy in fixed charges. The stronger the field in V/m, the more force an electric charge in the field will feel. The strength of the electric field

diminishes with the square of the distance from its source, the electric charge.

2.7.2 The Capacitor

Suppose two flat metal plates are placed close to each other (but not touching) and are connected to a battery through a switch, as illustrated in Fig 2.29A. At the instant the switch is closed, electrons are attracted from the upper plate to the positive terminal of the battery, while the same quantity is repelled from the negative battery terminal and pushed into the lower plate. This imbalance of charge creates a voltage between the plates. Eventually, enough electrons move into one plate and out of the other to make the voltage between the plates the same as the battery voltage.

Fig 2.28 — Schematic symbol for a fixed capacitor is shown at A. The symbols for a variable capacitor are shown at B.

Fig 2.29 — A simple capacitor showing the basic charging arrangement at A, and the retention of the charge due to the electrostatic field at B.

At this point, the voltage between the plates opposes further movement of electrons and no further current flow occurs.

If the switch is opened after the plates have been charged in this way, the top plate is left with a deficiency of electrons and the bottom plate with an excess. Since there is no current path between the two plates, they remain charged despite the fact that they are no longer connected to the battery which is the source of the voltage. As illustrated in Fig 2.29B, the separated charges create an electrostatic field between the plates. The electrostatic field contains the energy that was expended by the battery in causing the electrons to flow off of or onto the plates. These two plates create a *capacitor*, a device that has the property of storing electrical energy in an electric field, a property called *capacitance*.

The amount of electric charge that is held on the capacitor plates is proportional to the applied voltage and to the capacitance of the capacitor:

$$Q = CV \quad (43)$$

where

Q = charge in coulombs,
 C = capacitance in farads (F), and
 V = electrical potential in volts. (The symbol E is also commonly used instead of V in this and the following equation.)

The energy stored in a capacitor is also a function of voltage and capacitance:

$$W = \frac{V^2 C}{2} \quad (44)$$

where W = energy in joules (J) or watt-seconds.

If a wire is simultaneously touched to the two plates (short circuiting them), the voltage between the plates causes the excess electrons on the bottom plate to flow through the wire to the upper plate, restoring electrical neutrality. The plates are then *discharged*.

Fig 2.30 illustrates the voltage and current in the circuit, first, at the moment the switch is closed to charge the capacitor and, second, at the moment the shorting switch is closed to discharge the capacitor. Note that the periods of charge and discharge are very short, but that they are not zero. This finite charging and discharging time can be controlled and that will prove useful in the creation of timing circuits.

During the time the electrons are moving—that is, while the capacitor is being charged or discharged—a current flows in the circuit even though the circuit apparently is broken by the gap between the capacitor plates. The current flows only during the time of charge and discharge, however, and this time is usually very short. There is no continuous flow of direct current through a capacitor.

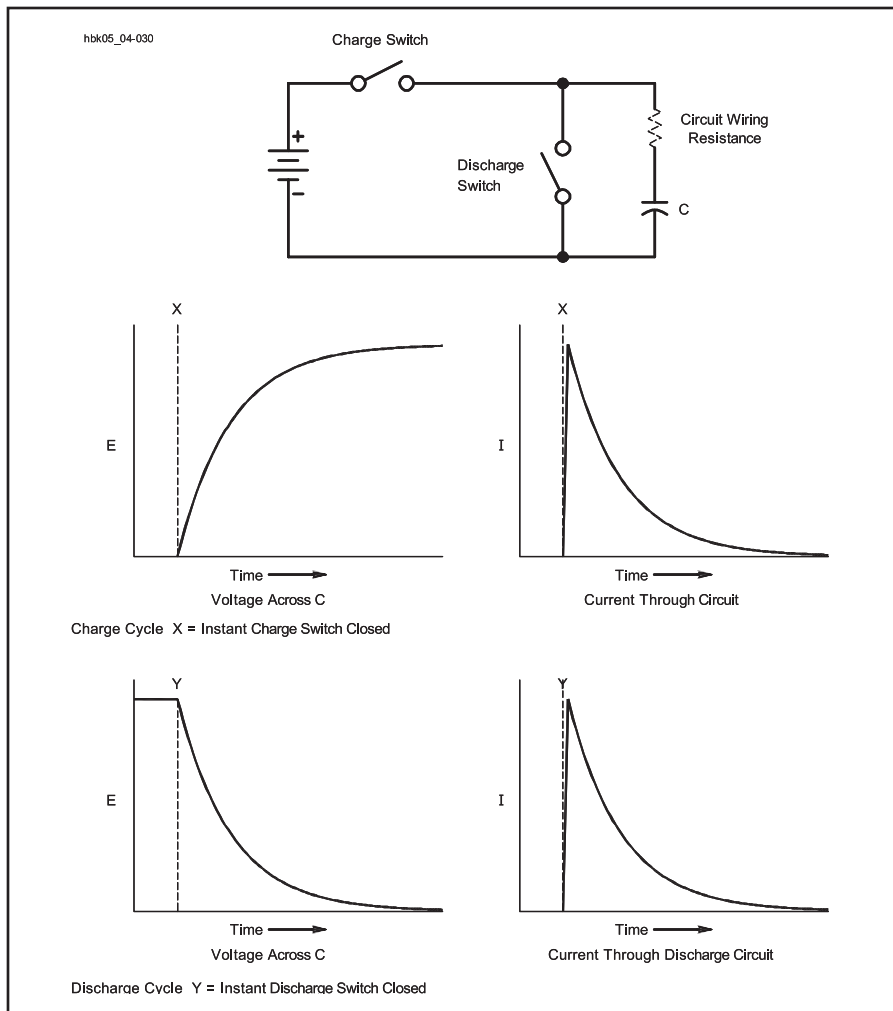

Fig 2.30 — The flow of current during the charge and discharge of a capacitor. The charging graphs assume that the charge switch is closed and the discharge switch is open. The discharging graphs assume just the opposite.

Although dc cannot pass through a capacitor, alternating current can. At the same time one plate is charged positively by the positive excursion of the alternating current, the other plate is being charged negatively at the same rate. (Remember that conventional current is shown as the flow of positive charge, equal to and opposite the actual flow of electrons.) The reverse process occurs during the second half of the cycle as the changing polarity of the applied voltage causes the flow of charge to change direction, as well. The continual flow into and out of the capacitor caused by ac voltage appears as an ac current, although with a phase difference between the voltage and current flow as described below.

UNITS OF CAPACITANCE

The basic unit of capacitance, the ability to store electrical energy in an electrostatic field, is the *farad*. This unit is generally too large for practical radio circuits, although capacitors of several farads in value are used in place of small batteries or as a power supply

filter for automotive electronics. Capacitance encountered in radio and electronic circuits is usually measured in microfarads (abbreviated μF), nanofarads (abbreviated nF) or picofarads (pF). The microfarad is one millionth of a farad (10^{-6} F), the nanofarad is one thousandth of a microfarad (10^{-9} F) and the picofarad is one millionth of a microfarad (10^{-12} F). Old articles and texts use the obsolete term micromicrofarad ($\mu\mu\text{F}$) in place of picofarad.

CAPACITOR CONSTRUCTION

An ideal capacitor is a pair of parallel metal plates separated by an insulating or *dielectric* layer, ideally a vacuum. The capacitance of a vacuum-dielectric capacitor is given by

$$C = \frac{A \epsilon_r \epsilon_0}{d} \quad (45)$$

where

C = capacitance, in farads
 A = area of plates, in cm^2
 d = spacing of the plates in cm

ϵ_r = dielectric constant of the insulating material
 ϵ_0 = permittivity of free space, 8.85×10^{-14} F/cm.

The actual capacitance of such a parallel-plate capacitor is somewhat higher due to *end effect* caused by the electric field that exists just outside the edges of the plates.

The *larger* the plate area and the *smaller* the spacing between the plates, the *greater* the amount of energy that can be stored for a given voltage, and the *greater* the capacitance. The more general name for the capacitor's plates is *electrodes*. However, amateur radio literature generally refers to a capacitor's electrodes as plates and that is the convention in this text.

The amount of capacitance also depends on the material used as insulating material between the plates; capacitance is smallest with air or a vacuum as the insulator. Substituting other insulating materials for air may greatly increase the capacitance.

The ratio of the capacitance with a material other than a vacuum or air between the plates to the capacitance of the same capacitor with air insulation is called the *dielectric constant*, or *K*, of that particular insulating material. The dielectric constants of a number of materials commonly used as dielectrics in capacitors are given in **Table 2.6**. For example, if polystyrene is substituted for air in a capacitor, the capacitance will be 2.6 times greater.

In practice, capacitors often have more than two plates, with alternating plates being connected in parallel to form two sets, as shown in **Fig 2.31**. This practice makes it possible to obtain a fairly large capacitance in a small space, since several plates of smaller

individual area can be stacked to form the equivalent of a single large plate of the same total area. Also, all plates except the two on the ends of the stack are exposed to plates of the other group on both sides, and so are twice as effective in increasing the capacitance.

The formula for calculating capacitance from these physical properties is:

$$C = \frac{0.2248 K A (n - 1)}{d} \quad (46)$$

where

- C = capacitance in pF,
- K = dielectric constant of material between plates,
- A = area of one side of one plate in square inches,
- d = separation of plate surfaces in inches, and
- n = number of plates.

If the area (A) is in square centimeters and the separation (d) is in centimeters, then the

Fig 2.31 — A multiple-plate capacitor. Alternate plates are connected to each other, increasing the total area available for storing charge.

formula for capacitance becomes

$$C = \frac{0.0885 K A (n - 1)}{d} \quad (47)$$

If the plates in one group do not have the same area as the plates in the other, use the area of the smaller plates.

Example: What is the capacitance of two copper plates, each 1.50 square inches in area, separated by a distance of 0.00500 inch, if the dielectric is air?

$$C = \frac{0.2248 K A (n - 1)}{d}$$

$$C = \frac{0.2248 \times 1 \times 1.50 (2 - 1)}{0.00500}$$

$$C = 67.4 \text{ pF}$$

What is the capacitance if the dielectric is mineral oil? (See Table 2.6 for the appropriate dielectric constant.)

$$C = \frac{0.2248 \times 2.23 \times 1.50 (2 - 1)}{0.00500}$$

$$C = 150.3 \text{ pF}$$

2.7.3 Capacitors in Series and Parallel

When a number of capacitors are connected in parallel, as in **Fig 2.32A**, the total capacitance of the group is equal to the sum of the individual capacitances:

$$C_{\text{total}} = C_1 + C_2 + C_3 + C_4 + \dots + C_n \quad (48)$$

When two or more capacitors are con-

Table 2.6
Relative Dielectric Constants of Common Capacitor Dielectric Materials

Material	Dielectric Constant (k)	(O)rganic or
		(I)norganic
Vacuum	1 (by definition)	
Air	1.0006	
Ruby mica	6.5 - 8.7	
Glass (flint)	10	
Barium titanate (class I)	5 - 450	
Barium titanate (class II)	200 - 12000	
Kraft paper	≈ 2.6	O
Mineral Oil	≈ 2.23	O
Castor Oil	≈ 4.7	O
Halowax	≈ 5.2	O
Chlorinated diphenyl	≈ 5.3	O
Polyisobutylene	≈ 2.2	O
Polytetrafluoroethylene	≈ 2.1	O
Polyethylene terephthalate	≈ 3	O
Polystyrene	≈ 2.6	O
Polycarbonate	≈ 3.1	O
Aluminum oxide	≈ 8.4	
Tantalum pentoxide	≈ 28	
Niobium oxide	≈ 40	
Titanium dioxide	≈ 80	

(Adapted from: Charles A. Harper, *Handbook of Components for Electronics*, p 8-7.)

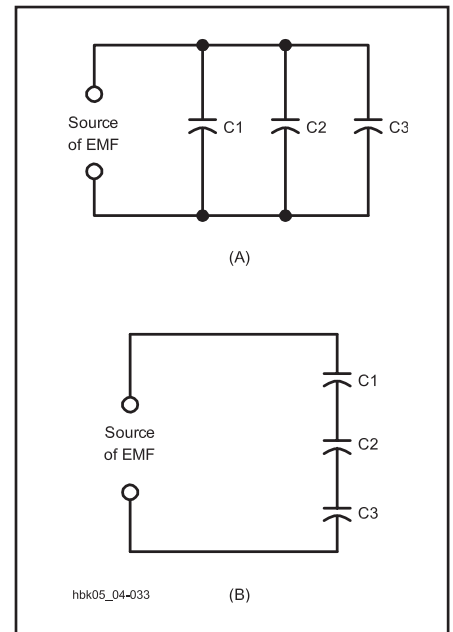

Fig 2.32 — Capacitors in parallel are shown at A, and in series at B.

nected in series, as in Fig 2.32B, the total capacitance is less than that of the smallest capacitor in the group. The rule for finding the capacitance of a number of series-connected capacitors is the same as that for finding the resistance of a number of parallel-connected resistors.

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \dots + \frac{1}{C_n}} \quad (49)$$

For only two capacitors in series, the formula becomes:

$$C_{\text{total}} = \frac{C_1 \times C_2}{C_1 + C_2} \quad (50)$$

The same units must be used throughout; that is, all capacitances must be expressed in μF , nF or pF , etc. Different units cannot be combined in the same equation.

Capacitors are often connected in parallel to obtain a larger total capacitance than is available in one unit. The voltage rating of capacitors connected in parallel is the lowest voltage rating of any of the capacitors.

When capacitors are connected in series, the applied voltage is divided between them according to Kirchhoff's Voltage Law. The situation is much the same as when resistors are in series and there is a voltage drop across each. The voltage that appears across each series-connected capacitor is inversely proportional to its capacitance, as compared with the capacitance of the whole group. (This assumes ideal capacitors.)

Example: Three capacitors having capacitances of 1, 2 and 4 μF , respectively, are connected in series as shown in Fig 2.33. The voltage across the entire series is 2000 V. What is the total capacitance? (Since this is a calculation using theoretical values to illustrate a technique, we will not follow the rules of significant figures for the calculations.)

$$\begin{aligned} C_{\text{total}} &= \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}} \\ &= \frac{1}{\frac{1}{1\ \mu\text{F}} + \frac{1}{2\ \mu\text{F}} + \frac{1}{4\ \mu\text{F}}} \\ &= \frac{1}{\frac{4}{4} + \frac{2}{4} + \frac{1}{4}} = \frac{4\ \mu\text{F}}{7} = 0.5714\ \mu\text{F} \end{aligned}$$

The voltage across each capacitor is proportional to the total capacitance divided by the capacitance of the capacitor in question. So the voltage across C_1 is:

$$E_1 = \frac{0.5714\ \mu\text{F}}{1\ \mu\text{F}} \times 2000\ \text{V} = 1143\ \text{V}$$

Similarly, the voltages across C_2 and C_3 are:

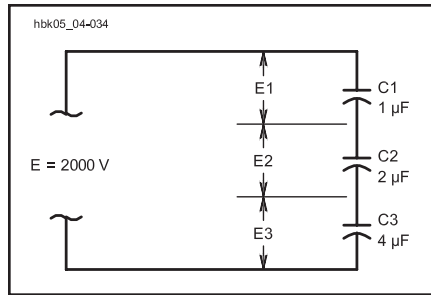

Fig 2.33 — An example of capacitors connected in series. The text shows how to find the voltage drops, E1 through E3.

Fig 2.34 — An RC circuit. The series resistance delays the process of charging (A) and discharging (B) when the switch, S, is closed.

$$E_2 = \frac{0.5714\ \mu\text{F}}{2\ \mu\text{F}} \times 2000\ \text{V} = 571\ \text{V}$$

and

$$E_3 = \frac{0.5714\ \mu\text{F}}{4\ \mu\text{F}} \times 2000\ \text{V} = 286\ \text{V}$$

The sum of these three voltages equals 2000 V, the applied voltage.

Capacitors may be connected in series to enable the group to withstand a larger voltage than any individual capacitor is rated to withstand. The trade-off is a decrease in the total capacitance. As shown by the previous example, the applied voltage does not divide equally between the capacitors except when all the capacitances are precisely the same. Use care to ensure that the voltage rating of any capacitor in the group is not exceeded. If you use capacitors in series to withstand a higher voltage, you should also connect an "equalizing resistor" across each capacitor as described in the **Power Sources** chapter.

2.7.4 RC Time Constant

Connecting a dc voltage source directly to the terminals of a capacitor charges the capacitor to the full source voltage almost instantaneously. Any resistance added to the

circuit (as R in Fig 2.34A) limits the current, lengthening the time required for the voltage between the capacitor plates to build up to the source-voltage value. During this charging period, the current flowing from the source into the capacitor gradually decreases from its initial value. The increasing voltage stored in the capacitor's electric field offers increasing opposition to the steady source voltage.

While it is being charged, the voltage between the capacitor terminals is an exponential function of time, and is given by:

$$V(t) = E \left(1 - e^{-\frac{t}{RC}} \right) \quad (51)$$

where

- $V(t)$ = capacitor voltage at time t ,
- E = power source potential in volts,
- t = time in seconds after initiation of charging current,
- e = natural logarithmic base = 2.718,
- R = circuit resistance in ohms, and
- C = capacitance in farads.

(References that explain exponential equations, e , and other mathematical topics are found in the "Radio Mathematics" article on this book's CD-ROM.)

If $t = RC$, the above equation becomes:

$$V(RC) = E(1 - e^{-1}) \approx 0.632\ E \quad (52)$$

The product of R in ohms times C in farads is called the *time constant* (also called the *RC time constant*) of the circuit and is the time in seconds required to charge the capacitor to 63.2% of the applied voltage. (The lower-case Greek letter tau, τ , is often used to represent the time constant in electronics circuits.) After two time constants ($t = 2\tau$) the capacitor charges another 63.2% of the difference between the capacitor voltage at one time constant and the applied voltage, for a total charge of 86.5%. After three time constants the capacitor reaches 95% of the applied voltage, and so on, as illustrated in the curve of Fig 2.35A. After five time constants, a capacitor is considered fully charged, having reached 99.24% of the applied voltage. Theoretically, the charging process is never really finished, but eventually the charging current drops to an immeasurably small value and the voltage is effectively constant.

If a charged capacitor is discharged through a resistor, as in Fig 2.34B, the same time constant applies to the decay of the capacitor voltage. A direct short circuit applied between the capacitor terminals would discharge the capacitor almost instantly. The resistor, R , limits the current, so a capacitor discharging through a resistance exhibits the same time-constant characteristics (calculated in the same way as above) as a charging capacitor. The voltage, as a function of time while the capacitor is being discharged, is given by:

Fig 2.35 — At A, the curve shows how the voltage across a capacitor rises, with time, when charged through a resistor. The curve at B shows the way in which the voltage decreases across a capacitor when discharging through the same resistance. For practical purposes, a capacitor may be considered charged or discharged after five RC periods.

$$V(t) = E \left(e^{-\frac{t}{RC}} \right) \quad (53)$$

where t = time in seconds after initiation of discharge and E is the fully-charged capacitor voltage prior to beginning discharge.

Again, by letting $t = RC$, the time constant of a discharging capacitor represents a decrease in the voltage across the capacitor of about 63.2%. After five time-constants, the capacitor is considered fully discharged, since the voltage has dropped to less than 1% of the full-charge voltage. **Fig 2.35B** is a graph of the discharging capacitor voltage in terms of time constants..

Time constant calculations have many uses in radio work. The following examples are all derived from practical-circuit applications.

Example 1: A 100- μF capacitor in a high-voltage power supply is shunted by a 100-k Ω resistor. What is the minimum time before the capacitor may be considered fully discharged? Since full discharge is approximately five RC periods,

$$\begin{aligned} t &= 5 \times RC = 5 \times 100 \times 10^3 \Omega \times 100 \times 10^{-6} \text{ F} \\ &= 50,000 \times 10^{-3} \\ t &= 50.0 \text{ s} \end{aligned}$$

Note: Although waiting almost a minute for the capacitor to discharge seems safe in this high-voltage circuit, never rely solely on capacitor-discharging resistors (often called *bleeder resistors*). Be certain the power source is removed and the capacitors are totally discharged before touching any circuit components. (See the **Power Sources** chapter for more information on bleeder resistors.)

Example 2: Smooth CW keying without clicks requires approximately 5 ms (0.005 s) of delay in both the rising and falling edges of the waveform, relative to full charging and discharging of a capacitor in the circuit. What typical values might a builder choose for an RC delay circuit in a keyed voltage line? Since full charge and discharge require 5 RC periods,

$$RC = \frac{t}{5} = \frac{0.005 \text{ s}}{5} = 0.001 \text{ s}$$

Any combination of resistor and capacitor whose values, when multiplied together, equal 0.001 would do the job. A typical capacitor might be 0.05 μF . In that case, the necessary resistor would be:

$$\begin{aligned} R &= \frac{0.001 \text{ s}}{0.05 \times 10^{-6} \text{ F}} \\ &= 0.02 \times 10^6 \Omega = 20,000 \Omega = 20 \text{ k}\Omega \end{aligned}$$

In practice, a builder would use the calculated value as a starting point. The final value would be selected by monitoring the waveform on an oscilloscope.

Example 3: Many modern integrated circuit (IC) devices use RC circuits to control their timing. To match their internal circuitry, they may use a specified threshold voltage as the trigger level. For example, a certain IC uses a trigger level of 0.667 of the supply voltage. What value of capacitor and resistor would be required for a 4.5-second timing period?

First we will solve equation 51 for the time constant, RC. The threshold voltage is 0.667 times the supply voltage, so we use this value for $V(t)$.

$$\begin{aligned} V(t) &= E \left(1 - e^{-\frac{t}{RC}} \right) \\ 0.667 E &= E \left(1 - e^{-\frac{t}{RC}} \right) \\ e^{-\frac{t}{RC}} &= 1 - 0.667 \\ \ln \left(e^{-\frac{t}{RC}} \right) &= \ln(0.333) \\ -\frac{t}{RC} &= -1.10 \end{aligned}$$

We want to find a capacitor and resistor combination that will produce a 4.5 s timing period, so we substitute that value for t .

$$RC = \frac{4.5 \text{ s}}{1.10} = 4.1 \text{ s}$$

If we select a value of 10 μF , we can solve for R.

$$R = \frac{4.1 \text{ s}}{10 \times 10^{-6} \text{ F}} = 0.41 \times 10^6 \Omega = 410 \text{ k}\Omega$$

A 1% tolerance resistor and capacitor will give good results. You could also use a variable resistor and an accurate method of measuring time to set the circuit to a 4.5 s period.

As the examples suggest, RC circuits have numerous applications in electronics. The number of applications is growing steadily, especially with the introduction of integrated circuits controlled by part or all of a capacitor charge or discharge cycle.

2.7.5 Alternating Current in Capacitance

Whereas a capacitor in a dc circuit will appear as an open circuit except for the brief charge and discharge periods, the same capacitor in an ac circuit will both pass and limit current. A capacitor in an ac circuit does not handle electrical energy like a resistor, however. Instead of converting the energy to heat and dissipating it, capacitors store electrical energy when the applied voltage is greater than that across the capacitor and return it to the circuit when the opposite is true.

In **Fig 2.36** a sine-wave ac voltage having a maximum value of 100 V is applied to a capacitor. In the period OA, the applied voltage increases from 0 to 38, storing energy in the capacitor; at the end of this period the capacitor is charged to that voltage. In interval AB the voltage increases to 71; that is, by an additional 33 V. During this interval a smaller quantity of charge has been added than in OA, because the voltage rise during interval AB is smaller. Consequently the average current during interval AB is smaller than during OA. In the third interval, BC, the voltage rises from 71 to 92, an increase of 21 V. This is less than the voltage increase during AB, so the quantity of charge added is less; in other words, the average current during interval

RC Timesaver

When calculating time constants, it is handy to remember that if R is in units of M Ω and C is in units of μF , the result of $R \times C$ will be in seconds. Expressed as an equation: $\text{M}\Omega \times \mu\text{F} = \text{seconds}$

Fig 2.36 — Voltage and current phase relationships when an alternating current is applied to a capacitor.

BC is still smaller. In the fourth interval, CD, the voltage increases only 8 V; the charge added is smaller than in any preceding interval and therefore the current also is smaller.

By dividing the first quarter-cycle into a very large number of such intervals, it can be shown that the current charging the capacitor has the shape of a sine wave, just as the applied voltage does. The current is largest at the beginning of the cycle and becomes zero at the maximum value of the voltage, so there is a phase difference of 90° between the voltage and the current. During the first quarter-cycle the current is flowing in the original (positive) direction through the circuit as indicated by the dashed line in Fig 2.36, since the capacitor is being charged. The increasing capacitor voltage indicates that energy is being stored in the capacitor.

In the second quarter-cycle — that is, in the time from D to H — the voltage applied to the capacitor decreases. During this time the capacitor loses charge, returning the stored energy to the circuit. Applying the same reasoning, it is evident that the current is small in interval DE and continues to increase during each succeeding interval. The current is flowing *against* the applied voltage, however, because the capacitor is returning energy to (discharging into) the circuit. The current thus flows in the *negative* direction during this quarter-cycle.

The third and fourth quarter-cycles repeat the events of the first and second, respectively, although the polarity of the applied voltage has reversed, and so the current changes to correspond. In other words, an alternating current flows in the circuit because of the alternate charging and discharging of the capacitance. As shown in Fig 2.36, the current starts its cycle 90° before the voltage, so the

current in a capacitor *leads* the applied voltage by 90°. You might find it helpful to remember the word “ICE” as a mnemonic because the current (I) in a capacitor (C) comes before voltage (E). (see the sidebar “ELI the ICE man” in the section on inductors.) We can also turn this statement around, to say the voltage in a capacitor *lags* the current by 90°.

2.7.6 Capacitive Reactance and Susceptance

The quantity of electric charge that can be placed on a capacitor is proportional to the applied voltage and the capacitance. If the applied voltage is ac, this amount of charge moves back and forth in the circuit once each cycle. Therefore, the rate of movement of charge (the current) is proportional to voltage, capacitance and frequency. Stated in another way, capacitor current is proportional to capacitance for a given applied voltage and frequency.

When the effects of capacitance and frequency are considered together, they form a quantity called *reactance* that relates voltage and current in a capacitor, similar to the role of resistance in Ohm’s Law. Because the reactance is created by a capacitor, it is called *capacitive reactance*. The units for reactance are ohms, just as in the case of resistance. Although the units of reactance are ohms, there is no power dissipated in reactance. The energy stored in the capacitor during one portion of the cycle is simply returned to the circuit in the next.

The formula for calculating the reactance of a capacitor at a given frequency is:

$$X_C = \frac{1}{2\pi f C} \quad (54)$$

where

X_C = capacitive reactance in ohms,

f = frequency in hertz,

C = capacitance in farads

$\pi = 3.1416$

Note: In many references and texts, angular frequency $\omega = 2\pi f$ is used and equation 54 would read

$$X_C = \frac{1}{\omega C}$$

Example: What is the reactance of a capacitor of 470 pF (0.000470 μ F) at a frequency of 7.15 MHz?

$$\begin{aligned} X_C &= \frac{1}{2\pi f C} \\ &= \frac{1}{2\pi \times 7.15 \text{ MHz} \times 0.000470 \mu\text{F}} \\ &= \frac{1\Omega}{0.0211} = 47.4 \Omega \end{aligned}$$

Example: What is the reactance of the same capacitor, 470 pF (0.000470 μ F), at a frequency of 14.29 MHz?

$$\begin{aligned} X_C &= \frac{1}{2\pi f C} \\ &= \frac{1}{2\pi \times 14.3 \text{ MHz} \times 0.000470 \mu\text{F}} \\ &= \frac{1\Omega}{0.0422} = 23.7 \Omega \end{aligned}$$

Current in a capacitor is directly related to the rate of change of the capacitor voltage. The maximum rate of change of voltage in a sine wave increases directly with the frequency, even if its peak voltage remains fixed. Therefore, the maximum current in the capacitor must also increase directly with

Fig 2.37 — A graph showing the general relationship of reactance to frequency for a fixed value of capacitance.

Capacitive Reactance Timesaver

The fundamental units for frequency and capacitance (hertz and farads) are too cumbersome for practical use in radio circuits. If the capacitance is specified in microfarads (μF) and the frequency is in megahertz (MHz), however, the reactance calculated from equation 54 is in units of ohms (Ω).

frequency. Since, if voltage is fixed, an increase in current is equivalent to a decrease in reactance, the reactance of any capacitor decreases proportionally as the frequency increases. Fig 2.37 illustrates the decrease in reactance of an arbitrary-value capacitor with respect to increasing frequency. The only limitation on the application of the graph is the physical construction of the capacitor, which may favor low-frequency uses or high-frequency applications.

CAPACITIVE SUSCEPTANCE

Just as conductance is sometimes the most useful way of expressing a resistance's ability to conduct current, the same is true for capacitors and ac current. This ability is called *susceptance* (abbreviated B). The units of susceptance are siemens (S), the same as that of conductance and admittance.

Susceptance in a capacitor is *capacitive susceptance*, abbreviated B_C . In an ideal capacitor with no losses, susceptance is simply the reciprocal of reactance. Hence,

$$B_C = \frac{1}{X_C}$$

where

X_C is the capacitive reactance, and
 B_C is the capacitive susceptance.

2.7.7 Characteristics of Capacitors

The ideal capacitor does not conduct any current at dc, dissipates none of the energy stored in it, has the same value at all temperatures, and operates with any amount of voltage applied across it or ac current flowing through it. Practical capacitors deviate considerably from that ideal and have imperfections that must be considered when selecting capacitors and designing circuits that use capacitors. (The characteristics of capacitors at high frequencies is discussed in the **RF Techniques** chapter.)

LEAKAGE RESISTANCE

If we use anything other than a vacuum for the insulating layer, even air, two imperfections are created. Because there are

Table 2.7
Typical Temperature Coefficients and Leakage Resistances for Various Capacitor Constructions

Type	TC @ 20°C (PPM/°C)	DC Leakage Resistance (Ω)
Ceramic Disc	± 300 (NP0)	> 10 M
	+150/−150(GP)	> 10 M
Mica	−20 to +100	> 100,000 M
Polyester	± 500	> 10 M
Tantalum Electrolytic	± 1500	> 10 M Ω
Small Al Electrolytic($\approx 100 \mu\text{F}$)	−20,000	500 k - 1 M
Large Al Electrolytic($\approx 10 \text{ mF}$)	−100,000	10 k
Vacuum (glass)	+100	$\approx \infty$
Vacuum (ceramic)	+50	$\approx \infty$

atoms between the plates, some electrons will be available to create a current between the plates when a dc voltage is applied. The magnitude of this *leakage current* will depend on the insulator quality, and the current is usually very small. Leakage current can be modeled by a resistance R_L in parallel with the capacitance (in an ideal capacitor, R_L is infinite). Table 2.7 shows typical dc leakage resistances for different dielectric materials. Leakage also generally increases with increasing temperature.

CAPACITOR LOSSES

When an ac current flows through the capacitor (even at low frequencies), capacitors dissipate some of the energy stored in the dielectric due to the electromagnetic properties of dielectric materials. This loss can be thought of as a resistance in series with the capacitor and it is often specified in the manufacturer's data for the capacitor as *effective (or equivalent) series resistance (ESR)*.

Loss can also be specified as the capacitor's *loss angle*, θ . (Some literature uses δ for loss angle.) Loss angle is the angle between X_C (the reactance of the capacitor without any loss) and the impedance of the capacitor (impedance is discussed later in this chapter) made up of the combination of ESR and X_C . Increasing loss increases loss angle. The loss angle is usually quite small, and is zero for an ideal capacitor.

Dissipation Factor (DF) or *loss tangent* = $\tan \theta = \text{ESR} / X_C$ and is the ratio of loss resistance to reactance. The loss angle of a given capacitor is relatively constant over frequency, meaning that $\text{ESR} = (\tan \theta) / 2\pi fC$ goes down as frequency goes up. For this reason, ESR must be specified at a given frequency.

TOLERANCE AND TEMPERATURE COEFFICIENT

As with resistors, capacitor values vary in production, and most capacitors have a toler-

ance rating either printed on them or listed on a data sheet. Typical capacitor tolerances and the labeling of tolerance are described in the chapter on **Component Data and References**.

Because the materials that make up a capacitor exhibit mechanical changes with temperature, capacitance also varies with temperature. This change in capacitance with temperature is the capacitor's *temperature coefficient* or *tempco (TC)*. The lower a capacitor's TC, the less its value changes with temperature.

TC is important to consider when constructing a circuit that will carry high power levels, operate in an environment far from room temperature, or must operate consistently at different temperatures. Typical temperature coefficients for several capacitor types are given in Table 2.7. (Capacitor temperature coefficient behaviors are listed in the **Component Data and References** chapter.)

VOLTAGE RATINGS AND BREAKDOWN

When voltage is applied to the plates of a capacitor, force is exerted on the atoms and molecules of the dielectric by the electrostatic field between the plates. If the voltage is high enough, the atoms of the dielectric will ionize (one or more of the electrons will be pulled away from the atom), causing a large dc current to flow discharging the capacitor. This is *dielectric breakdown*, and it is generally destructive to the capacitor because it creates punctures or defects in solid dielectrics that provide permanent low-resistance current paths between the plates. (*Self-healing* dielectrics have the ability to seal off this type of damage.) With most gas dielectrics such as air, once the voltage is removed, the arc ceases and the capacitor is ready for use again.

The *breakdown voltage* of a dielectric depends on the chemical composition and thickness of the dielectric. Breakdown voltage is not directly proportional to the thickness;

doubling the thickness does not quite double the breakdown voltage. A thick dielectric must be used to withstand high voltages. Since capacitance is inversely proportional to dielectric thickness (plate spacing) for a given plate area, a high-voltage capacitor must have more plate area than a low-voltage one of the same capacitance. High-voltage, high-capacitance capacitors are therefore physically large.

Dielectric strength is specified in terms of a *dielectric withstanding voltage* (DWV), given in volts per mil (0.001 inch) at a specified temperature. Taking into account the design temperature range of a capacitor and a safety margin, manufacturers specify *dc working voltage* (dcwv) to express the maximum safe limits of dc voltage across a capacitor to prevent dielectric breakdown.

For use with ac voltages, the peak value of ac voltage should not exceed the dc working voltage, unless otherwise specified in component ratings. In other words, the RMS

value of sine-wave ac waveforms should be 0.707 times the dcwv value, or lower. With many types of capacitors, further derating is required as the operating frequency increases. An additional safety margin is good practice.

Dielectric breakdown in a gas or air dielectric capacitor occurs as a spark or arc between the plates. Spark voltages are generally given with the units *kilovolts per centimeter*. For air, the spark voltage or V_s may range from more than 120 kV/cm for gaps as narrow as 0.006 cm down to 28 kV/cm for gaps as wide as 10 cm. In addition, a large number of variables enter into the actual breakdown voltage in a real situation. Among the variables are the plate shape, the gap distance, the air pressure or density, the voltage, impurities in the air (or any other dielectric material) and the nature of the external circuit (with air, for instance, the humidity affects conduction on the surface of the capacitor plate).

Dielectric breakdown occurs at a lower voltage between pointed or sharp-edged surfaces than between rounded and polished surfaces. Consequently, the breakdown voltage between metal plates of any given spacing in air can be increased by buffing the edges of the plates. If the plates are damaged so they are no longer smooth and polished, they may have to be polished or the capacitor replaced.

2.7.8 Capacitor Types and Uses

Quite a variety of capacitors are used in radio circuits, differing considerably in physical size, construction and capacitance. Some of the different types are shown in **Fig 2.38** and many other types and packages are available. (See the **Component Data and References** chapter for illustrations of capacitor types and labeling conventions.)

The dielectric determines many properties of the capacitor, although the construction of the plates strongly affects the capacitor's ac performance and some dc parameters. Various materials are used for different reasons such as working voltage and current, availability, cost, and desired capacitance range.

Fixed capacitors having a single, non-adjustable value of capacitance can also be made with metal plates and with air as the dielectric, but are usually constructed from strips of metal foil with a thin, solid or liquid dielectric sandwiched between, so that a relatively large capacitance can be obtained in a small package. Solid dielectrics commonly used in fixed capacitors are plastic films, mica, paper and special ceramics. Two typical types of fixed capacitor construction are shown in **Fig 2.39**.

For capacitors with wire leads, there are

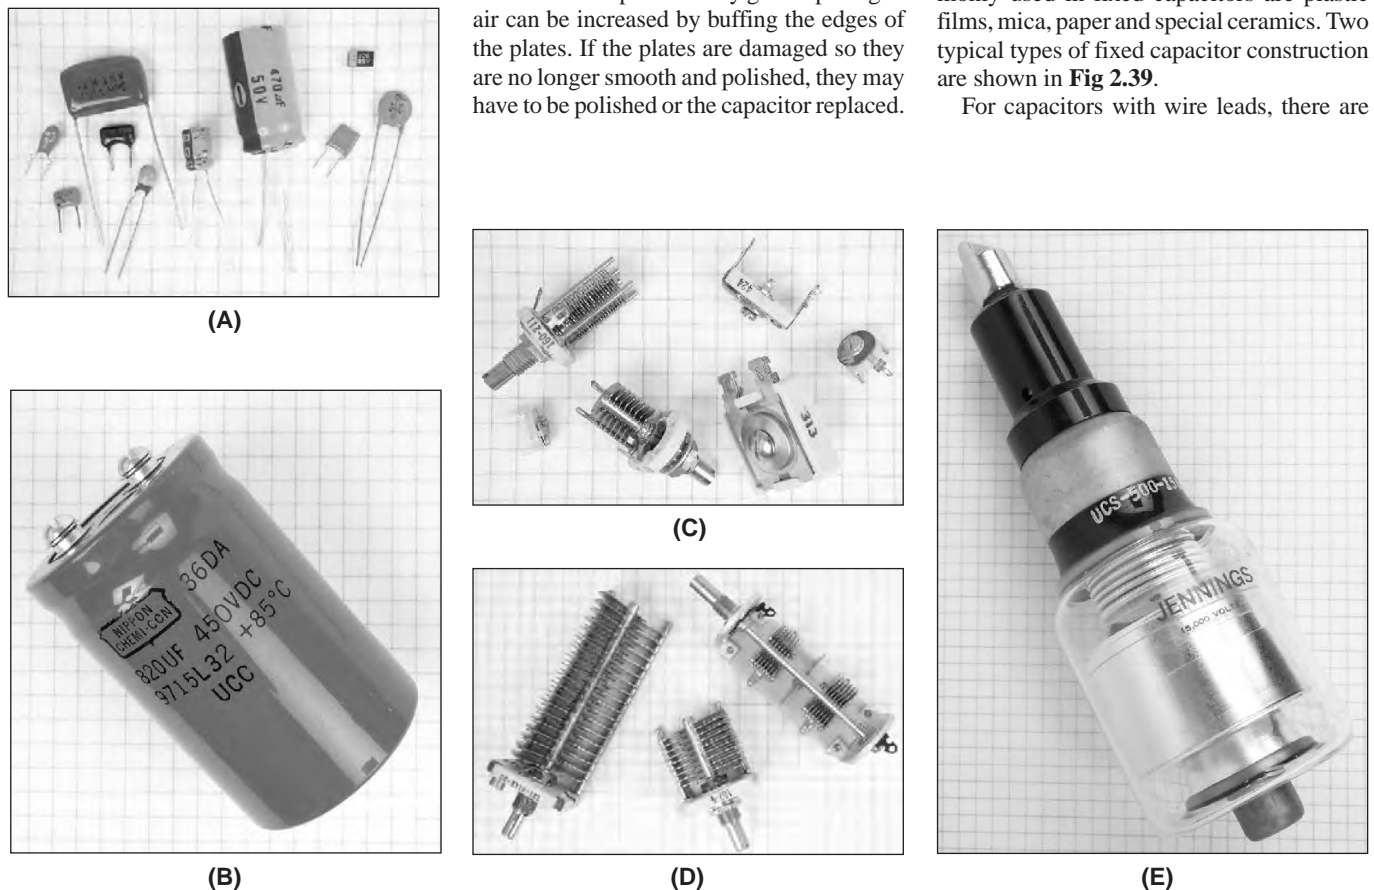

Fig 2.38 — Fixed-value capacitors are shown in parts A and B. Aluminum electrolytic capacitors are pictured near the center of photo A. The small tear-drop units to the left of center are tantalum electrolytic capacitors. The rectangular units are silvered-mica, polystyrene film and monolithic ceramic. At the right edge is a disc-ceramic capacitor and near the top right corner is a surface-mount capacitor. B shows a large “computer-grade” electrolytic. These have very low equivalent series resistance (ESR) and are often used as filter capacitors in switch-mode power supplies, and in series-strings for high-voltage supplies of RF power amplifiers. Parts C and D show a variety of variable capacitors, including air variable capacitors and mica compression units. Part E shows a vacuum variable capacitor such as is sometimes used in high-power amplifier circuits. The ¼-inch-ruled graph paper backgrounds provide size comparisons.

Fig 2.39 — Two common types of capacitor construction. A shows the roll method for film capacitors with axial leads. B shows the alternating layer method for ceramic capacitors. Axial leads are shown in A and radial leads in B.

two basic types of lead orientation; *axial* (shown in Fig 2.39A) in which the leads are aligned with the long axis of the capacitor body and *radial* (shown in Fig 2.39B) in which the leads are at right angles to the capacitor's length or width.

Vacuum. Both fixed and variable vacuum capacitors are available. They are rated by their maximum working voltages (3 to 60 kV) and currents. Losses are specified as negligible for most applications. The high working voltage and low losses make vacuum capacitors widely used in transmitting applications. Vacuum capacitors are also unaffected by humidity, moisture, contamination, or dust, unlike air-dielectric capacitors discussed next. This allows them to be used in environments for which air-dielectric capacitors would be unsuitable.

Air. Since $K \approx 1$ for air, air-dielectric capacitors are large when compared to those of the same value using other dielectrics. Their capacitance is very stable over a wide temperature range, leakage losses are low, and therefore a high Q can be obtained. They also can withstand high voltages. Values range from a few tens to hundreds of pF.

For these reasons (and ease of construction) most variable capacitors in tuning circuits are *air-variable* capacitors made with one set of plates movable with respect to the other set to vary the area of overlap and thus the capacitance. A *transmitting-variable* capacitor has heavy plates far enough apart to withstand the high voltages and currents encountered in a transmitter. (Air variable capacitors with more closely-spaced plates are often referred to as *receiving-variables*.)

Plastic film. Capacitors with plastic film (such as polystyrene, polyethylene or Mylar) dielectrics are widely used in bypassing and coupling applications up to several mega-

hertz. They have high leakage resistances (even at high temperatures) and low TCs. Values range from tens of pF to 1 μ F. Plastic-film variable capacitors are also available.

Most film capacitors are not polarized; however, the body of the capacitor is usually marked with a color band at one end. The band indicates the terminal that is connected to the outermost plate of the capacitor. This terminal should be connected to the side of the circuit at the lower potential as a safety precaution.

Mica. The capacitance of mica capacitors is very stable with respect to time, temperature and electrical stress. Leakage and losses are very low and they are often used in transmitting equipment. Values range from 1 pF to 0.1 μ F. High working voltages are possible, but they must be derated severely as operating frequency increases.

Silver-mica capacitors are made by depositing a thin layer of silver on the mica dielectric. This makes the value even more stable, but it presents the possibility of silver migration through the dielectric. The migration problem worsens with increased dc voltage, temperature and humidity. Avoid using silver-mica capacitors under such conditions. Silver-mica capacitors are often used in RF circuits requiring stable capacitor values, such as oscillators and filters.

Ceramic. Ceramic capacitors are available with values from 1 pF to 1 μ F and with voltage ratings up to 1 kV. *Monolithic ceramic* capacitors are constructed from a stack of thin ceramic layers with a metal coating on one side. The layer is then compressed with alternating metal coatings connected together to form the capacitor's plates. The high dielectric constant makes these capacitors physically small for their capacitance, but their value is not as stable and their dielectric properties vary with temperature, applied

voltage and operating frequency. They also exhibit piezoelectric behavior. Use them only in coupling and bypass roles. *Disc ceramic* capacitors are made similarly to monolithic ceramic capacitors but with a lower dielectric constant so they are larger and tend to have higher voltage ratings. Ceramic capacitors are useful into the VHF and UHF ranges.

Transmitting ceramic capacitors are made, like transmitting air-variables, with heavy plates and high-voltage ratings. They are relatively large, but very stable and have nearly as low losses as mica capacitors at HF.

Electrolytic. Electrolytic capacitors are constructed with plates made of aluminum-foil strips and a semi-liquid conducting chemical compound between them. They are sometimes called *aluminum electrolytics*. The actual dielectric is a very thin film of insulating material that forms on one set of plates through electrochemical action when a dc voltage is applied to the capacitor. The capacitance of an electrolytic capacitor is very large compared to capacitors having other dielectrics, because the dielectric film is so thin — much thinner than is practical with a solid dielectric. Electrolytic capacitors are available with values from approximately 1 μ F to 1 F and with voltage ratings up to hundreds of volts.

Electrolytic capacitors are popular because they provide high capacitance values in small packages at a reasonable cost. Leakage resistance is comparatively low and they are polarized — there is a definite positive and negative plate, due to the chemical reaction that creates the dielectric. Internal inductance restricts aluminum-foil electrolytics to low-frequency applications such as power-supply filtering and bypassing in audio circuits. To maintain the dielectric film, electrolytic capacitors should not be used if the applied dc potential will be well below the capacitor working voltage.

A cautionary note is warranted regarding electrolytic capacitors found in older equipment, both vacuum tube and solid-state. The chemical paste in electrolytics dries out when the component is heated and with age, causing high losses and reduced capacitance. The dielectric film also disappears when the capacitor is not used for long periods. It is possible to "reform" the dielectric by applying a low voltage to an old or unused capacitor and gradually increasing the voltage. However, old electrolytics rarely perform as well as new units. To avoid expensive failures and circuit damage, it is recommended that electrolytic capacitors in old equipment be replaced if they have not been in regular use for more than ten years.

Tantalum. Related to the electrolytic capacitor, *tantalum* capacitors substitute a *slug* of extremely porous tantalum (a rare-earth metallic element) for the aluminum-foil strips as one plate. As in the electrolytic

capacitor, the dielectric is an oxide film that forms on the surface of the tantalum. The slug is immersed in a liquid compound contained in a metal can that serves as the other plate. Tantalum capacitors are commonly used with values from 0.1 to several hundred μF and voltage ratings of less than 100 V. Tantalum capacitors are smaller, lighter and more stable, with less leakage and inductance than their aluminum-foil electrolytic counterparts but their cost is higher.

Paper. Paper capacitors are generally not

used in new designs and are largely encountered in older equipment; capacitances from 500 pF to 50 μF are available. High working voltages are possible, but paper-dielectric capacitors have low leakage resistances and tolerances are no better than 10 to 20%.

Trimming capacitors. Small-value variable capacitors are often referred to as *trimmers* because they are used for fine-tuning or frequency adjustments, called *trimming*. Trimmers have dielectrics of Teflon, air, or ceramic and generally have values of less than

100 pF. *Compression trimmers* have higher values of up to 1000 pF and are constructed with mica dielectrics.

Oil-filled. Oil-filled capacitors use special high-strength dielectric oils to achieve voltage ratings of several kV. Values of up to 100 μF are commonly used in high-voltage applications such as high-voltage power supplies and energy storage. (See the chapter on **Power Sources** for additional information about the use of oil-filled and electrolytic capacitors.)

2.8 Inductance and Inductors

A second way to store electrical energy is in a *magnetic field*. This phenomenon is called *inductance*, and the devices that exhibit inductance are called *inductors*. Inductance is derived from some basic underlying magnetic properties.

2.8.1 Magnetic Fields and Magnetic Energy Storage

MAGNETIC FLUX

As an electric field surrounds an electric charge, magnetic fields surround *magnets*. You are probably familiar with metallic bar, disc, or horseshoe-shaped magnets. **Fig 2.40** shows a bar magnet, but particles of matter as small as an atom can also be magnets.

Fig 2.40 also shows the magnet surrounded by lines of force called *magnetic flux*, representing a *magnetic field*. (More accurately, a *magnetostatic field*, since the field is not changing.) Similar to those of an electric field, magnetic lines of force (or *flux lines*) show the direction in which a magnet would feel a force in the field.

There is no “magnetic charge” comparable to positive and negative electric charges. All magnets and magnetic fields have a polarity, represented as *poles*, and every magnet — from atoms to bar magnets — possesses both a *north* and *south pole*. The size of the source of the magnetism makes no difference. The north pole of a magnet is defined as the one attracted to the Earth’s north magnetic pole. (Confusingly, this definition means the Earth’s North Magnetic Pole is magnetically a south pole!) Like conventional current, the direction of magnetic lines of force was assigned arbitrarily by early scientists as pointing *from* the magnet’s north pole *to* the south pole.

An electric field is *open* — that is, its lines of force have one end on an electric charge and can extend to infinity. A magnetic field is *closed* because all magnetic lines of force form a loop passing through a magnet’s north and south poles.

Magnetic fields exist around two types

of materials; *permanent magnets* and *electromagnets*. Permanent magnets consist of *ferromagnetic* and *ferrimagnetic* materials whose atoms are or can be aligned so as to produce a magnetic field. Ferro- or ferrimagnetic materials are strongly attracted to magnets. They can be *magnetized*, meaning to be made magnetic, by the application of a magnetic field. Lodestone, magnetite, and ferrites are examples of ferrimagnetic materials. Iron,

nickel, cobalt, Alnico alloys and other materials are ferromagnetic. Magnetic materials with high *retentivity* form permanent magnets because they retain their magnetic properties for long periods. Other materials, such as soft iron, yield temporary magnets that lose their magnetic properties rapidly.

Paramagnetic substances are very weakly attracted to a magnet and include materials such as platinum, aluminum, and oxygen. *Diamagnetic* substances, such as copper, carbon, and water, are weakly repelled by a magnet.

The second type of magnet is an electrical conductor with a current flowing through it. As shown in **Fig 2.41**, moving electrons are surrounded by a closed magnetic field, illustrated as the circular lines of force around the wire lying in planes perpendicular to the current’s motion. The magnetic needle of a compass placed near a wire carrying direct current will be deflected as its poles respond to the forces created by the magnetic field around the wire.

If the wire is coiled into a *solenoid* as shown in **Fig 2.42**, the magnetic field greatly intensifies. This occurs as the magnetic fields from each successive turn in the coil add together

Fig 2.40 — The magnetic field and poles of a permanent magnet. The magnetic field direction is from the north to the south pole.

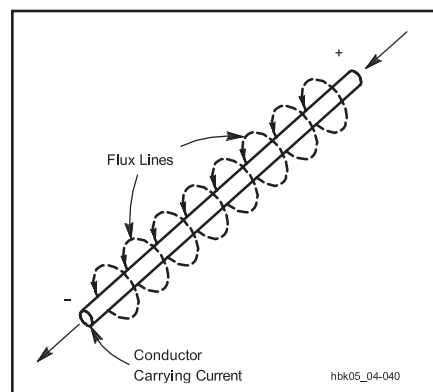

Fig 2.41 — The magnetic field around a conductor carrying an electrical current. If the thumb of your right hand points in the direction of the conventional current (plus to minus), your fingers curl in the direction of the magnetic field around the wire.

Fig 2.42 — Cross section of an inductor showing its flux lines and overall magnetic field.

The Right-hand Rule

How do you remember which way the magnetic field around a current is pointing? Luckily, there is a simple method, called the *right-hand rule*. Make your right hand into a fist, then extend your thumb, as in **Fig 2.A2**. If your thumb is pointing in the direction of conventional current flow, then your fingers curl in the same direction as the magnetic field. (If you are dealing with electronic current, use your left hand, instead!)

Fig 2.A2 — Use the right-hand rule to determine magnetic field direction from the direction of current flow.

because the current in each turn is flowing in the same direction.

Note that the resulting *electromagnet* has magnetic properties identical in principle to those of a permanent magnet, including poles and lines of force or flux. The strength of the magnetic field depends on several factors: the number and shape of turns of the coil, the magnetic properties of the materials surrounding the coil (both inside and out), the length of the coil and the amplitude of the current.

Magnetic fields and electric current have a

Table 2.8

Magnetic Quantities

Value	Symbol	MKS	cgs
Magnetic Flux	lines	Weber, $Wb = V\cdot s$	Maxwell, $Mx = 10^{-8} Wb$

Note – Magnetic circuit analogies as described by Shen and Kong, *Applied Electromagnetism*

special two-way relationship: voltage causing an electrical current (moving charges) in a conductor will produce a magnetic field and a moving magnetic field will create an electrical field (voltage) that produces current in a conductor. This is the principle behind motors and generators, converting mechanical energy into electrical energy and vice-versa.

MAGNETIC FLUX

Magnetic flux is measured in the SI unit (International System of Units) of the weber, which is a volt-second ($Wb = Vs$). In the *centimeter-gram-second (cgs)* metric system units, magnetic flux is measured in maxwells ($1 Mx = 10^{-8} Wb$). The volt-second is used because of the relationship described in the previous paragraph: 1 volt of electromotive force will be created in a loop of wire in which magnetic flux through the loop changes at the rate of 1 weber per second. The relationship between current and magnetic fields is one of motion and change.

Magnetic field intensity, known as *flux density*, decreases with the square of the distance from the source, either a magnet or current. Flux density (B) is represented in gauss (G), where one gauss is equivalent to one line of force (1 Mx) per square centimeter of area measured perpendicularly to the direction of the field ($G = Mx/cm^2$). The Earth's magnetic field at the surface is approximately one gauss. The gauss is a *cgs* unit. In SI units, flux density is represented by the tesla (T), which is one weber per square meter ($T = Wb/m^2$ and $1T = 10,000 G$).

Magnetomotive Force and Field Strength

The magnetizing or *magnetomotive force* (\mathfrak{F}) that produces a flux or total magnetic field is measured in gilberts (Gb). Magnetomotive force is analogous to electromotive force in that it produces the magnetic field. The SI unit of magnetomotive force is the ampere-turn, abbreviated A, just like the ampere. ($1 Gb = 0.79577 A$)

Fig 2.43 — A coil of wire wound around a laminated iron core.

$$\mathfrak{F} = \frac{10 N I}{4\pi} \quad (55)$$

where

\mathfrak{F} = magnetomotive strength in gilberts,
 N = number of turns in the coil creating the field,
 I = dc current in amperes in the coil, and
 $\pi = 3.1416$.

MAGNETIC FIELD STRENGTH

The magnetic field strength (H) measured in oersteds (Oe) produced by any particular magnetomotive force (measured in gilberts) is given by:

$$H = \frac{\mathfrak{F}}{\ell} = \frac{10 N I}{4 \pi \ell} \quad (56)$$

where

H = magnetic field strength in oersteds, and
 ℓ = mean magnetic path length in centimeters.

The *mean magnetic path length* is the average length of the lines of magnetic flux. If the inductor is wound on a closed core as shown in the next section, ℓ is approximately the average of the inner and outer circumfer-

ences of the core. The SI unit of magnetic field strength is the ampere-turn per meter. (1 Oe = 79.58 A/m)

2.8.2 Magnetic Core Properties

PERMEABILITY

The nature of the material within the coil of an electromagnet, where the lines of force are most concentrated, has the greatest effect upon the magnetic field established by the coil. All core materials are compared relatively to air. The ratio of flux density produced by a given material compared to the flux density produced by an air core is the *permeability* (μ) of the material. Air and non-magnetic materials have a permeability of one.

Suppose the coil in **Fig 2.43** is wound on an iron core having a cross-sectional area of 2 square inches. When a certain current is sent through the coil, it is found that there are 80,000 lines of force in the core. Since the area is 2 square inches, the magnetic flux density is 40,000 lines per square inch. Now suppose that the iron core is removed and the same current is maintained in the coil. Also suppose the flux density without the iron core is found to be 50 lines per square inch. The ratio of these flux densities, iron core to air, is 40,000 / 50 or 800. This ratio is the core's permeability.

Permeabilities as high as 10^6 have been attained. The three most common types of materials used in magnetic cores are these:

A. stacks of thin steel laminations (for power and audio applications, see the discussion on eddy currents below);

B. various ferrite compounds (for cores shaped as rods, toroids, beads and numerous

other forms); and

C. powdered iron (shaped as slugs, toroids and other forms for RF inductors).

The permeability of silicon-steel power-transformer cores approaches 5000 in high-quality units. Powdered-iron cores used in RF tuned circuits range in permeability from 3 to about 35, while ferrites of nickel-zinc and manganese-zinc range from 20 to 15,000. Not all materials have permeabilities higher than air. Brass has a permeability of less than one. A brass core inserted into a coil will decrease the magnetic field compared to an air core.

Table 2.9 lists some common magnetic materials, their composition and their permeabilities. Core materials are often frequency sensitive, exhibiting excessive losses outside the frequency band of intended use. (Ferrite materials are discussed separately in a later section of the chapter on **RF Techniques**.)

As a measure of the ease with which a magnetic field may be established in a material as compared with air, permeability (μ) corresponds roughly to electrical conductivity. Higher permeability means that it is easier to establish a magnetic field in the material. Permeability is given as:

$$\mu = \frac{B}{H} \quad (57)$$

where

B is the flux density in gauss, and

H is the magnetic field strength in oersteds.

RELUCTANCE

That a force (the magnetomotive force) is required to produce a given magnetic field strength implies that there is some opposition to be overcome. This opposition to the

creation of a magnetic field is called *reluctance*. Reluctance (\mathfrak{R}) is the reciprocal of permeability and corresponds roughly to resistance in an electrical circuit. Carrying the electrical resistance analogy a bit further, the magnetic equivalent of Ohm's Law relates reluctance, magnetomotive force, and flux density: $\mathfrak{R} = \mathfrak{L} / B$.

SATURATION

Unlike electrical conductivity, which is independent of other electrical parameters, the permeability of a magnetic material varies with the flux density. At low flux densities (or with an air core), increasing the current through the coil will cause a proportionate increase in flux. This occurs because the current passing through the coil forces the atoms of the iron (or other material) to line up, just like many small compass needles. The magnetic field that results from the atomic alignment is *much* larger than that produced by the current with no core. As more and more atoms align, the magnetic flux density also increases.

At very high flux densities, increasing the current beyond a certain point may cause no appreciable change in the flux because all of the atoms are aligned. At this point, the core is said to be *saturated*. Saturation causes a rapid decrease in permeability, because it decreases the ratio of flux lines to those obtainable with the same current using an air core. **Fig 2.44** displays a typical permeability curve, showing the region of saturation. The saturation point varies with the makeup of different magnetic materials. Air and other nonmagnetic materials do not saturate.

HYSTERESIS

Retentivity in magnetic core materials is caused by atoms retaining their alignment from an applied magnetizing force. Retentivity is desirable if the goal is to create a

Fig 2.44 — A typical permeability curve for a magnetic core, showing the point where saturation begins.

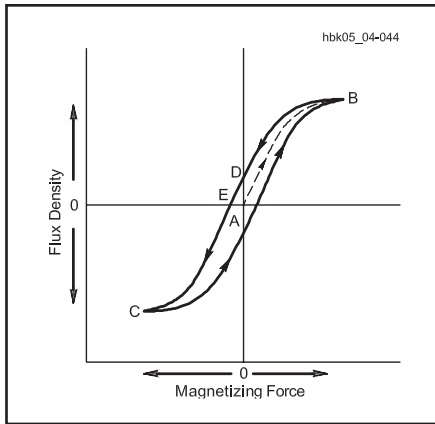

Fig 2.45 — A typical hysteresis curve for a magnetic core, showing the additional energy needed to overcome residual flux.

permanent magnet. In an electronic circuit, however, the changes caused by retentivity cause the properties of the core material to depend on the history of how the magnetizing force was applied.

Fig 2.45 illustrates the change of flux density (B) with a changing magnetizing force (H). From starting point A, with no flux in the core, the flux reaches point B at the maximum magnetizing force. As the force decreases, so too does the flux, but it does not reach zero simultaneously with the force at point D. As the force continues in the opposite direction, it brings the flux density to point C. As the force decreases to zero, the flux once more lags behind. This occurs because some of the atoms in core retain their alignment, even after the external magnetizing force is removed. This creates *residual flux* that is present even with no applied magnetizing force. This is the property of *hysteresis*.

In effect, a *coercive force* is necessary to reverse or overcome the residual magnetism retained by the core material. If a circuit carries a large ac current (that is, equal to or larger than saturation), the path shown in Fig 2.45 will be retraced with every cycle and the reversing force each time. The result is a power loss to the magnetic circuit, which appears as heat in the core material. Air cores are immune to hysteresis effects and losses.

2.8.3 Inductance and Direct Current

In an electrical circuit, any element whose operation is based on the transfer of energy into and out of magnetic fields is called an *inductor* for reasons to be explained shortly.

Fig 2.46 shows schematic-diagram symbols and photographs of a few representative inductors. The photograph shows an air-core inductor, a slug-tuned (variable-core) inductor with a nonmagnetic core and an inductor

with a magnetic (iron) core. Inductors are often called *coils* because of their construction.

As explained above, when current flows through any conductor—even a straight wire—a magnetic field is created. The transfer of energy to the magnetic field represents work performed by the source of the voltage. Power is required for doing work, and since power is equal to current multiplied by voltage, there must be a voltage drop across the inductor while energy is being stored in the field. This voltage drop, exclusive of any voltage drop caused by resistance in the conductor, is the result of an opposing voltage created in the conductor while the magnetic field is building up to its final value. Once the field becomes constant, the *induced voltage* or *back-voltage* disappears, because no further energy is being stored. Back voltage is analogous to the opposition to current flow in a capacitor from the increasing capacitor voltage.

The induced voltage opposes the voltage of the source, preventing the current from rising rapidly when voltage is applied. **Fig 2.47A** illustrates the situation of energizing an inductor or magnetic circuit, showing the relative amplitudes of induced voltage and the delayed rise in current to its full value.

The amplitude of the induced voltage is proportional to the rate at which the current changes (and consequently, the rate at which the magnetic field changes) and to a constant associated with the inductor itself, *inductance* (L). (*Self-inductance* is sometimes used to distinguish between mutual inductance as described below.) The basic unit of inductance is the *henry* (abbreviated H).

$$V = L \frac{\Delta I}{\Delta t} \quad (58)$$

where

V is the induced voltage in volts,
 L is the inductance in henries, and
 $\Delta I/\Delta t$ is the rate of change of the current in amperes per second.

An inductance of 1 H generates an induced voltage of one volt when the inducing current is varying at a rate of one ampere per second.

The energy stored in the magnetic field of an inductor is given by the formula:

$$W = \frac{I^2 L}{2} \quad (59)$$

where

W = energy in joules,
 I = current in amperes, and
 L = inductance in henrys.

This formula corresponds to the energy-storage formula for capacitors: energy storage is a function of current squared. Inductance is proportional to the amount of energy stored in an inductor's magnetic field for a given amount of current. The magnetic field strength, H , is proportional to the number of

Rate of Change

The symbol Δ represents change in the following variable, so that ΔI represents "change in current" and Δt "change in time". A rate of change per unit of time is often expressed in this manner. When the amount of time over which the change is measured becomes very small, the letter d replaces Δ in both the numerator and denominator to indicate infinitesimal changes. This notation is used in the derivation and presentation of the functions that describe the behavior of electric circuits.

Fig 2.46 — Photos and schematic symbols for representative inductors. A, an air-core inductor; B, a variable inductor with a nonmagnetic slug and C, an inductor with a toroidal magnetic core. The 1/4-inch-ruled graph paper background provides a size comparison.

Fig 2.47 — Inductive circuit showing the generation of induced voltage and the rise of current when voltage is applied to an inductor at A, and the decay of current as the coil shorted at B.

turns in the inductor's winding, N , (see equation 56) and for a given amount of current, to the value of μ for the core. Thus, inductance is directly proportional to both N and μ .

The polarity of the induced voltage is always such as to oppose any change in the circuit current. (This is why the term "back" is used, as in back-voltage or *back-EMF* for this reason.) This means that when the current in the circuit is increasing, work is being done against the induced voltage by storing energy in the magnetic field. Likewise, if the current in the circuit tends to decrease, the stored energy of the field returns to the circuit, and adds to the energy being supplied by the voltage source. The net effect of storing and releasing energy is that inductors oppose changes in current just as capacitors oppose changes in voltage. This phenomenon tends to keep the current flowing even though the applied voltage may be decreasing or be removed entirely. Fig 2.47B illustrates the decreasing but continuing flow of current caused by the induced voltage after the source voltage is removed from the circuit.

Inductance depends on the physical configuration of the inductor. All conductors, even straight wires, have inductance. Coiling a conductor increases its inductance. In

effect, the growing (or shrinking) magnetic field of each turn produces magnetic lines of force that — in their expansion (or contraction) — intercept the other turns of the coil, inducing a voltage in every other turn. (Recall the two-way relationship between a changing magnetic field and the voltage it creates in a conductor.) The mutuality of the effect, called *magnetic flux linkage* (ψ), multiplies the ability of the coiled conductor to store magnetic energy.

A coil of many turns will have more inductance than one of few turns, if both coils are otherwise physically similar. Furthermore, if an inductor is placed around a magnetic core, its inductance will increase in proportion to the permeability of that core, if the circuit current is below the point at which the core saturates.

In various aspects of radio work, inductors may take values ranging from a fraction of a nanohenry (nH) through millihenrys (mH) up to about 20 H.

EFFECTS OF SATURATION

An important concept for using inductors is that as long as the coil current remains below saturation, the inductance of the coil is essentially constant. Fig 2.48 shows graphs of magnetic flux linkage (ψ) and inductance (L)

Fig 2.48 — Magnetic flux linkage and inductance plotted versus coil current for (A) a typical iron-core inductor. As the flux linkage $N\phi$ in the coil saturates, the inductance begins to decrease since inductance = flux linkage / current. The curves marked B show the effect of adding an air gap to the core. The current-handling capability has increased, but at the expense of reduced inductance.

vs. current (I) for a typical iron-core inductor both saturated and non-saturated. These quantities are related by the equation

$$\psi = N\phi = LI \quad (60)$$

where

- ψ = the flux linkage
- N = number of turns,
- ϕ = flux density in webers
- L = inductance in henrys, and
- I = current in amperes.

In the lower graph, a line drawn from any point on the curve to the (0,0) point will show the effective inductance, $L = N\phi / I$, at that current. These results are plotted on the upper graph.

Note that below saturation, the inductance is constant because both ψ and I are increasing at a steady rate. Once the saturation current is reached, the inductance decreases because ψ does not increase anymore (except for the tiny additional magnetic field the current itself provides).

One common method of increasing the saturation current level is to cut a small air gap in the core (see Fig 2.49). This gap forces the flux lines to travel through air for a short dis-

Fig 2.49 — Typical construction of a magnetic-core inductor. The air gap greatly reduces core saturation at the expense of reducing inductance. The insulating laminations between the core layers help to minimize eddy currents, as well.

tance, reducing the permeability of the core. Since the saturation flux linkage of the core is unchanged, this method works by requiring a higher current to achieve saturation. The price that is paid is a reduced inductance below saturation. The curves in Fig 2.48B show the result of an air gap added to that inductor.

Manufacturer’s data sheets for magnetic cores usually specify the saturation flux density. Saturation flux density (ϕ) in gauss can be calculated for ac and dc currents from the following equations:

$$\phi_{ac} = \frac{3.49 V}{fNA}$$

$$\phi_{dc} = \frac{NIA_L}{10A}$$

where

- V = RMS ac voltage
- f = frequency, in MHz
- N = number of turns
- A = equivalent area of the magnetic path in square inches (from the data sheet)
- I = dc current, in amperes, and
- A_L = inductance index (also from the data sheet).

2.8.4 Mutual Inductance and Magnetic Coupling

MUTUAL INDUCTANCE

When two inductors are arranged with their axes aligned as shown in Fig 2.50, current flowing in through inductor 1 creates a magnetic field that intercepts inductor 2. Consequently, a voltage will be induced in inductor 2 whenever the field strength of inductor 1

Fig 2.50 — Mutual inductance: When S is closed, current flows through coil number 1, setting up a magnetic field that induces a voltage in the turns of coil number 2.

is changing. This induced voltage is similar to the voltage of self-induction, but since it appears in the second inductor because of current flowing in the first, it is a mutual effect and results from the *mutual inductance* between the two inductors.

When all the flux set up by one coil intercepts all the turns of the other coil, the mutual inductance has its maximum possible value. If only a small part of the flux set up by one coil intercepts the turns of the other, the mutual inductance is relatively small. Two inductors having mutual inductance are said to be *coupled*.

The ratio of actual mutual inductance to the maximum possible value that could theoretically be obtained with two given inductors is called the *coefficient of coupling* between the inductors. It is expressed as a percentage or as a value between 0 and 1. Inductors that have nearly the maximum possible mutual inductance (coefficient = 1 or 100%) are said to be closely, or tightly, coupled. If the mutual inductance is relatively small the inductors are said to be loosely coupled. The degree of coupling depends upon the physical spacing between the inductors and how they are placed with respect to each other. Maximum coupling exists when they have a common or parallel axis and are as close together as possible (for example, one wound over the other). The coupling is least when the inductors are far apart or are placed so their axes are at right angles.

The maximum possible coefficient of coupling is closely approached when the two inductors are wound on a closed iron core. The coefficient with air-core inductors may run as high as 0.6 or 0.7 if one inductor is wound over the other, but will be much less if the two inductors are separated. Although unity coupling is suggested by Fig 2.50, such coupling is possible only when the inductors are wound on a closed magnetic core.

Coupling between inductors can be minimized by using separate closed magnetic cores for each. Since an inductor’s magnetic field

is contained almost entirely in a closed core, two inductors with separate closed cores, such as the toroidal inductor in Fig 2.46 C, can be placed close together in almost any relative orientation without coupling.

UNWANTED COUPLING

The inductance of a short length of straight wire is small, but it may not be negligible. (In free-space, round wire has an inductance on the order of 1 $\mu\text{H}/\text{m}$, but this is affected by wire diameter and the total circuit’s physical configuration.) Appreciable voltage may be induced in even a few inches of wire carrying ac by changing magnetic fields with a frequency on the order of 100 MHz or higher. At much lower frequencies or at dc, the inductance of the same wire might be ignored because the induced voltage would be very small.

There are many phenomena, both natural and man-made, that create sufficiently strong or rapidly-changing magnetic fields to induce voltages in conductors. Many of them create brief but intense pulses of energy called *transients* or “spikes.” The magnetic fields from these transients intercept wires leading into and out of — and wires wholly within — electronic equipment, inducing unwanted voltages by mutual coupling.

Lightning is a powerful natural source of magnetically-coupled transients. Strong transients can also be generated by sudden changes in current in nearby circuits or wiring. High-speed digital signals and pulses can also induce voltages in adjacent conductors.

2.8.5 Inductances in Series and Parallel

When two or more inductors are connected in series (Fig 2.51A), the total inductance is equal to the sum of the individual inductances, provided that the inductors are sufficiently

Fig 2.51 — Part A shows inductances in series, and Part B shows inductances in parallel.

separated so that there is no coupling between them (see the preceding section). That is:

$$L_{\text{total}} = L_1 + L_2 + L_3 \dots + L_n \quad (61)$$

If inductors are connected in parallel (Fig 2.51B), again assuming no mutual coupling, the total inductance is given by:

$$L_{\text{total}} = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \dots + \frac{1}{L_n}} \quad (62)$$

For only two inductors in parallel, the formula becomes:

$$L_{\text{total}} = \frac{L_1 \times L_2}{L_1 + L_2} \quad (63)$$

Thus, the rules for combining inductances in series and parallel are the same as those for resistances, assuming there is no coupling between the inductors. When there is coupling between the inductors, the formulas given above will not yield correct results.

2.8.6 RL Time Constant

As with capacitors, the time dependence of inductor current is a significant property. A comparable situation to an RC circuit exists when resistance and inductance are connected in series. In Fig 2.52, first consider the case in which R is zero. Closing S1 sends a current through the circuit. The instantaneous transition from no current to a finite value, however small, represents a rapid change in current, and an opposing voltage is induced in L. The value of the opposing voltage is almost equal to the applied voltage, so the resulting initial current is very small.

The opposing voltage is created by change

Fig 2.52 — Time constant of an RL circuit being energized.

in the inductor current and would cease to exist if the current did not continue to increase. With no resistance in the circuit, the current would increase forever, always growing just fast enough to keep the self-induced opposing voltage just below the applied voltage.

When resistance in the circuit limits the current, the opposing voltage induced in L must only equal the difference between E and the drop across R, because that is the voltage actually applied to L. This difference becomes smaller as the current approaches its final value, limited by Ohm's Law to $I = E/R$. Theoretically, the opposing voltage never quite disappears, and so the current never quite reaches the Ohm's Law limit. In practical terms, the difference eventually becomes insignificant, just as described above for capacitors charging to an applied voltage through a resistor.

The inductor current at any time after the switch in Fig 2.52 has been closed, can be found from:

$$I(t) = \frac{E}{R} \left(1 - e^{-\frac{tR}{L}} \right) \quad (64)$$

where

- I(t) = current in amperes at time t,
- E = power source potential in volts,
- t = time in seconds after application of voltage,
- e = natural logarithmic base = 2.718,
- R = circuit resistance in ohms, and
- L = inductance in henrys.

(References that explain exponential equations, e, and other mathematical topics are found in the "Radio Mathematics" article on this book's CD-ROM.) The term E/R in this equation represents the dc value of I, or the value of I(t) when t becomes very large; this is the *steady-state value* of I. If $t = L/R$, the above equation becomes:

$$V(L/R) = \frac{E}{R} (1 - e^{-1}) \approx 0.632 \frac{E}{R} \quad (65)$$

The time in seconds required for the current to build up to 63.2% of the maximum value is called the *time constant* (also the *RL time constant*), and is equal to L/R , where L is in henrys and R is in ohms. (Time constants are also discussed in the section on RC circuits above.) After each time interval equal to this constant, current increases by an additional 63.2% closer to the final value of E/R . This behavior is graphed in Fig 2.52. As is the case with capacitors, after five time constants the current is considered to have reached its maximum value. As with capacitors, we often use the lower-case Greek tau (τ) to represent the time constant.

Example: If a circuit has an inductor of 5.0 mH in series with a resistor of 10Ω , how long will it take for the current in the circuit to reach full value after power is applied?

Since achieving maximum current takes approximately five time constants,

$$t = \frac{5L}{R} = \frac{5 \times 5.0 \times 10^{-3} \text{ H}}{10 \Omega} = 2.5 \times 10^{-3} \text{ seconds} = 2.5 \text{ ms}$$

Note that if the inductance is increased to 5.0 H, the required time increases by a factor of 1000 to 2.5 seconds. Since the circuit resistance didn't change, the final current is the same for both cases in this example. Increasing inductance increases the time required to reach full current.

Zero resistance would prevent the circuit from ever achieving full current. All practical inductors have some resistance in the wire making up the inductor.

An inductor cannot be discharged in the simple circuit of Fig 2.52 because the magnetic field ceases to exist or "collapses" as soon as the current ceases. Opening S1 does not leave the inductor charged in the way that a capacitor would remain charged. Energy storage in a capacitor depends on the separated charges staying in place. Energy storage in an inductor depends on the charges continuing to move as current.

The energy stored in the inductor's magnetic field attempts to return instantly to the circuit when S1 is opened. The rapidly changing (collapsing) field in the inductor causes a very large voltage to be induced across the inductor. Because the change in current is now in the opposite direction, the induced voltage also reverses polarity. This induced voltage (called *inductive kick-back*) is usually many times larger than the originally applied

Fig 2.53 — Time constant of an RL circuit being de-energized. This is a theoretical model only, since a mechanical switch cannot change state instantaneously.

voltage, because the induced voltage is proportional to the rate at which the field changes.

The common result of opening the switch in such a circuit is that a spark or arc forms at the switch contacts during the instant the switch opens. When the inductance is large and the current in the circuit is high, large amounts of energy are released in a very short time. It is not at all unusual for the switch contacts to burn or melt under such circumstances.

The spark or arc at the opened switch can be reduced or suppressed by connecting a suitable capacitor and resistor in series across the contacts to absorb the energy non-destructively. Such an RC combination is called a *snubber network*. The current rating for a switch may be significantly reduced if it is used in an inductive circuit.

Transistor switches connected to and controlling inductors, such as relays and solenoids, also require protection from the high kick-back voltages. In most cases, a small power diode connected across the relay coil so that it does not conduct current when the inductor is energized (called a *kick-back diode*) will protect the transistor.

If the excitation is removed without breaking the circuit, as shown in Fig 2.53, the current will decay according to the formula:

$$I(t) = \frac{E}{R} \left(e^{-\frac{tR}{L}} \right) \quad (66)$$

where t = time in seconds after removal of the source voltage.

After one time constant the current will decay by 63.2% of its steady-state value. (It will decay to 36.8% of the steady-state value.) The graph in Fig 2.53 shows the current-decay waveform to be identical to the voltage-discharge waveform of a capacitor. Be careful about applying the terms *charge* and *discharge* to an inductive circuit, however. These terms refer to energy storage in an electric field. An inductor stores energy in a magnetic field and the usual method of referring to the process is *energize* and *de-energize* (although it is not always followed).

2.8.7 Alternating Current in Inductors

For reasons similar to those that cause a phase difference between current and voltage in a capacitor, when an alternating voltage is applied to an ideal inductance with no resistance, the current is 90° out of phase with the applied voltage. In the case of an inductor, however, the current *lags* 90° behind the voltage as shown in Fig 2.54, the opposite of the capacitor current-voltage relationship. (Here again, we can also say the voltage across an inductor *leads* the current by 90°.) Interpreting Fig 2.54 begins with understanding that

the cause for current lag in an inductor is the opposing voltage that is induced in the inductor and that the amplitude of the opposing voltage is proportional to the rate at which the inductor current changes.

In time segment OA, when the applied voltage is at its positive maximum, the rate at which the current is changing is also the highest, a 38% change. This means that the opposing voltage is also maximum, allowing the least current to flow. In the segment AB, as a result of the decrease in the applied voltage, current changes by only 33% inducing a smaller opposing voltage. The process continues in time segments BC and CD, the latter producing only an 8% rise in current as the applied and induced opposing voltage approach zero.

In segment DE, the applied voltage changes polarity, causing current to begin to decrease, returning stored energy to the circuit from the inductor's magnetic field. As the current rate of change is now negative (decreasing) the induced opposing voltage also changes

polarity. Current flow is still in the original direction (positive), but is decreasing as less energy is stored in the inductor.

As the applied voltage continues to increase negatively, the current — although still positive — continues to decrease in value, reaching zero as the applied voltage reaches its negative maximum. The energy once stored in the inductor has now been completely returned to the circuit. The negative half-cycle then continues just as the positive half-cycle.

Similarly to the capacitive circuit discussed earlier, by dividing the cycle into a large number of intervals, it can be shown that the current and voltage are both sine waves, although with a difference in phase.

Compare Fig 2.54 with Fig 2.36. Whereas in a pure capacitive circuit, the current *leads* the voltage by 90°, in a pure inductive circuit, the current *lags* the voltage by 90°. These phenomena are especially important in circuits that combine inductors and capacitors. Remember that the phase difference between voltage and current in both types of circuits is a result of energy being stored and released as voltage across a capacitor and as current in an inductor.

ELI the ICE Man

If you have difficulty remembering the phase relationships between voltage and current with inductors and capacitors, you may find it helpful to think of the phrase, "ELI the ICE man." This will remind you that voltage across an inductor leads the current through it, because the E comes before (leads) I, with an L between them, as you read from left to right. (The letter L represents inductance.) Similarly, I comes before (leads) E with a C between them.

EDDY CURRENT

Since magnetic core material is usually conductive, the changing magnetic field produced by an ac current in an inductor also induces a voltage in the core. This voltage causes a current to flow in the core. This *eddy current* (so-named because it moves in a closed path, similarly to eddy currents in water) serves no useful purpose and results in energy being dissipated as heat from the core's resistance. Eddy currents are a particular problem in inductors with iron cores. Cores made of thin strips of magnetic material, called *laminations*, are used to reduce

Fig 2.54 — Phase relationships between voltage and current when an alternating current is applied to an inductance.

eddy currents. (See also the section on Practical Inductors elsewhere in the chapter.)

2.8.8 Inductive Reactance and Susceptance

The amount of current that can be created in an inductor is proportional to the applied voltage but inversely proportional to the inductance because of the induced opposing voltage. If the applied voltage is ac, the rate of change of the current varies directly with the frequency and this rate of change also determines the amplitude of the induced or reverse voltage. Hence, the opposition to the flow of current increases proportionally to frequency. Stated in another way, inductor current is inversely proportional to inductance for a given applied voltage and frequency.

The combined effect of inductance and frequency is called *inductive reactance*, which — like capacitive reactance — is expressed in ohms. As with capacitive reactance, no power is dissipated in inductive reactance. The energy stored in the inductor during one portion of the cycle is returned to the circuit in the next portion.

The formula for inductive reactance is:

$$X_L = 2 \pi f L \quad (67)$$

where

X_L = inductive reactance in ohms,
 f = frequency in hertz,

Inductive Reactance Timesaver

Similarly to the calculation of capacitive reactance, if inductance is specified in microhenrys (μH) and the frequency is in megahertz (MHz), the reactance calculated from equation 66 is in units of ohms (Ω). The same is true for the combination of mH and kHz.

L = inductance in henrys, and
 $\pi = 3.1416$.
 (If $\omega = 2 \pi f$, then $X_L = \omega L$.)

Example: What is the reactance of an inductor having an inductance of 8.00 H at a frequency of 120 Hz?

$$\begin{aligned} X_L &= 2 \pi f L \\ &= 6.2832 \times 120 \text{ Hz} \times 8.0 \text{ H} \\ &= 6030 \Omega \end{aligned}$$

Example: What is the reactance of a 15.0-microhenry inductor at a frequency of 14.0 MHz?

$$\begin{aligned} X_L &= 2 \pi f L \\ &= 6.2832 \times 14.0 \text{ MHz} \times 15.0 \mu\text{H} \\ &= 1320 \Omega \end{aligned}$$

The resistance of the wire used to wind the inductor has no effect on the reactance, but

simply acts as a separate resistor connected in series with the inductor.

Example: What is the reactance of the same inductor at a frequency of 7.0 MHz?

$$\begin{aligned} X_L &= 2 \pi f L \\ &= 6.2832 \times 7.0 \text{ MHz} \times 15.0 \mu\text{H} \\ &= 660 \Omega \end{aligned}$$

The direct relationship between frequency and reactance in inductors, combined with the inverse relationship between reactance and frequency in the case of capacitors, will be of fundamental importance in creating resonant circuits.

INDUCTIVE SUSCEPTANCE

As a measure of the ability of an inductor to limit the flow of ac in a circuit, inductive reactance is similar to capacitive reactance in having a corresponding *susceptance*, or ability to pass ac current in a circuit. In an ideal inductor with no resistive losses — that is, no energy lost as heat — susceptance is simply the reciprocal of reactance.

$$B = \frac{1}{X_L} \quad (68)$$

where

X_L = reactance, and
 B = susceptance.

The unit of susceptance for both inductors and capacitors is the *siemens*, abbreviated S.

2.9 Working with Reactance

2.9.1 Ohm's Law for Reactance

Only ac circuits containing capacitance or inductance (or both) have reactance. Despite the fact that the voltage in such circuits is 90° out of phase with the current, circuit reactance does oppose the flow of ac current in a manner that corresponds to resistance. That is, in a capacitor or inductor, reactance is equal to the ratio of ac voltage to ac current and the equations relating voltage, current and reactance take the familiar form of Ohm's Law:

$$E = I X \quad (69)$$

$$I = \frac{E}{X} \quad (70)$$

$$X = \frac{E}{I} \quad (71)$$

where

E = RMS ac voltage in volts,
 I = RMS ac current in amperes, and
 X = inductive or capacitive reactance in ohms.

Example: What is the voltage across a capacitor of 200 pF at 7.15 MHz, if the current

through the capacitor is 50 mA?

Since the reactance of the capacitor is a function of both frequency and capacitance, first calculate the reactance:

$$\begin{aligned} X_C &= \frac{1}{2 \pi f C} \\ &= \frac{1}{2 \times 3.1416 \times 7.15 \times 10^6 \text{ Hz} \times 200 \times 10^{-12} \text{ F}} \\ &= \frac{10^6 \Omega}{8980} = 111 \Omega \end{aligned}$$

Next, use equation 69:

$$E = I \times X_C = 0.050 \text{ A} \times 111 \Omega = 5.6 \text{ V}$$

Example: What is the current through an 8.0-H inductor at 120 Hz, if 420 V is applied?

$$\begin{aligned} X_L &= 2 \pi f L \\ &= 2 \times 3.1416 \times 120 \text{ Hz} \times 8.0 \text{ H} \\ &= 6030 \Omega \end{aligned}$$

$$I = E / X_L = 420 / 6030 = 69.6 \text{ mA}$$

Fig 2.55 charts the reactances of capacitors

from 1 pF to 100 μF , and the reactances of inductors from 0.1 μH to 10 H, for frequencies between 100 Hz and 100 MHz. Approximate values of reactance can be read or interpolated from the chart. The formulas will produce more exact values, however. (The chart can also be used to find the frequency at which an inductor and capacitor have equal reactances, creating resonance as described in the section "At and Near Resonance" below.)

Although both inductive and capacitive reactance oppose the flow of ac current, the two types of reactance differ. With capacitive reactance, the current *leads* the voltage by 90° , whereas with inductive reactance, the current *lags* the voltage by 90° . The convention for charting the two types of reactance appears in Fig 2.56. On this graph, inductive reactance is plotted along the $+90^\circ$ vertical line, while capacitive reactance is plotted along the -90° vertical line. This convention of assigning a positive value to inductive reactance and a negative value to capacitive reactance results from the mathematics used for working with impedance as described elsewhere in this chapter.

Fig 2.55 — Inductive and capacitive reactance vs frequency. Heavy lines represent multiples of 10, intermediate lines multiples of 5. For example, the light line between 10 μH and 100 μH represents 50 μH ; the light line between 0.1 μF and 1 μF represents 0.5 μF , and so on. Other values can be extrapolated from the chart. For example, the reactance of 10 H at 60 Hz can be found by taking the reactance of 10 H at 600 Hz and dividing by 10 for the 10 times decrease in frequency. (Originally from Terman, *Radio Engineer's Handbook*. See references.)

In summary:

- conductance is reciprocal of resistance,
 - susceptance is reciprocal of reactance,
- and
- admittance is reciprocal of impedance.

2.9.2 Reactances in Series and Parallel

If a circuit contains two reactances of the same type, whether in series or in parallel, the resulting reactance can be determined by applying the same rules as for resistances in series and in parallel. Series reactance is given by the formula

$$X_{\text{total}} = X_1 + X_2 + X_3 \dots + X_n \quad (72)$$

Example: Two noninteracting inductances are in series. Each has a value of 4.0 μH , and the operating frequency is 3.8 MHz. What is the resulting reactance?

The reactance of each inductor is:

$$X_L = 2 \pi f L$$

$$= 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 4 \times 10^{-6} \text{ H}$$

$$= 96 \Omega$$

$$X_{\text{total}} = X_1 + X_2 = 96 \Omega + 96 \Omega = 192 \Omega$$

We might also calculate the total reactance by first adding the inductances:

$$L_{\text{total}} = L_1 + L_2 = 4.0 \mu\text{H} + 4.0 \mu\text{H} = 8.0 \mu\text{H}$$

$$X_{\text{total}} = 2 \pi f L$$

$$= 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 8.0 \times 10^{-6} \text{ H}$$

$$= 191 \Omega$$

(The fact that the last digit differs by one illustrates the uncertainty of the calculation caused by the limited precision of the measured values in the problem, and differences

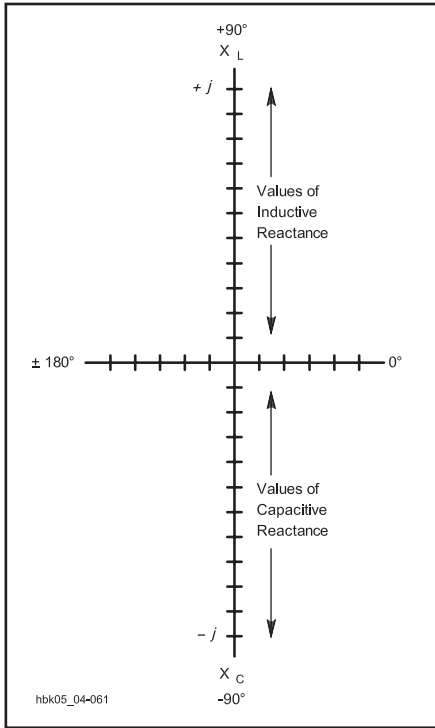

Fig 2.56 — The conventional method of plotting reactances on the vertical axis of a graph, using the upward or “plus” direction for inductive reactance and the downward or “minus” direction for capacitive reactance. The horizontal axis will be used for resistance in later examples.

caused by rounding off the calculated values. This also shows why it is important to follow the rules for significant figures.)

Example: Two noninteracting capacitors are in series. One has a value of 10.0 pF, the other of 20.0 pF. What is the resulting reactance in a circuit operating at 28.0 MHz?

$$X_{C1} = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 10.0 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{1760} = 568 \Omega$$

$$X_{C2} = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 20.0 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{3520} = 284 \Omega$$

$$X_{\text{total}} = X_{C1} + X_{C2} = 568 \Omega + 284 \Omega = 852 \Omega$$

Alternatively, combining the series capaci-

tors first, the total capacitance is 6.67×10^{-12} F or 6.67 pF. Then:

$$X_{\text{total}} = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 6.67 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{1170} = 852 \Omega$$

(Within the uncertainty of the measured values and the rounding of values in the calculations, this is the same result as the 852 Ω we obtained with the first method.)

This example serves to remind us that *series capacitance* is not calculated in the manner used by other series resistance and inductance, but *series capacitive reactance* does follow the simple addition formula.

For reactances of the same type in parallel, the general formula is:

$$X_{\text{total}} = \frac{1}{\frac{1}{X_1} + \frac{1}{X_2} + \frac{1}{X_3} + \dots + \frac{1}{X_n}} \quad (73)$$

or, for exactly two reactances in parallel

$$X_{\text{total}} = \frac{X_1 \times X_2}{X_1 + X_2} \quad (74)$$

Example: Place the capacitors in the last example (10.0 pF and 20.0 pF) in parallel in the 28.0 MHz circuit. What is the resultant reactance?

$$X_{\text{total}} = \frac{X_1 \times X_2}{X_1 + X_2}$$

$$= \frac{568 \Omega \times 284 \Omega}{568 \Omega + 284 \Omega} = 189 \Omega$$

Alternatively, two capacitors in parallel can be combined by adding their capacitances.

$$C_{\text{total}} = C_1 + C_2 = 10.0 \text{ pF} + 20.0 \text{ pF} = 30 \text{ pF}$$

$$X_C = \frac{1}{2\pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 30 \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{5280} = 189 \Omega$$

Example: Place the series inductors above (4.0 μH each) in parallel in a 3.8-MHz circuit. What is the resultant reactance?

$$X_{\text{total}} = \frac{X_{L1} \times X_{L2}}{X_{L1} + X_{L2}}$$

$$= \frac{96 \Omega \times 96 \Omega}{96 \Omega + 96 \Omega} = 48 \Omega$$

Of course, a number (n) of equal reactances (or resistances) in parallel yields a reactance that is the value of one of them divided by n, or:

$$X_{\text{total}} = \frac{X}{n} = \frac{96 \Omega}{2} = 48 \Omega$$

All of these calculations apply only to reactances of the same type; that is, all capacitive or all inductive. Mixing types of reactances requires a different approach.

UNLIKE REACTANCES IN SERIES

When combining unlike reactances — that is, combinations of inductive and capacitive reactance — in series, it is necessary to take into account that the voltage-to-current phase relationships differ for the different types of reactance. **Fig 2.57** shows a series circuit with both types of reactance. Since the reactances are in series, the current must be the same in both. The voltage across each circuit element differs in phase, however. The voltage E_L leads the current by 90°, and the voltage E_C lags the current by 90°. Therefore, E_L and E_C have opposite polarities and cancel each other in whole or in part. The line E in **Fig 2.57** approximates the resulting voltage, which is the *difference* between E_L and E_C .

Since for a constant current the reactance is directly proportional to the voltage, the net reactance is still the sum of the individual reactances as in equation 72. Because induc-

Fig 2.57 — A series circuit containing both inductive and capacitive components, together with representative voltage and current relationships.

tive reactance is considered to be positive and capacitive reactance negative, the resulting reactance can be either positive (inductive) or negative (capacitive) or even zero (no reactance).

Another common method of adding the unlike reactances is to use the absolute values of the reactances and subtract capacitive reactance from inductive reactance:

$$X_{\text{total}} = X_L - X_C \quad (75)$$

The convention of using absolute values for the reactances and building the sense of positive and negative into the formula is the preferred method used by hams and will be used in all of the remaining formulas in this chapter. Nevertheless, before using any formulas that include reactance, determine whether this convention is followed before assuming that the absolute values are to be used.

Example: Using Fig 2.57 as a visual aid, let $X_C = 20.0 \Omega$ and $X_L = 80.0 \Omega$. What is the resulting reactance?

$$\begin{aligned} X_{\text{total}} &= X_L - X_C \\ &= 80.0 \Omega - 20.0 \Omega = +60.0 \Omega \end{aligned}$$

Since the result is a positive value, reactance is inductive. Had the result been a negative number, the reactance would have been capacitive.

When reactance types are mixed in a series circuit, the resulting reactance is always smaller than the larger of the two reactances. Likewise, the resulting voltage across the series combination of reactances is always smaller than the larger of the two voltages across individual reactances.

Every series circuit of mixed reactance types with more than two circuit elements can be reduced to this simple circuit by combining all the reactances into one inductive and one capacitive reactance. If the circuit has more than one capacitor or more than one inductor in the overall series string, first use the formulas given earlier to determine the total series inductance alone and the total series capacitance alone (or their respective reactances). Then combine the resulting single capacitive

reactance and single inductive reactance as shown in this section.

UNLIKE REACTANCES IN PARALLEL

The situation of parallel reactances of mixed type appears in Fig 2.58. Since the elements are in parallel, the voltage is common to both reactive components. The current through the capacitor, I_C , leads the voltage by 90° , and the current through the inductor, I_L , lags the voltage by 90° . In this case, it is the currents that are 180° out of phase and thus cancel each other in whole or in part. The total current is the difference between the individual currents, as indicated by the line I in Fig 2.58.

Since reactance is the ratio of voltage to current, the total reactance in the circuit is:

$$X_{\text{total}} = \frac{E}{I_L - I_C} \quad (76)$$

In the drawing, I_C is larger than I_L , and the resulting differential current retains the phase of I_C . Therefore, the overall reactance, X_{total} , is for capacitive in this case. The total reactance of the circuit will be smaller than the larger of the individual reactances, because the total current is smaller than the larger of the two individual currents.

In parallel circuits, reactance and current are inversely proportional to each other for a constant voltage and equation 74 can be used, carrying the positive and negative signs:

$$X_{\text{total}} = \frac{X_L \times (-X_C)}{X_L - X_C} = \frac{-X_L \times X_C}{X_L - X_C} \quad (77)$$

As with the series formula for mixed reactances, follow the convention of using absolute values for the reactances, since the minus signs in the formula account for capacitive reactance being negative. If the solution yields a negative number, the resulting reactance is capacitive, and if the solution is positive, then the reactance is inductive.

Example: Using Fig 2.58 as a visual aid, place a capacitive reactance of 10.0Ω in parallel with an inductive reactance of 40.0Ω . What is the resulting reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{-X_L \times X_C}{X_L - X_C} \\ &= \frac{-40.0 \Omega \times 10.0 \Omega}{40.0 \Omega - 10.0 \Omega} \\ &= \frac{-400 \Omega}{30.0 \Omega} = -13.3 \Omega \end{aligned}$$

The reactance is capacitive, as indicated by the negative solution. Moreover, the resultant reactance is always smaller than the larger of the two individual reactances.

As with the case of series reactances, if each leg of a parallel circuit contains more than one reactance, first simplify each leg to a single reactance. If the reactances are of the same type in each leg, the series reactance formulas for reactances of the same type will apply. If the reactances are of different types, then use the formulas shown above for mixed series reactances to simplify the leg to a single value and type of reactance.

2.9.3 At and Near Resonance

Any series or parallel circuit in which the values of the two unlike reactances are equal is said to be *resonant*. For any given inductance or capacitance, it is theoretically possible to find a value of the opposite reactance type to produce a resonant circuit for any desired frequency.

When a series circuit like the one shown in Fig 2.57 is resonant, the voltages E_C and E_L are equal and cancel; their sum is zero. This is a *series-resonant* circuit. Since the reactance of the circuit is proportional to the sum of

Fig 2.58 — A parallel circuit containing both inductive and capacitive components, together with representative voltage and current relationships.

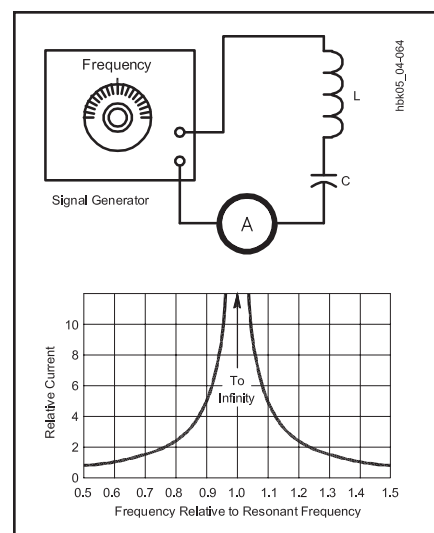

Fig 2.59 — The relative generator current with a fixed voltage in a series circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance.

these voltages, the net reactance also goes to zero. Theoretically, the current, as shown in Fig 2.59, can become infinite. In fact, it is limited only by losses in the components and other resistances that would exist in a real circuit of this type. As the frequency of operation moves slightly off resonance and the reactances no longer cancel completely, the net reactance climbs as shown in the figure. Similarly, away from resonance the current drops to a level determined by the net reactance.

In a *parallel-resonant* circuit of the type in Fig 2.58, the current I_L and I_C are equal and cancel to zero. Since the reactance is inversely proportional to the current, as the current ap-

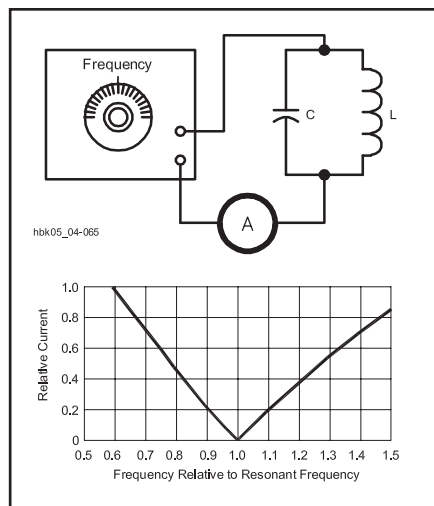

Fig 2.60 — The relative generator current with a fixed voltage in a parallel circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance. (The circulating current through the parallel inductor and capacitor is a maximum at resonance.)

Fig 2.61 — The transition from capacitive to inductive reactance in a series-resonant circuit as the frequency passes resonance.

proaches zero, the reactance becomes infinite. As with series circuits, component losses and other resistances in the circuit prevent the current from reaching zero. Fig 2.60 shows the theoretical current curve near and at resonance for a purely reactive parallel-resonant circuit. Note that in both Fig 2.59 and Fig 2.60, the departure of current from the resonance value is close to, but not quite, symmetrical above and below the resonant frequency.

Example: What is the reactance of a series L-C circuit consisting of a 56.04-pF capacitor and an 8.967- μ H inductor at 7.00, 7.10 and 7.20 MHz? Using the formulas from earlier in this chapter, we calculate a table of values:

Frequency (MHz)	X_L (Ω)	X_C (Ω)	X_{total} (Ω)
7.000	394.4	405.7	-11.3
7.100	400.0	400.0	0
7.200	405.7	394.4	11.3

The exercise shows the manner in which the reactance rises rapidly as the frequency moves above and below resonance. Note that in a series-resonant circuit, the reactance at frequencies below resonance is capacitive, and above resonance, it is inductive. Fig 2.61 displays this fact graphically. In a parallel-resonant circuit, where the reactance becomes infinite at resonance, the opposite condition exists: above resonance, the reactance is capacitive and below resonance it is inductive, as shown in Fig 2.62. Of course, all graphs and calculations in this section are theoretical and presume a purely reactive circuit. Real circuits are never purely reactive; they contain some resistance that modifies their performance considerably. Real resonant circuits will be discussed later in this chapter.

2.9.4 Reactance and Complex Waveforms

All of the formulas and relationships shown in this section apply to alternating current in the form of regular sine waves. Complex wave shapes complicate the reactive situation considerably. A complex or nonsinusoidal wave can be treated as a sine wave of some fundamental frequency and a series of harmonic frequencies whose amplitudes depend on the original wave shape. When such a complex wave — or collection of sine waves — is applied to a reactive circuit, the current through the circuit will not have the same wave shape as the applied voltage. The difference results because the reactance of an inductor and capacitor depend in part on the applied frequency.

For the second-harmonic component of the complex wave, the reactance of the inductor is twice and the reactance of the capacitor is half their respective values at the fundamental frequency. A third-harmonic component

Fig 2.62 — The transition from inductive to capacitive reactance in a parallel-resonant circuit as the frequency passes resonance.

Fig 2.63 — A signal path with a series inductor and a shunt capacitor. The circuit presents different reactances to an ac signal and to its harmonics.

produces inductive reactances that are triple and capacitive reactances that are one-third those at the fundamental frequency. Thus, the overall circuit reactance is different for each harmonic component.

The frequency sensitivity of a reactive circuit to various components of a complex wave shape creates both difficulties and opportunities. On the one hand, calculating the circuit reactance in the presence of highly variable as well as complex waveforms, such as speech, is difficult at best. On the other hand, the frequency sensitivity of reactive components and circuits lays the foundation for filtering, that is, for separating signals of different frequencies or acting upon them differently. For example, suppose a coil is in the series path of a signal and a capacitor is connected from the signal line to ground, as represented in Fig 2.63. The reactance of the coil to the second harmonic of the signal will be twice that at the fundamental frequency and oppose more effectively the flow of harmonic current. Likewise, the reactance of the capacitor to the harmonic will be half that to the fundamental, allowing the harmonic an easier current path away from the signal line toward ground. See the **RF and AF Filters** chapter for detailed information on filter theory and construction.

2.10 Impedance

When a circuit contains both resistance and reactance, the combined opposition to current is called *impedance*. Symbolized by the letter Z , impedance is a more general term than either resistance or reactance. Frequently, the term is used even for circuits containing only resistance or reactance. Qualifications such as “resistive impedance” are sometimes added to indicate that a circuit has only resistance, however.

The reactance and resistance comprising an impedance may be connected either in series or in parallel, as shown in **Fig 2.64**. In these circuits, the reactance is shown as a box to indicate that it may be either inductive or capacitive. In the series circuit at A, the current is the same in both elements, with (generally) different voltages appearing across the resistance and reactance. In the parallel circuit at B, the same voltage is applied to both elements, but different currents may flow in the two branches.

In a resistance, the current is in phase with the applied voltage, while in a reactance it is 90° out of phase with the voltage. Thus, the phase relationship between current and voltage in the circuit as a whole may be anything between zero and 90° , depending on the relative amounts of resistance and reactance.

As shown in Fig 2.56 in the preceding section, reactance is graphed on the vertical (Y) axis to record the phase difference between the voltage and the current. **Fig 2.65** adds resistance to the graph. Since the voltage is in phase with the current, resistance is recorded

on the horizontal axis, using the positive or right side of the scale.

2.10.1 Calculating Z From R and X in Series Circuits

Impedance is the complex combination of resistance and reactance. Since there is a 90° phase difference between resistance and reactance (whether inductive or capacitive), simply adding the two values does not correspond to what actually happens in a circuit and will not give the correct result. Therefore, expressions like “ $Z = R \pm X$ ” can be misleading, because they suggest simple addition. As a result, impedance is often expressed “ $Z = R \pm jX$.”

In pure mathematics, “ i ” indicates an imaginary number. Because i represents current in electronics, we use the letter “ j ” for the same mathematical operator, although there is nothing imaginary about what it represents in electronics. (References to explain imaginary numbers, rectangular coordinates, polar coordinates and how to work with them are provided in the “Radio Mathematics” article on this book’s CD-ROM.) With respect to resistance and reactance, the letter j is normally assigned to those figures on the vertical axis, 90° out of phase with the horizontal axis. The actual function of j is to indicate that calculating impedance from resistance and reactance requires *vector addition*.

A *vector* is a value with both magnitude and direction, such as velocity; “10 meters/sec to the north”. Impedance also has a “direction”

as described below. In vector addition, the result of combining two values with a 90° phase difference is a quantity different from the simple *algebraic addition* of the two values. The result will have a phase difference intermediate between 0° and 90° .

RECTANGULAR FORM OF IMPEDANCE

Because this form for impedances, $Z = R \pm jX$, can be plotted on a graph using rectangular coordinates, this is the *rectangular form* of impedance. The rectangular coordinate system in which one axis represents real numbers and the other axis imaginary numbers is called the *complex plane* and impedance with both real (R) and imaginary (X) components is called *complex impedance*. Unless specifically noted otherwise, assume that “impedance” means “complex impedance” and that both R and X may be present.

Consider **Fig 2.66**, a series circuit consisting of an inductive reactance and a resistance. As given, the inductive reactance is 100Ω and the resistance is 50Ω . Using *rectangular coordinates*, the impedance becomes

$$Z = R + jX \quad (78)$$

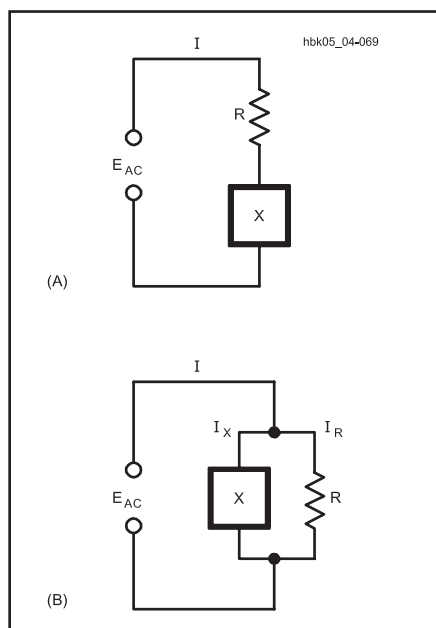

Fig 2.64 — Series and parallel circuits containing resistance and reactance.

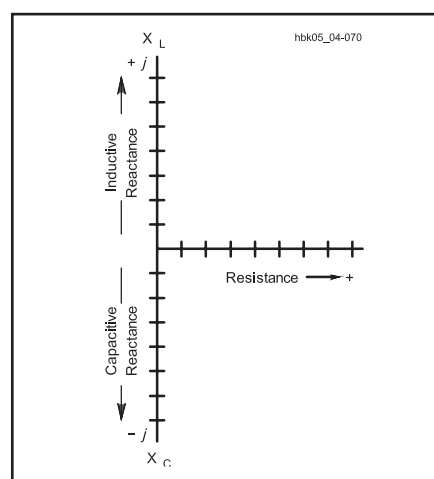

Fig 2.65 — The conventional method of charting impedances on a graph, using the vertical axis for reactance (the upward or “plus” direction for inductive reactance and the downward or “minus” direction for capacitive reactance), and using the horizontal axis for resistance.

Fig 2.66 — A series circuit consisting of an inductive reactance of 100Ω and a resistance of 50Ω . At B, the graph plots the resistance, reactance, and impedance.

where

Z = the impedance in ohms,
 R = the resistance in ohms, and
 X = the reactance in ohms.

In the present example,

$$Z = 50 + j100 \Omega$$

This point is located at the tip of the arrow drawn on the graph where the dashed lines cross.

POLAR FORM OF IMPEDANCE AND PHASE ANGLE

As the graph in Fig 2.66 shows, the impedance that results from combining R and X can also be represented by a line completing a right triangle whose sides are the resistance and reactance. The point at the end of the line — the complex impedance — can be described by how far it is from the origin of the graph where the axes cross (the *magnitude* of the impedance, $|Z|$) and the angle made by the line with the horizontal axis representing 0° (the *phase angle* of the impedance, θ). This is the *polar form* of impedance and it is written in the form

$$Z = |Z| \angle \theta \quad (79)$$

Occasionally, θ may be given in radians. The convention in this handbook is to use degrees unless specifically noted otherwise.

The length of the hypotenuse of the right triangle represents the magnitude of the impedance and can be calculated using the formula for calculating the hypotenuse of a right triangle, in which the square of the hypotenuse equals the sum of the squares of the two sides:

$$|Z| = \sqrt{R^2 + X^2} \quad (80)$$

In this example:

$$\begin{aligned} |Z| &= \sqrt{(50 \Omega)^2 + (100 \Omega)^2} \\ &= \sqrt{2500 \Omega^2 + 10,000 \Omega^2} \\ &= \sqrt{12,500 \Omega^2} = 112 \Omega \end{aligned}$$

The magnitude of the impedance that results from combining 50Ω of resistance with 100Ω of inductive reactance is 112Ω . From trigonometry, the tangent of the phase angle is the side opposite the angle (X) divided by the side adjacent to the angle (R), or

$$\tan \theta = \frac{X}{R} \quad (81)$$

where

X = the reactance, and
 R = the resistance.

Find the angle by taking the inverse tangent, or arctan:

$$\theta = \arctan \frac{X}{R} \quad (82)$$

Calculators sometimes label the inverse tangent key as “tan⁻¹”. Remember to be sure your calculator is set to use the right angular units, either degrees or radians.

In the example shown in Fig 2.66,

$$\theta = \arctan \frac{100 \Omega}{50 \Omega} = \arctan 2.0 = 63.4^\circ$$

Using the information just calculated, the complex impedance in polar form is:

$$Z = 112 \Omega \angle 63.4^\circ$$

This is stated verbally as “112 ohms at an angle of 63 point 4 degrees.”

POLAR TO RECTANGULAR CONVERSION

The expressions $R \pm jX$ and $|Z| \angle \theta$ both provide the same information, but in two different forms. The procedure just given permits conversion from rectangular coordinates into polar coordinates. The reverse procedure is also important. Fig 2.67 shows an imped-

ance composed of a capacitive reactance and a resistance. Since capacitive reactance appears as a negative value, the impedance will be at a negative phase angle, in this case, 12.0Ω at a phase angle of -42.0° or $Z = |12.0 \Omega| \angle -42.0^\circ$.

Remember that the impedance forms a triangle with the values of X and R from the rectangular coordinates. The reactance axis forms the side opposite the angle θ .

$$\sin \theta = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{X}{|Z|}$$

Solving this equation for reactance, we have:

$$X = |Z| \times \sin \theta \text{ (ohms)} \quad (83)$$

Likewise, the resistance forms the side adjacent to the angle.

$$\cos \theta = \frac{\text{side adjacent}}{\text{hypotenuse}} = \frac{R}{|Z|}$$

Solving for resistance, we have:

$$R = |Z| \times \cos \theta \text{ (ohms)} \quad (84)$$

Then from our example:

$$\begin{aligned} X &= 12.0 \Omega \times \sin (-42^\circ) \\ &= 12.0 \Omega \times -0.669 = -8.03 \Omega \end{aligned}$$

$$\begin{aligned} R &= 12.0 \Omega \times \cos (-42^\circ) \\ &= 12.0 \Omega \times 0.743 = 8.92 \Omega \end{aligned}$$

Since X is a negative value, it is plotted on the lower vertical axis, as shown in Fig 2.67, indicating capacitive reactance. In rectangular form, $Z = 8.92 \Omega - j8.03 \Omega$.

In performing impedance and related calculations with complex circuits, rectangular coordinates are most useful when formulas require the addition or subtraction of values. Polar notation is most useful for multiplying and dividing complex numbers. (See the section on “Radio Math” on this book’s CD-ROM for references dealing with the mathematics of complex numbers.)

All of the examples shown so far in this section presume a value of reactance that contributes to the circuit impedance. Reactance is a function of frequency, however, and many impedance calculations may begin with a value of capacitance or inductance and an operating frequency. In terms of these values, equation 80 can be expressed in either of two forms, depending on whether the reactance is inductive (equation 85) or capacitive (equation 86):

$$|Z| = \sqrt{R^2 + (2 \pi f L)^2} \quad (85)$$

$$|Z| = \sqrt{R^2 + \left(\frac{1}{2 \pi f C} \right)^2} \quad (86)$$

Fig 2.67 — A series circuit consisting of a capacitive reactance and a resistance: the impedance is given as 12.0Ω at a phase angle θ of -42 degrees. At B, the graph plots the resistance, reactance, and impedance.

Example: What is the impedance of a circuit like Fig 2.66 with a resistance of 100 Ω and a 7.00-μH inductor operating at a frequency of 7.00 MHz? Using equation 85,

$$\begin{aligned}
 |Z| &= \sqrt{R^2 + (2\pi fL)^2} \\
 &= \sqrt{(100\ \Omega)^2 + (2\pi \times 7.0 \times 10^{-6}\ \text{H} \times 7.0 \times 10^6\ \text{Hz})^2} \\
 &= \sqrt{10,000\ \Omega^2 + (308\ \Omega)^2} \\
 &= \sqrt{10,000\ \Omega^2 + 94,900\ \Omega^2} \\
 &= \sqrt{104,900\ \Omega^2} = 323.9\ \Omega
 \end{aligned}$$

Since 308 Ω is the value of inductive reactance of the 7.00-μH coil at 7.00 MHz, the phase angle calculation proceeds as given in the earlier example (equation 82):

$$\begin{aligned}
 \theta &= \arctan \frac{X}{R} = \arctan \left(\frac{308.0\ \Omega}{100.0\ \Omega} \right) \\
 &= \arctan (3.08) = 72.0^\circ
 \end{aligned}$$

Since the reactance is inductive, the phase angle is positive.

2.10.2 Calculating Z From R and X in Parallel Circuits

In a parallel circuit containing reactance and resistance, such as shown in Fig 2.68, calculation of the resultant impedance from the values of R and X does not proceed by direct combination as for series circuits. The general formula for parallel circuits is:

$$|Z| = \frac{RX}{\sqrt{R^2 + X^2}} \quad (87)$$

Fig 2.68 — A parallel circuit containing an inductive reactance of 30.0 Ω and a resistor of 40.0 Ω. No graph is given, since parallel impedances can not be manipulated graphically in the simple way of series impedances.

where the formula uses the absolute (unsigned) reactance value. The phase angle for the parallel circuit is given by:

$$\theta = \arctan \left(\frac{R}{X} \right) \quad (88)$$

The sign of θ has the same meaning in both series and parallel circuits: if the parallel reactance is capacitive, then θ is a negative angle, and if the parallel reactance is inductive, then θ is a positive angle.

Example: An inductor with a reactance of 30.0 Ω is in parallel with a resistor of 40.0 Ω. What is the resulting impedance and phase angle?

$$\begin{aligned}
 |Z| &= \frac{RX}{\sqrt{R^2 + X^2}} = \frac{30.0\ \Omega \times 40.0\ \Omega}{\sqrt{(30.0\ \Omega)^2 + (40.0\ \Omega)^2}} \\
 &= \frac{1200\ \Omega^2}{\sqrt{900\ \Omega^2 + 1600\ \Omega^2}} = \frac{1200\ \Omega^2}{\sqrt{2500\ \Omega^2}} \\
 &= \frac{1200\ \Omega^2}{50.0\ \Omega} = 24.0\ \Omega
 \end{aligned}$$

$$\theta = \arctan \left(\frac{R}{X} \right) = \arctan \left(\frac{40.0\ \Omega}{30.0\ \Omega} \right)$$

$$\theta = \arctan (1.33) = 53.1^\circ$$

Since the parallel reactance is inductive, the resultant angle is positive.

Example: A capacitor with a reactance of 16.0 Ω is in parallel with a resistor of 12.0 Ω. What is the resulting impedance and phase angle? (Remember that capacitive reactance is negative when used in calculations.)

$$\begin{aligned}
 |Z| &= \frac{RX}{\sqrt{R^2 + X^2}} = \frac{-16.0\ \Omega \times 12.0\ \Omega}{\sqrt{(16.0\ \Omega)^2 + (12.0\ \Omega)^2}} \\
 &= \frac{-192\ \Omega^2}{\sqrt{256\ \Omega^2 + 144\ \Omega^2}} = \frac{-192\ \Omega^2}{\sqrt{400\ \Omega^2}} \\
 &= \frac{-192\ \Omega^2}{20.0\ \Omega} = -9.60\ \Omega
 \end{aligned}$$

$$\theta = \arctan \left(\frac{R}{X} \right) = \arctan \left(\frac{12.0\ \Omega}{-16.0\ \Omega} \right)$$

$$\theta = \arctan (-0.750) = -36.9^\circ$$

Because the parallel reactance is capacitive and the reactance negative, the resultant phase angle is negative.

2.10.3 Admittance

Just as the inverse of resistance is conductance (G) and the inverse of reactance is susceptance (B), so, too, impedance has an inverse: admittance (Y), measured in

siemens (S). Thus,

$$Y = \frac{1}{Z} \quad (89)$$

Since resistance, reactance and impedance are inversely proportional to the current (Z = E / I), conductance, susceptance and admittance are directly proportional to current. That is,

$$Y = \frac{I}{E} \quad (90)$$

Admittance can be expressed in rectangular and polar forms, just like impedance,

$$Y = G \pm jB = |Y| \angle \theta \quad (91)$$

The phase angle for admittance has the same sign convention as for impedance; if the susceptance component is inductive, the phase angle is positive, and if the susceptive component is capacitive, the phase angle is negative.

One handy use for admittance is in simplifying parallel circuit impedance calculations. Similarly to the rules stated previously for combining conductance, the admittance of a parallel combination of reactance and resistance is the vector addition of susceptance and conductance. In other words, for parallel circuits:

$$|Y| = \sqrt{G^2 + B^2} \quad (92)$$

where

|Y| = magnitude of the admittance in siemens,

G = conductance or 1 / R in siemens, and B = susceptance or 1 / X in siemens.

Example: An inductor with a reactance of 30.0 Ω is in parallel with a resistor of 40.0 Ω. What is the resulting impedance and phase angle? The susceptance is 1 / 30.0 Ω = 0.0333 S and the conductance is 1 / 40.0 Ω = 0.0250 S.

$$Y = \sqrt{(0.0333\ \text{S})^2 + (0.0250\ \text{S})^2}$$

$$Y = \sqrt{0.00173\ \text{S}^2} = 0.0417\ \text{S}$$

$$Z = \frac{1}{Y} = \frac{1}{0.0417\ \text{S}} = 24.0\ \Omega$$

The phase angle in terms of conductance and susceptance is:

$$\theta = \arctan \left(\frac{B}{G} \right) \quad (93)$$

In this example,

$$\theta = \arctan \left(\frac{0.0333\ \text{S}}{0.0250\ \text{S}} \right) = \arctan (1.33) = 53.1^\circ$$

Again, since the reactive component is in-

ductive, the phase angle is positive. For a capacitively reactive parallel circuit, the phase angle would have been negative. Compare these results with the example calculation of the impedance for the same circuit earlier in the section.

Conversion between resistance, reactance and impedance and conductance, susceptance and admittance is very useful in working with complex circuits and in impedance matching of antennas and transmission lines. There are many on-line calculators that can perform these operations and many programmable calculators and suites of mathematical computer software have these functions built-in. Knowing when and how to use them, however, demands some understanding of the fundamental strategies shown here.

2.10.4 More than Two Elements in Series or Parallel

When a circuit contains several resistances or several reactances in series, simplify the circuit before attempting to calculate the impedance. Resistances in series add, just as in a purely resistive circuit. Series reactances of the same kind — that is, all capacitive or all inductive — also add, just as in a purely reactive circuit. The goal is to produce a single value of resistance and a single value of reactance that can be used in the impedance calculation.

Fig 2.69 illustrates a more difficult case in which a circuit contains two different reactive elements in series, along with a series resistance. The series combination of X_C and X_L reduce to a single value using the same rules of combination discussed in the section on purely reactive components. As **Fig 2.69B** demonstrates, the resultant reactance is the difference between the two series reactances.

For parallel circuits with multiple resistances or multiple reactances of the same type, use the rules of parallel combination to reduce the resistive and reactive components to single elements. Where two or more reactive components of different types appear in the same circuit, they can be combined using formulas shown earlier for pure reactances. As **Fig 2.70** suggests, however, they can also be combined as susceptances. Parallel susceptances of different types add, with attention to their differing signs. The resulting single susceptance can then be combined with the conductance to arrive at the overall circuit admittance whose inverse is the final circuit impedance.

2.10.5 Equivalent Series and Parallel Circuits

The two circuits shown in **Fig 2.64** are equivalent if the same current flows when a given voltage of the same frequency is ap-

plied, and if the phase angle between voltage and current is the same in both cases. It is possible, in fact, to transform any given series circuit into an equivalent parallel circuit, and vice versa.

A series RX circuit can be converted into its parallel equivalent by means of the formulas:

$$R_P = \frac{R_S^2 + X_S^2}{R_S} \quad (94)$$

$$X_P = \frac{R_S^2 + X_S^2}{X_S} \quad (95)$$

where the subscripts P and S represent

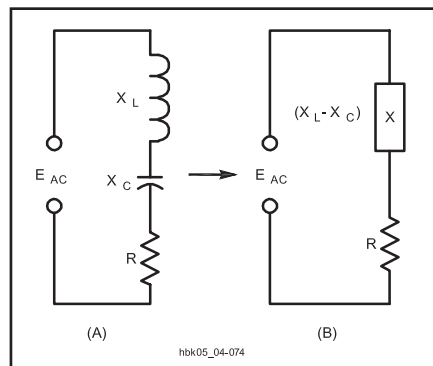

Fig 2.69 — A series impedance containing mixed capacitive and inductive reactances can be reduced to a single reactance plus resistance by combining the reactances algebraically.

Fig 2.70 — A parallel impedance containing mixed capacitive and inductive reactances can be reduced to a single reactance plus resistance using formulas shown earlier in the chapter. By converting reactances to susceptances, as shown in A, you can combine the susceptances algebraically into a single susceptance, as shown in B.

the parallel- and series-equivalent values, respectively. If the parallel values are known, the equivalent series circuit can be found from:

$$R_S = \frac{R_P X_P^2}{R_P^2 + X_P^2} \quad (96)$$

and

$$X_S = \frac{R_P^2 X_P}{R_P^2 + X_P^2} \quad (97)$$

Example: Let the series circuit in **Fig 2.64** have a series reactance of -50.0Ω (indicating a capacitive reactance) and a resistance of 50.0Ω . What are the values of the equivalent parallel circuit?

$$\begin{aligned} R_P &= \frac{R_S^2 + X_S^2}{R_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{50.0 \Omega} \\ &= \frac{2500 \Omega^2 + 2500 \Omega^2}{50.0 \Omega} = \frac{5000 \Omega^2}{50 \Omega} = 100 \Omega \\ X_P &= \frac{R_S^2 + X_S^2}{X_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{-50.0 \Omega} \\ &= \frac{2500 \Omega^2 + 2500 \Omega^2}{-50.0 \Omega} = \frac{5000 \Omega^2}{-50 \Omega} = -100 \Omega \end{aligned}$$

A capacitive reactance of 100Ω in parallel with a resistance of 100Ω is the equivalent circuit to the series circuit.

2.10.6 Ohm's Law for Impedance

Ohm's Law applies to circuits containing impedance just as readily as to circuits having resistance or reactance only. The formulas are:

$$E = IZ \quad (98)$$

$$I = \frac{E}{Z} \quad (99)$$

$$Z = \frac{E}{I} \quad (100)$$

where

- E = voltage in volts,
- I = current in amperes, and
- Z = impedance in ohms.

Z must now be understood to be a complex number, consisting of resistive and reactive components. If Z is complex, then so are E and I, with a magnitude and phase angle. The rules of complex mathematics are then applied and the variables are written in boldface type as \mathbf{Z} , \mathbf{E} , and \mathbf{I} , or an arrow is added above them to indicate that they are complex, such as,

$$\vec{E} = \vec{I} \vec{Z}$$

Fig 2.71 — A series circuit consisting of an inductive reactance of $100\ \Omega$ and a resistance of $75.0\ \Omega$. Also shown is the applied voltage, voltage drops across the circuit elements, and the current.

If only the magnitude of impedance, voltage, and currents are important, however, then the magnitudes of the three variables can be combined in the familiar ways without regard to the phase angle. In this case E and I are assumed to be RMS values (or some other steady-state value such as peak, peak-to-peak, or average). **Fig 2.71** shows a simple circuit consisting of a resistance of $75.0\ \Omega$ and a reactance of $100\ \Omega$ in series. From the series-impedance formula previously given, the impedance is

$$\begin{aligned} Z &= \sqrt{R^2 + X_L^2} = \sqrt{(75.0\ \Omega)^2 + (100\ \Omega)^2} \\ &= \sqrt{5630\ \Omega^2 + 10,000\ \Omega^2} \\ &= \sqrt{15,600\ \Omega^2} = 125\ \Omega \end{aligned}$$

If the applied voltage is $250\ \text{V}$, then

$$I = \frac{E}{Z} = \frac{250\ \text{V}}{125\ \Omega} = 2.0\ \text{A}$$

This current flows through both the resistance and reactance, so the voltage drops are:

$$E_R = I R = 2.0\ \text{A} \times 75.0\ \Omega = 150\ \text{V}$$

$$E_{X_L} = I X_L = 2.0\ \text{A} \times 100\ \Omega = 200\ \text{V}$$

Illustrating one problem of working only with RMS values, the simple arithmetical sum of these two drops, $350\ \text{V}$, is greater than the applied voltage because the two voltages are 90° out of phase. When phase is taken into account,

$$\begin{aligned} E &= \sqrt{(150\ \text{V})^2 + (200\ \text{V})^2} \\ &= \sqrt{22,500\ \text{V}^2 + 40,000\ \text{V}^2} \\ &= \sqrt{62,500\ \text{V}^2} = 250\ \text{V} \end{aligned}$$

2.10.7 Reactive Power and Power Factor

Although purely reactive circuits, whether simple or complex, show a measurable ac voltage and current, we cannot simply multiply the two together to arrive at power. Power is the rate at which energy is consumed by a circuit, and purely reactive circuits do not consume energy. The charge placed on a capacitor during part of an ac cycle is returned to the circuit during the next part of a cycle. Likewise, the energy stored in the magnetic field of an inductor returns to the circuit as the field collapses later in the ac cycle. A reactive circuit simply cycles and recycles energy into and out of the reactive components. If a purely reactive circuit were possible in reality, it would consume no energy at all.

In reactive circuits, circulation of energy accounts for seemingly odd phenomena. For example, in a series circuit with capacitance and inductance, the voltages across the components may exceed the supply voltage. That condition can exist because, while energy is being stored by the inductor, the capacitor is returning energy to the circuit from its previously charged state, and vice versa. In a parallel circuit with inductive and capacitive branches, the current circulating through the components may exceed the current drawn from the source. Again, the phenomenon occurs because the inductor's collapsing magnetic field supplies current to the capacitor, and the discharging capacitor provides current to the inductor.

To distinguish between the non-dissipated energy circulating in a purely reactive circuit and the dissipated or *real power* in a resistive circuit, the unit of *reactive power* is called the *volt-ampere reactive*, or VAR. The term watt is not used and sometimes reactive power is called “wattless” power. VAR has only limited use in radio circuits. Formulas similar to those for resistive power are used to calculate VAR:

$$\text{VAR} = I \times E \quad (101)$$

$$\text{VAR} = I^2 \times X \quad (102)$$

$$\text{VAR} = \frac{E^2}{X} \quad (103)$$

where E and I are RMS values of voltage and current.

Real, or dissipated, power is measured in watts. *Apparent power* is the product of the voltage across and the current through an impedance. To distinguish apparent power from real power, apparent power is measured in *volt-amperes (VA)*.

In the circuit of Fig 2.71, an applied voltage of $250\ \text{V}$ results in a current of $2.00\ \text{A}$, giving an apparent power of $250\ \text{V} \times 2.00\ \text{A} = 500\ \text{W}$. Only the resistance actually consumes power, however. The real power dissipated by the resistance is:

$$E = I^2 R = (2.0\ \text{A})^2 \times 75.0\ \Omega = 300\ \text{W}$$

and the reactive power is:

$$\text{VAR} = I^2 \times X_L = (2.0\ \text{A})^2 \times 100\ \Omega = 400\ \text{VA}$$

The ratio of real power to the apparent power is called the circuit's *power factor (PF)*.

$$\text{PF} = \frac{P_{\text{consumed}}}{P_{\text{apparent}}} = \frac{R}{Z} \quad (104)$$

Power factor is frequently expressed as a percentage. The power factor of a purely resistive circuit is 100% or 1, while the power factor of a pure reactance is zero. In the example of Fig 2.71 the power factor would be $300\ \text{W} / 500\ \text{W} = 0.600$ or 60%.

Apparent power has no direct relationship to the power actually dissipated unless the power factor of the circuit is known.

$$P = \text{Apparent Power} \times \text{power factor} \quad (105)$$

An equivalent definition of power factor is:

$$\text{PF} = \cos \theta \quad (106)$$

AC Component Summary

	Resistor	Capacitor	Inductor
Basic Unit	ohm (Ω)	farad (F)	henry (H)
Units Commonly Used		microfarads (μF) picofarads (pF)	millihenrys (mH) microhenrys (μH)
Time constant	(None)	RC	L/R
Voltage-Current Phase	In phase	Current leads voltage Voltage lags current	Voltage leads current Current lags voltage
Resistance or Reactance	Resistance	$X_C = 1 / 2\pi fC$	$X_L = 2\pi fL$
Change with increasing frequency	No	Reactance decreases	Reactance increases
Q of circuit	Not defined	X_C / R	X_L / R

where θ is the phase angle of the circuit impedance.

Since the phase angle in the example equals:

$$\theta = \arctan \left(\frac{X}{R} \right) = \arctan \left(\frac{100 \Omega}{75.0 \Omega} \right)$$

$$\theta = \arctan (1.33) = 53.1^\circ$$

and the power factor is:

$$\text{PF} = \cos 53.1^\circ = 0.600$$

as the earlier calculation confirms.

Since power factor is always rendered as a positive number, the value must be followed by the words “leading” or “lagging” to identify the phase of the voltage with respect to

the current. Specifying the numerical power factor is not always sufficient. For example, many dc-to-ac power inverters can safely operate loads having a large net reactance of one sign but only a small reactance of the opposite sign. Hence, the final calculation of the power factor in this example would be reported as “0.600, leading.”

2.11 Quality Factor (Q) of Components

Components that store energy, such as capacitors and inductors, may be compared in terms of *quality factor* or *Q factor*, abbreviated *Q*. The concept of *Q* originated in 1914 (then dubbed *K*) and first appeared in print in 1923 when Kenneth S. Johnson used it to represent the ratio of reactance to resistance as a “figure of merit” for inductors in US patent 1,628,983. For a series or parallel representation of a reactive circuit element:

$$Q = \frac{X_S}{R_S} = \frac{R_P}{X_P} \quad (107)$$

where for series-connected reactance and its series loss resistance (such as an inductor)

Q = quality factor (no units),

X_S = series reactance of the component (in ohms), and

R_S = the sum of all series resistances associated with the energy losses in the component (in ohms).

For a parallel connected reactance and its parallel loss resistance (such as a capacitor)

Q = quality factor (no units),

X_P = parallel-connected reactance of the component (in ohms), and

R_P = the total parallel resistance associated with the energy losses in the component (in ohms).

Several exactly equivalent formulas for Q may be seen in **Table 2.10**. In Table 2.10, equation [a] most naturally represents the Q of an inductor, while equation [b] is useful for a capacitor. Both representations are equivalent to equation [c] which relates the energy storage to energy losses in inductors and capacitors. Note that in a series circuit representation, the series resistance is proportional to energy loss, and the series reactance is proportional to stored energy. In a parallel circuit, however, the reciprocal of the resistance is proportional to the lost energy and the reciprocal of the reactance is proportional to the stored energy. The Q of a tuned circuit may be found by measuring the upper and lower frequencies where the resistance

Table 2.10

Equivalent Formulas for Expressing Q and Their Uses

[a]	$Q = \frac{\text{Series Reactance}}{\text{Series Resistance}}$	Johnson's historical definition of Q for inductors, used for series circuits
[b]	$Q = \frac{\text{Parallel Resistance}}{\text{Parallel Reactance}}$	Parallel equivalent circuit definition of Q , useful for capacitors.
[c]	$Q = \frac{2\pi \times \text{Stored energy}}{\text{Energy lost in one cycle}}$	Fundamental energy definition, useful with antennas, reactive components, and mechanical systems.
[d]	$Q = \frac{\sqrt{f_U f_L}}{f_U - f_L} = \frac{\text{Frequency}}{\text{Bandwidth}}$	Bandwidth formula for simple resonant circuits. Impedance $Z = R + jX$, and f_U is the upper frequency where $R = X$, and f_L is the lower frequency where $R = -X$, and $f_U - f_L$ represents the -3 dB bandwidth.

equals the magnitude of the reactance, and applying equation [d]. The geometrical mean frequency is $f = \sqrt{f_U f_L}$ and may be replaced by the center frequency for high- Q circuits. In circuits having several reactive components, such as the tuned circuits in Fig 2.84, the circuit Q is the parallel combination of the individual Q factors. For example:

$$Q = 1 / \left(\frac{1}{Q_C} + \frac{1}{Q_L} \right)$$

where Q_C is the capacitor Q (sometimes specified by a manufacturer) and the inductor Q is Q_L .

The Q of capacitors is ordinarily high. Good quality ceramic capacitors and mica capacitors may have Q values of 1200 or more. Microwave capacitors can have poor Q values — 10 or less at 10 GHz and higher frequencies because X_C will be low. Capacitors are subject to predominantly dielectric losses which are modeled as a parallel loss resistance across the capacitive reactance. Capacitors also have a series loss resistance associated with the conductor leads and capacitor plates, but this loss is often small enough to ignore.

Inductors are subject to several types of

electrical energy losses such as wire resistance (including skin effect) and core losses. All electrical conductors have some resistance through which electrical energy is lost as heat. Wire conductors suffer additional ac losses because alternating current tends to flow on the conductor surface due to the skin effect discussed in the chapter on **RF Techniques**. If the inductor's core is iron, ferrite or brass, the core will introduce additional losses of energy. Note that core losses for inductors are modeled as a resistor in parallel with the inductor (analogous to capacitor dielectric losses). The specific details of these losses are discussed in connection with each type of core material.

The sum of all core losses may be depicted by showing an equivalent series connected resistor with the inductor (as in Figs 2.52 and 2.53), although there is no separate component represented by the resistor symbol. As a result of inherent energy losses, inductor Q rarely approaches capacitor Q in a circuit where both components work together. Although many circuits call for the highest Q inductor obtainable, other circuits may call for a specific Q , even a very low one.

2.12 Practical Inductors

Various facets of radio circuits make use of inductors ranging from the tiny up to the massive. Small values of inductance, such as those inductors in **Fig 2.72A**, serve mostly in RF circuits. They may be self-supporting, air-core or air-wound inductors or the winding may be supported by nonmagnetic strips or a form. Phenolic, certain plastics and ceramics are the most common *coil forms* for air-core inductors. These inductors range in value from a few hundred μH for medium- and high-frequency circuits down to tenths of a μH at VHF and UHF.

The most common inductor in small-signal RF circuits is the *encapsulated inductor*. These components look a lot like carbon-composition or film resistors and are often marked with colored paint stripes to indicate value. (The chapter **Component Data and References** contains information on inductor color codes and marking schemes.) These inductors have values from less than 1 μH to a few mH. They cannot handle much current without saturating or over-heating.

It is possible to make solenoid inductors variable by inserting a moveable *slug* in the center of the inductor. (Slug-tuned inductors normally have a ceramic, plastic or phenolic insulating form between the conductive slug and the inductor winding.) If the slug material is magnetic, such as powdered iron, the inductance increases as the slug is moved into the center of the inductor. If the slug is brass or some other nonmagnetic material,

inserting the slug will reduce the inductor's inductance.

An alternative to air-core inductors for RF work are *toroidal* inductors (or *toroids*) wound on powdered-iron or ferrite cores. The availability of many types and sizes of powdered-iron cores has made these inductors popular for low-power fixed-value service. The toroidal shape concentrates the inductor's field nearly completely inside the inductor, eliminating the need in many cases for other forms of shielding to limit the interaction of the inductor's magnetic field with the fields of other inductors. (Ferrite core materials are discussed here and in the chapter on **RF Techniques**.)

Fig 2.72B shows samples of inductors in the millihenry (mH) range. Among these inductors are multi-section RF chokes designed to block RF currents from passing beyond them to other parts of circuits. Low-frequency radio work may also use inductors in this range of values, sometimes wound with *litz wire*. Litz wire is a special version of stranded wire, with each strand insulated from the others, and is used to minimize losses associated with skin effect.

For audio filters, toroidal inductors with values up to 100 mH are useful. Resembling powdered-iron-core RF toroids, these inductors are wound on ferrite or molybdenum-permalloy cores having much higher permeabilities.

Audio and power-supply inductors appear

in Fig 2.72C. Lower values of these iron-core inductors, in the range of a few henrys, are useful as audio-frequency chokes. Larger values up to about 20 H may be found in power supplies, as choke filters, to suppress 120-Hz ripple. Although some of these inductors are open frame, most have iron covers to confine the powerful magnetic fields they produce.

Although builders and experimenters rarely construct their own capacitors, inductor fabrication is common. In fact, it is often necessary, since commercially available units may be unavailable or expensive. Even if available, they may consist of inductor stock to be trimmed to the required value. Core materials and wire for winding both solenoid and toroidal inductors are readily available. The following information includes fundamental formulas and design examples for calculating practical inductors, along with additional data on the theoretical limits in the use of some materials.

2.12.1 Air-Core Inductors

Many circuits require air-core inductors using just one layer of wire. The approximate inductance of a single-layer air-core inductor may be calculated from the simplified formula:

$$L (\mu\text{H}) = \frac{d^2 n^2}{18d + 40\ell} \quad (108)$$

(A)

(B)

(C)

Fig 2.72 — Part A shows small-value air-wound inductors. Part B shows some inductors with values in the range of a few millihenrys and C shows a large inductor such as might be used in audio circuits or as power-supply chokes. The $\frac{1}{4}$ -inch-ruled graph paper background provides a size comparison.

where

- L = inductance in microhenrys,
- d = inductor diameter in inches (from wire center to wire center),
- ℓ = inductor length in inches, and
- n = number of turns.

The notation is illustrated in **Fig 2.73**. This formula is a close approximation for inductors having a length equal to or greater than 0.4d. (Note: Inductance varies as the square of the turns. If the number of turns is doubled, the inductance is quadrupled. This relationship

Fig 2.73 — Coil dimensions used in the inductance formula for air-core inductors.

is inherent in the equation, but is often overlooked. For example, to double the inductance, add additional turns equal to 1.4 times the original number of turns, or 40% more turns.)

Example: What is the inductance of an inductor if the inductor has 48 turns wound at 32 turns per inch and a diameter of $\frac{3}{4}$ inch? In this case, $d = 0.75$, $\ell = 48/32 = 1.5$ and $n = 48$.

$$L (\mu\text{H}) = \frac{0.75^2 \times 48^2}{(18 \times 0.75) + (40 \times 1.5)}$$

$$= \frac{1300}{74} = 18 \mu\text{H}$$

To calculate the number of turns of a single-layer inductor for a required value of inductance, the formula becomes:

$$n = \frac{\sqrt{L(18d + 40\ell)}}{d} \quad (109)$$

Example: Suppose an inductance of 10.0 μH is required. The form on which the inductor is to be wound has a diameter of one inch and is long enough to accommodate an inductor of $\frac{1}{4}$ inches. Then $d = 1.00$ inch, $\ell = 1.25$ inches and $L = 10.0$. Substituting:

$$n = \frac{\sqrt{10.0[(18 \times 1.0) + (40 \times 1.25)]}}{1}$$

$$= \sqrt{680} = 26.1 \text{ turns}$$

A 26-turn inductor would be close enough in practical work. Since the inductor will be 1.25 inches long, the number of turns per inch will be $26.1 / 1.25 = 20.9$. Consulting the wire table in the **Component Data and References** chapter, we find that #17 AWG enameled wire (or anything smaller) can be used. The proper inductance is obtained by winding the required number of turns on the form and then adjusting the spacing between the turns to make a uniformly spaced inductor 1.25 inches long.

Most inductance formulas lose accuracy when applied to small inductors (such as are used in VHF work and in low-pass filters built for reducing harmonic interference to televisions) because the conductor thickness is no longer negligible in comparison with the size of the inductor. **Fig 2.74** shows the measured inductance of VHF inductors and may be used as a basis for circuit design. Two curves are given; curve A is for inductors wound to an inside diameter of $\frac{1}{2}$ inch; curve B is for inductors of $\frac{3}{4}$ -inch inside diameter. In both curves, the wire size is #12 AWG and the winding pitch is eight turns to the inch ($\frac{1}{8}$ -inch turn spacing). The inductance values include leads $\frac{1}{2}$ -inch long.

Machine-wound inductors with the preset diameters and turns per inch are available in many radio stores, under the trade names of B&W Miniductor and Airdux. Information on using such coil stock is provided in the **Component Data and References** chapter to simplify the process of designing high-quality inductors for most HF applications.

Forming a wire into a solenoid increases its inductance, but also introduces distributed capacitance. Since each turn is at a slightly different ac potential, each pair of turns effectively forms a capacitor in parallel with part of the inductor. (See the chapter on **RF Techniques** for information on the effects of these and other factors that affect the behavior of the "ideal" inductors discussed in this chapter.)

Moreover, the Q of air-core inductors is, in part, a function of the inductor shape, specifically its ratio of length to diameter. Q tends to be highest when these dimensions are nearly equal. With wire properly sized to the current carried by the inductor, and with high-caliber construction, air-core inductors can achieve Q above 200.

For a large collection of formulas useful in constructing air-core inductors of many configurations, see the "Circuit Elements" section in Terman's *Radio Engineers' Handbook*.

Fig 2.74 — Measured inductance of coils wound with #12 bare wire, eight turns to the inch. The values include half-inch leads.

2.12.2 Straight-Wire Inductance

At low frequencies the inductance of a straight, round, nonmagnetic wire in free space is given by:

$$L = 0.00508 b \left\{ \left[\ln \left(\frac{2b}{a} \right) \right] - 0.75 \right\} \quad (110)$$

where

- L = inductance in μH ,
- a = wire radius in inches,
- b = wire length in inches, and
- ln = natural logarithm = $2.303 \times$ common logarithm (base 10).

If the dimensions are expressed in millimeters instead of inches, the equation may still be used, except replace the 0.00508 value with 0.0002.

Skin effect reduces the inductance at VHF and above. As the frequency approaches infinity, the 0.75 constant within the brackets approaches unity. As a practical matter, skin effect will not reduce the inductance by more than a few percent.

Example: What is the inductance of a wire that is 0.1575 inch in diameter and 3.9370 inches long? For the calculations, $a = 0.0787$ inch (radius) and $b = 3.9370$ inch.

$$\begin{aligned} L &= 0.00508 b \left\{ \left[\ln \left(\frac{2b}{a} \right) \right] - 0.75 \right\} \\ &= 0.00508 (3.9370) \times \\ &\quad \left\{ \left[\ln \left(\frac{2 \times 3.9370}{0.0787} \right) \right] - 0.75 \right\} \\ &= 0.020 \times [\ln(100) - 0.75] \\ &= 0.020 \times (4.60 - 0.75) \\ &= 0.020 \times 3.85 = 0.077 \mu\text{H} \end{aligned}$$

Fig 2.75 is a graph of the inductance for wires of various radii as a function of length.

A VHF or UHF tank circuit can be fabricated from a wire parallel to a ground plane, with one end grounded. A formula for the

Fig 2.75 — Inductance of various conductor sizes as straight wires.

inductance of such an arrangement is given in Fig 2.76.

Example: What is the inductance of a wire 3.9370 inches long and 0.0787 inch in radius, suspended 1.5748 inch above a ground plane? (The inductance is measured between the free end and the ground plane, and the formula includes the inductance of the 1.5748-inch grounding link.) To demonstrate the use of the formula in Fig 2.76, begin by evaluating these quantities:

$$\begin{aligned} b + \sqrt{b^2 + a^2} &= 3.9370 + \sqrt{3.9370^2 + 0.0787^2} \\ &= 3.9370 + 3.94 = 7.88 \end{aligned}$$

$$\begin{aligned} b + \sqrt{b^2 + 4(h^2)} &= 3.9370 + \sqrt{3.9370^2 + 4(1.5748^2)} \\ &= 3.9370 + \sqrt{15.50 + 4(2.480)} \\ &= 3.9370 + \sqrt{15.50 + 9.920} \\ &= 3.9370 + 5.0418 = 8.9788 \end{aligned}$$

$$\frac{2h}{a} = \frac{2 \times 1.5748}{0.0787} = 40.0$$

$$\frac{b}{a} = \frac{3.9370}{0.0787} = 0.98425$$

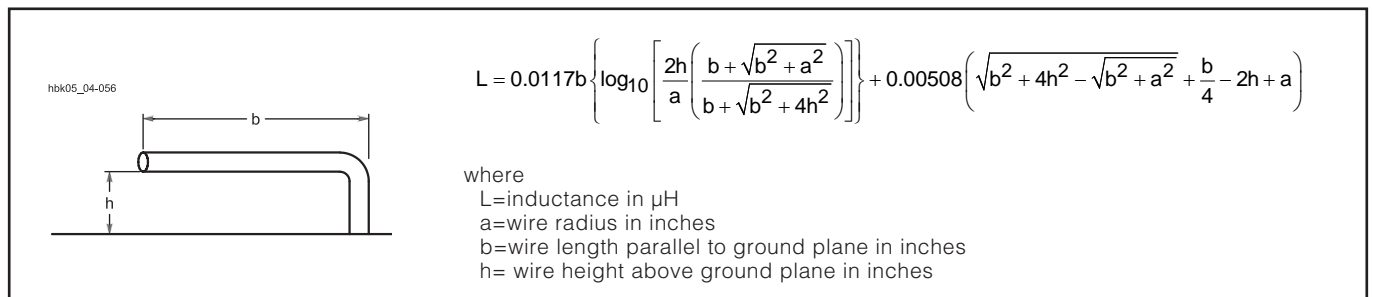

Fig 2.76 — Equation for determining the inductance of a wire parallel to a ground plane, with one end grounded. If the dimensions are in millimeters, the numerical coefficients become 0.0004605 for the first term and 0.0002 for the second term.

Substituting these values into the formula yields:

$$L = 0.0117 \times 3.9370$$

$$\left\{ \log_{10} \left[40.0 \times \left(\frac{7.88}{8.9788} \right) \right] \right\}$$

$$+ 0.00508 \times (5.0418 - 3.94 + 0.98425 - 3.1496 + 0.0787)$$

$$L = 0.0662 \mu\text{H}$$

Another conductor configuration that is frequently used is a flat strip over a ground plane. This arrangement has lower skin-effect loss at high frequencies than round wire because it has a higher surface-area to volume ratio. The inductance of such a strip can be found from the formula in Fig 2.77.

2.12.3 Iron-Core Inductors

If the permeability of an iron core in an inductor is 800, then the inductance of any given air-wound inductor is increased 800 times by inserting the iron core. The inductance will be proportional to the magnetic flux through the inductor, other things being equal. The inductance of an iron-core inductor is highly dependent on the current flowing in the inductor, in contrast to an air-core inductor, where the inductance is independent of current because air does not saturate.

Iron-core inductors such as the one sketched in Fig 2.49 are used chiefly in power-supply equipment. They usually have direct current flowing through the winding, and any variation in inductance with current is usually undesirable. Inductance variations may be overcome by keeping the flux density below the saturation point of the iron. Opening the core so there is a small air gap will achieve this goal, as discussed in the earlier section on inductors. The reluctance or magnetic resistance introduced by such a gap is very large compared with that of the iron, even though the gap is only a small fraction of an inch. Therefore, the gap — rather than the iron — controls the flux density. Air gaps in iron cores reduce the inductance, but they hold the value practically constant regardless of the current magnitude.

When alternating current flows through an inductor wound on an iron core, a voltage is induced. Since iron is a conductor, eddy currents also flow in the core as discussed earlier. Eddy currents represent lost power because they flow through the resistance of the iron and generate heat. Losses caused by eddy currents can be reduced by laminating the core (cutting the core into thin strips). These strips or laminations are then insulated from each other by painting them with some insulating material such as varnish or shellac. Eddy current losses add to hysteresis losses, which are

Fig 2.77 — Equation for determining the inductance of a flat strip inductor.

also significant in iron-core inductors.

Eddy-current and hysteresis losses in iron increase rapidly as the frequency of the alternating current increases. For this reason, ordinary iron cores can be used only at power-line and audio frequencies — up to approximately 15000 Hz. Even then, a very good grade of iron or steel is necessary for the core to perform well at the higher audio frequencies. Laminated iron cores become completely useless at radio frequencies because of eddy current and hysteresis losses.

2.12.4 Slug-Tuned Inductors

For RF work, the losses in iron cores can be reduced to a more useful level by grinding the iron into a powder and then mixing it with a binder of insulating material in such a way that the individual iron particles are insulated from each other. Using this approach, cores can be made that function satisfactorily even into the VHF range. Because a large part of the magnetic path is through a nonmagnetic material (the binder), the permeability of the powdered iron core is low compared with the values for solid iron cores used at power-line frequencies.

The slug is usually shaped in the form of a cylinder that fits inside the insulating form on which the inductor is wound. Despite the fact that the major portion of the magnetic path for the flux is in air, the slug is quite effective in increasing the inductor inductance. By pushing (or screwing) the slug in and out

of the inductor, the inductance can be varied over a considerable range.

2.12.5 Powdered-Iron Toroidal Inductors

For fixed-value inductors intended for use at HF and VHF, the powdered-iron toroidal core has become the standard in low- and medium-power circuits. Fig 2.78 shows the general outlines of a toroidal inductor on a magnetic core.

Manufacturers offer a wide variety of core materials, or *mixes*, to create conductor cores that will perform over a desired frequency range with a reasonable permeability. Permeabilities for powdered-iron cores fall in the range of 3 to 35 for various mixes. In addition, core sizes are available in the range of 0.125-inch outside diameter (OD) up to 1.06-inch OD, with larger sizes to 5-inch OD available in certain mixes. The range of sizes permits the builder to construct single-layer inductors for almost any value using wire sized to meet the circuit current demands.

The use of powdered iron in a binder reduces core losses usually associated with iron, while the permeability of the core permits a reduction in the wire length and associated resistance in forming an inductor of a given inductance. Therefore, powdered-iron-core toroidal inductors can achieve Q well above 100, often approaching or exceeding 200 within the frequency range specified for a given core. Moreover, these inductors are considered *self-shielding* since most of the magnetic flux is within the core, a fact that simplifies circuit design and construction.

Each powdered-iron core has an *inductance factor* or *index* A_L determined by the manufacturer. Amidon Corp. is the most common supplier of cores for amateurs (see the Component Data and References chapter) and specifies A_L in μH per 100 turns-squared. The following calculations are based on the Amidon specification. Other manufacturers specify A_L in μH per turn-squared.

To calculate the inductance of a powdered-iron toroidal inductor using the Amidon convention for A_L when the number of turns and the core material are known:

$$L = \frac{A_L \times N^2}{10,000} \quad (111)$$

where

L = the inductance in μH ,

A_L = the inductance index in μH per 100 turns-squared, and

N = the number of turns.

The builder must then ensure that the core is capable of holding the calculated number of turns of wire of the required wire size.

Example: What is the inductance of a 60-turn inductor on a core with an A_L of 55? This

Fig 2.78 — A typical toroidal inductor wound on a powdered-iron or ferrite core. Some key physical dimensions are noted. Equally important are the core material, its permeability, its intended range of operating frequencies, and its A_L value. This is an 11-turn toroid.

A_L value was selected from manufacturer's information about a 0.8-inch OD core with an initial permeability of 10. This particular core is intended for use in the range of 2 to 30 MHz. See the **Component Data and References** chapter for more detailed data on the range of available cores.

$$L = \frac{A_L \times N^2}{10,000} = \frac{55 \times 60^2}{10,000}$$

$$= \frac{198,000}{10,000} = 19.8 \mu\text{H}$$

To calculate the number of turns needed for a particular inductance, use the formula:

$$N = 100 \sqrt{\frac{L}{A_L}} \quad (112)$$

Example: How many turns are needed for a 12.0- μH inductor if the A_L for the selected core is 49?

$$N = 100 \sqrt{\frac{L}{A_L}} = 100 \sqrt{\frac{12.0}{49}}$$

$$N = 100 \sqrt{0.245} = 100 \times 0.495 = 49.5 \text{ turns}$$

If the value is critical, experimenting with 49-turn and 50-turn inductors is in order, especially since core characteristics may vary slightly from batch to batch. Count turns by each pass of the wire through the center of the core. (A straight wire through a toroidal

core amounts to a one-turn inductor.) Fine adjustment of the inductance may be possible by spreading or compressing inductor turns.

The power-handling ability of toroidal cores depends on many variables, which include the cross-sectional area through the core, the core material, the numbers of turns in the inductor, the applied voltage and the operating frequency. Although powdered-iron cores can withstand dc flux densities up to 5000 gauss without saturating, ac flux densities from sine waves above certain limits can overheat cores. Manufacturers provide guideline limits for ac flux densities to avoid overheating. The limits range from 150 gauss at 1 MHz to 30 gauss at 28 MHz, although the curve is not linear. To calculate the maximum anticipated flux density for a particular inductor, use the formula:

$$B_{\text{max}} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f} \quad (113)$$

where

- B_{max} = the maximum flux density in gauss,
- E_{RMS} = the voltage across the inductor,
- A_e = the cross-sectional area of the core in square centimeters,
- N = the number of turns in the inductor, and
- f = the operating frequency in Hz.

Example: What is the maximum ac flux density for an inductor of 15 turns if the frequency is 7.0 MHz, the RMS voltage is 25 V and the cross-sectional area of the core is 0.133 cm^2 ?

$$B_{\text{max}} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f}$$

$$= \frac{25 \times 10^8}{4.44 \times 0.133 \times 15 \times 7.0 \times 10^6}$$

$$= \frac{25 \times 10^8}{62 \times 10^6} = 40 \text{ gauss}$$

Since the recommended limit for cores operated at 7 MHz is 57 gauss, this inductor is well within guidelines.

2.12.6 Ferrite Toroidal Inductors

Although nearly identical in general appearance to powdered-iron cores, ferrite cores differ in a number of important characteristics. Composed of nickel-zinc ferrites for lower permeability ranges and of manganese-zinc ferrites for higher permeabilities, these cores span a permeability range from 20 to above 10000. Nickel-zinc cores with permeabilities from 20 to 800 are useful in high-Q applications, but function more commonly in amateur applications as RF chokes. They are also useful in wide-band transformers, discussed in the chapter **RF Techniques**.

Ferrite cores are often unpainted, unlike powdered-iron toroids. Ferrite toroids and rods often have sharp edges, while powdered-iron toroids usually have rounded edges.

Because of their higher permeabilities, the A_L values for ferrite cores are higher than for powdered-iron cores. Amidon Corp. is the most common supplier of cores for amateurs (see the **Component Data and References** chapter) and specifies A_L in mH per 1000 turns-squared. Other manufacturers specify A_L in nH per turns-squared.

To calculate the inductance of a ferrite toroidal inductor using the Amidon convention for A_L when the number of turns and the core material are known:

$$L = \frac{A_L \times N^2}{1,000,000} \quad (114)$$

where

- L = the inductance in mH,
- A_L = the inductance index in mH per 1000 turns-squared, and
- N = the number of turns.

The builder must then ensure that the core is capable of holding the calculated number of turns of wire of the required wire size.

Example: What is the inductance of a 60-turn inductor on a core with an A_L of 523? (See the chapter **Component Data and References** for more detailed data on the range of available cores.)

$$L = \frac{A_L \times N^2}{1,000,000} = \frac{523 \times 60^2}{1,000,000}$$

$$= \frac{1.88 \times 10^6}{1 \times 10^6} = 1.88 \text{ mH}$$

To calculate the number of turns needed for a particular inductance, use the formula:

$$N = 1000 \sqrt{\frac{L}{A_L}} \quad (115)$$

Example: How many turns are needed for a 1.2-mH inductor if the A_L for the selected core is 150?

$$N = 1000 \sqrt{\frac{L}{A_L}} = 1000 \sqrt{\frac{1.2}{150}}$$

$$N = 1000 \sqrt{0.008} = 1000 \times 0.089 = 89 \text{ turns}$$

For inductors carrying both dc and ac currents, the upper saturation limit for most ferrites is a flux density of 2000 gauss, with power calculations identical to those used for powdered-iron cores. More detailed information is available on specific cores and manufacturers in the **Component Data and References** chapter.

2.13 Resonant Circuits

A circuit containing both an inductor and a capacitor — and therefore, both inductive and capacitive reactance — is often called a *tuned circuit* or a *resonant circuit*. For any such circuit, there is a particular frequency at which the inductive and capacitive reactances are the same, that is, $X_L = X_C$. For most purposes, this is the *resonant frequency* of the circuit. At the resonant frequency — or at *resonance*, for short:

$$X_L = 2 \pi f L = X_C = \frac{1}{2 \pi f C}$$

By solving for f , we can find the resonant frequency of any combination of inductor and capacitor from the formula:

$$f = \frac{1}{2 \pi \sqrt{L C}} \quad (116)$$

where

- f = frequency in hertz (Hz),
- L = inductance in henrys (H),
- C = capacitance in farads (F), and
- $\pi = 3.1416$.

For most high-frequency (HF) radio work, smaller units of inductance and capacitance and larger units of frequency are more convenient. The basic formula becomes:

$$f = \frac{10^3}{2 \pi \sqrt{L C}} \quad (117)$$

where

- f = frequency in megahertz (MHz),
- L = inductance in microhenrys (μH),
- C = capacitance in picofarads (pF), and
- $\pi = 3.1416$.

Example: What is the resonant frequency of a circuit containing an inductor of 5.0 μH and a capacitor of 35 pF?

$$f = \frac{10^3}{2 \pi \sqrt{L C}} = \frac{10^3}{6.2832 \sqrt{5.0 \times 35}}$$

$$= \frac{10^3}{83} = 12 \text{ MHz}$$

To find the matching component (inductor or capacitor) when the frequency and one component is known (capacitor or inductor) for general HF work, use the formula:

$$f^2 = \frac{1}{4 \pi^2 L C} \quad (118)$$

where f , L and C are in basic units. For HF work in terms of MHz, μH and pF, the basic relationship rearranges to these handy formulas:

$$L = \frac{25,330}{f^2 C} \quad (119)$$

$$C = \frac{25,330}{f^2 L} \quad (120)$$

where

- f = frequency in MHz,
- L = inductance in μH , and
- C = capacitance in pF

For most radio work, these formulas will permit calculations of frequency and component values well within the limits of component tolerances.

Example: What value of capacitance is needed to create a resonant circuit at 21.1 MHz, if the inductor is 2.00 μH ?

$$C = \frac{25,330}{f^2 L} = \frac{25,330}{(21.1^2 \times 2.0)}$$

$$= \frac{25,330}{890} = 28.5 \text{ pF}$$

Fig 2.55 can also be used if an approximate answer is acceptable. From the horizontal axis, find the vertical line closest to the desired resonant frequency. Every pair of diagonals that cross on that vertical line represent a combination of inductance and capacitance that will resonate at that frequency. For example, if the desired frequency is 10 MHz, the pair of diagonals representing 5 μH and 50 pF cross quite close to that frequency. Interpolating between the given diagonals will provide more resolution — remember that all three sets of lines are spaced logarithmically.

Resonant circuits have other properties of importance, in addition to the resonant frequency, however. These include impedance, voltage drop across components in series-resonant circuits, circulating current in parallel-resonant circuits, and bandwidth. These properties determine such factors as the selectivity of a tuned circuit and the component ratings for circuits handling significant amounts of power. Although the basic determination of the tuned-circuit resonant frequency ignored any resistance in the circuit, that resistance will play a vital role in the circuit's other characteristics.

2.13.1 Series-Resonant Circuits

Fig 2.79 presents a basic schematic diagram of a *series-resonant circuit*. Although most schematic diagrams of radio circuits would show only the inductor and the capacitor, resistance is always present in such circuits. The most notable resistance is associated with the series resistance losses in the inductor at HF. The dominant losses in the capacitor may be modeled as a parallel

resistance (not shown), but these losses are low enough at HF to be ignored. The current meter shown in the circuit is a reminder that in series circuits, the same current flows through all elements.

At resonance, the reactance of the capacitor cancels the reactance of the inductor. The voltage and current are in phase with each other, and the impedance of the circuit is determined solely by the resistance. The actual current through the circuit at resonance, and for frequencies near resonance, is determined by the formula:

$$I = \frac{E}{Z}$$

$$= \frac{E}{\sqrt{R^2 + \left[2 \pi f L - \frac{1}{(2 \pi f C)} \right]^2}} \quad (121)$$

where all values are in basic units.

At resonance, the reactive factor in the formula is zero (the bracketed expression under the square root symbol). As the frequency is shifted above or below the resonant frequency without altering component values, however, the reactive factor becomes significant, and the value of the current becomes smaller than at resonance. At frequencies far from resonance, the reactive components become dominant, and the resistance no longer significantly affects the current amplitude.

The exact curve created by recording the current as the frequency changes depends on the ratio of reactance to resistance. When the reactance of either the coil or capacitor is of the same order of magnitude as the resistance, the current decreases rather slowly as the fre-

Fig 2.79 — A series circuit containing L , C , and R is resonant at the applied frequency when the reactance of C is equal to the reactance of L . The I in the circle is the schematic symbol for an ammeter.

Fig 2.80 — Relative current in series-resonant circuits with various values of series resistance and Q . (An arbitrary maximum value of 1.0 represents current at resonance.) The reactance at resonance for all curves is $1000\ \Omega$. Note that the current is hardly affected by the resistance in the circuit at frequencies more than 10% away from the resonant frequency.

quency is moved in either direction away from resonance. Such a curve is said to be *broad*. Conversely, when the reactance is considerably larger than the resistance, the current decreases rapidly as the frequency moves away from resonance, and the circuit is said to be *sharp*. A sharp circuit will respond a great deal more readily to the resonant frequency than to frequencies quite close to resonance; a broad circuit will respond almost equally well to a group or band of frequencies centered around the resonant frequency.

Both types of resonance curves are useful. A sharp circuit gives good selectivity — the ability to respond strongly (in terms of current amplitude) at one desired frequency and to discriminate against others. A broad circuit is used when the apparatus must give about the same response over a band of frequencies, rather than at a single frequency alone.

Fig 2.80 presents a family of curves, showing the decrease in current as the frequency deviates from resonance. In each case, the inductive and capacitive reactances are assumed to be $1000\ \Omega$. The maximum current, shown as a relative value on the graph, occurs with the lowest resistance, while the lowest peak current occurs with the highest resistance. Equally important, the rate at which the current decreases from its maximum value also changes with the ratio of reactance to resistance. It decreases most rapidly when the ratio is high and most slowly when the ratio is low.

Fig 2.81 — Relative current in series-resonant circuits having different values of Q_U . The current at resonance is normalized to the same level for all curves in order to show the rate of change of decrease in current for each value of Q_U . The half-power points are shown to indicate relative bandwidth of the response for each curve. The bandwidth is indicated for a circuit with a Q_U of 10.

UNLOADED Q

As noted in equation [a] of Table 2.10 earlier in this chapter, Q is the ratio of series reactance representing 2π times the stored energy (equation [c] in Table 2.10) to series resistance or consumed energy. Since both terms of the ratio are measured in ohms, Q has no units and is known as the *quality factor* (and less frequently, the *figure of merit* or the *multiplying factor*). The series resistive losses of the coil often dominate the energy consumption in HF series-resonant circuits, so the inductor Q largely determines the resonant-circuit Q . Since this value of Q is independent of any external load to which the circuit might transfer power, it is called the *unloaded Q* or Q_U of the circuit.

Example: What is the unloaded Q of a series-resonant circuit with a series loss resistance of $5\ \Omega$ and inductive and capacitive components having a reactance of $500\ \Omega$ each? With a reactance of $50\ \Omega$ each?

$$Q_{U1} = \frac{X1}{R} = \frac{500\ \Omega}{5\ \Omega} = 100$$

$$Q_{U2} = \frac{X2}{R} = \frac{50\ \Omega}{5\ \Omega} = 10$$

BANDWIDTH

Fig 2.81 is an alternative way of drawing the family of curves that relate current to frequency for a series-resonant circuit. By

assuming that the peak current of each curve is the same, the rate of change of current for various values of Q_U and the associated ratios of reactance to resistance are more easily compared. From the curves, it is evident that the lower Q_U circuits pass current across a greater *bandwidth* of frequencies than the circuits with a higher Q_U . For the purpose of comparing tuned circuits, bandwidth is often defined as the frequency spread between the two frequencies at which the current amplitude decreases to 0.707 (or $1/\sqrt{2}$) times the maximum value. Since the power consumed by the resistance, R , is proportional to the square of the current, the power at these points is half the maximum power at resonance, assuming that R is constant for the calculations. The half-power, or $-3\ \text{dB}$, points are marked on Fig 2.81.

For Q values of 10 or greater, the curves shown in Fig 2.81 are approximately symmetrical. On this assumption, bandwidth (BW) can be easily calculated by inverting equation [d] in Table 2.10, and approximating the geometrical mean $-3\ \text{dB}$ frequency by f :

$$BW = \frac{f}{Q_U} \quad (122)$$

where BW and f are in the same units, that is, in Hz, kHz or MHz.

Example: What is the 3 dB bandwidth of a series-resonant circuit operating at 14 MHz with a Q_U of 100?

$$\begin{aligned} BW &= \frac{f}{Q_U} = \frac{14\ \text{MHz}}{100} = 0.14\ \text{MHz} \\ &= 140\ \text{kHz} \end{aligned}$$

The relationship between Q_U , f and BW provides a means of determining the value of circuit Q when inductor losses may be difficult to measure. By constructing the series-resonant circuit and measuring the current as the frequency varies above and below resonance, the half-power points can be determined. Then:

$$Q_U = \frac{f}{BW} \quad (123)$$

Example: What is the Q_U of a series-resonant circuit operating at 3.75 MHz, if the $-3\ \text{dB}$ bandwidth is 375 kHz?

$$Q_U = \frac{f}{BW} = \frac{3.75\ \text{MHz}}{0.375\ \text{MHz}} = 10.0$$

Table 2.11 provides some simple formulas for estimating the maximum current and phase angle for various bandwidths, if both f and Q_U are known.

Table 2.11

The Selectivity of Resonant Circuits

Approximate percentage of current at resonance ¹ or of impedance at resonance ²	Bandwidth (between half-power or -3 dB points on response curve)	Series circuit current phase angle (degrees)
95	f / 3Q	18.5
90	f / 2Q	26.5
70.7	f / Q	45
44.7	2f / Q	63.5
24.2	4f / Q	76
12.4	8f / Q	83

¹For a series resonant circuit
²For a parallel resonant circuit

Fig 2.82 — A typical parallel-resonant circuit, with the resistance shown in series with the inductive leg of the circuit. Below a Q_U of 10, resonance definitions may lead to three separate frequencies which converge at higher Q_U levels. See text.

VOLTAGE DROP ACROSS COMPONENTS

The voltage drop across the coil and across the capacitor in a series-resonant circuit are each proportional to the reactance of the component for a given current (since $E = I X$). These voltages may be many times the applied voltage for a high-Q circuit. In fact, at resonance, the voltage drop is:

$$E_X = Q_U E_{AC} \quad (124)$$

where

E_X = the voltage across the reactive component,

Q_U = the circuit unloaded Q, and

E_{AC} = the applied voltage in Fig 2.79.

(Note that the voltage drop across the inductor is the vector sum of the voltages across the resistance and the reactance; however, for Q greater than 10, the error created by using this is not ordinarily significant.) Since the calculated value of E_X is the RMS voltage, the peak voltage will be higher by a factor of 1.414. Antenna couplers and other high-Q circuits handling significant power may experience arcing from high values of E_X , even though the source voltage to the circuit is well within component ratings.

CAPACITOR LOSSES

Although capacitor energy losses tend to be insignificant compared to inductor losses up to about 30 MHz, the losses may affect circuit Q in the VHF range. Leakage resistance, principally in the solid dielectric that forms the insulating support for the capacitor plates, appears as a resistance in parallel with the capacitor plates. Instead of forming a series resistance, capacitor leakage usually forms a parallel resistance with the capacitive reactance. If the leakage resistance of a capacitor is significant enough to affect the Q of a series-resonant circuit, the parallel resistance (R_p) may be converted to an equivalent series resistance (R_s) before adding it to the inductor's resistance.

$$R_S = \frac{X_C^2}{R_P} = \frac{1}{R_P \times (2 \pi f C)^2} \quad (125)$$

Example: A 10.0 pF capacitor has a leakage resistance of 10,000 Ω at 50.0 MHz. What is the equivalent series resistance?

$$R_S = \frac{1}{R_P \times (2 \pi f C)^2}$$

$$= \frac{1}{1.0 \times 10^4 \times (6.283 \times 50.0 \times 10^6 \times 10.0 \times 10^{-12})^2}$$

$$= \frac{1}{1.0 \times 10^4 \times 9.87 \times 10^{-6}}$$

$$= \frac{1}{0.0987} = 10.1 \Omega$$

In calculating the impedance, current and bandwidth for a series-resonant circuit in which this capacitor might be used, the series-equivalent resistance of the unit is added to the loss resistance of the coil. Since inductor losses tend to increase with frequency because of skin effect in conductors, and capacitor dielectric losses also tend to increase with frequency, the combined losses in the capacitor and the inductor can seriously reduce circuit Q.

2.13.2 Parallel-Resonant Circuits

Although series-resonant circuits are common, the vast majority of resonant circuits used in radio work are *parallel-resonant circuits*. **Fig 2.82** represents a typical HF parallel-resonant circuit. As is the case for series-resonant circuits, the inductor is the chief source of resistive losses (that is, the parallel loss resistance across the capacitor is not shown), and these losses appear in series with the coil. Because current through parallel-resonant circuits is lowest at resonance, and impedance is highest, they are sometimes called *antiresonant* circuits. (You may encounter the old terms *acceptor* and *rejector*

referring to series- and parallel-resonant circuits, respectively.)

Because the conditions in the two legs of the parallel circuit in Fig 2.82 are not the same — the resistance is shown in only one of the legs — all of the conditions by which series resonance is determined do not occur simultaneously in a parallel-resonant circuit.

Fig 2.83 graphically illustrates the situation by showing the currents through the two components. (Currents are drawn in the manner of complex impedances shown previously to show the phase angle for each current.) When the inductive and capacitive reactances are identical, the condition defined for series resonance is met as shown at point (a). The impedance of the inductive leg is composed of both X_L and R, which yields an impedance greater than X_C and that is not 180° out of phase with X_C . The resultant current is greater than the minimum possible value and is not in phase with the voltage.

By altering the value of the inductor slightly (and holding the Q constant), a new frequency can be obtained at which the current reaches its minimum. When parallel circuits are tuned using a current meter as an indicator, this point (b) is ordinarily used as an indication of resonance. The current “dip” indicates a condition of maximum impedance and is sometimes called the *antiresonant* point or *maximum impedance resonance* to distinguish it from the condition at which $X_C = X_L$. Maximum impedance is achieved at this point by vector addition of X_C , X_L and R, however, and the result is a current somewhat out of phase with the voltage.

Point (c) in the figure represents the *unity-power-factor* resonant point. Adjusting the inductor value and hence its reactance (while holding Q constant) produces a new resonant frequency at which the resultant current is in phase with the voltage. The new value of

Fig 2.84 — Series and parallel equivalents when both circuits are resonant. The series resistance, R_S in A, is replaced by the parallel resistance, R_P in B, and vice versa. $R_P = X_L^2 / R_S$.

inductive reactance is the value required for a parallel-equivalent inductor and its parallel-equivalent resistor (calculated according to the formulas in the last section) to just cancel the capacitive reactance. The value of the parallel-equivalent inductor is always smaller than the actual inductor in series with the resistor and has a proportionally smaller reactance. (The parallel-equivalent resistor, conversely, will always be larger than the

coil-loss resistor shown in series with the inductor.) The result is a resonant frequency slightly different from the one for minimum current and the one for $X_L = X_C$.

The points shown in the graph in Fig 2.83 represent only one of many possible situations, and the relative positions of the three resonant points do not hold for all possible cases. Moreover, specific circuit designs can draw some of the resonant points together, for example, compensating for the resistance of the coil by retuning the capacitor. The differences among these resonances are significant for circuit Q below 10, where the inductor's series resistance is a significant percentage of the reactance. Above a Q of 10, the three points converge to within a percent of the frequency and the differences between them can be ignored for practical calculations. Tuning for minimum current will not introduce a sufficiently large phase angle between voltage and current to create circuit difficulties.

PARALLEL CIRCUITS OF MODERATE TO HIGH Q

The resonant frequencies defined above converge in parallel-resonant circuits with Q higher than about 10. Therefore, a single set of formulas will sufficiently approximate circuit performance for accurate predictions. Indeed, above a Q of 10, the performance

of a parallel circuit appears in many ways to be simply the inverse of the performance of a series-resonant circuit using the same components.

Accurate analysis of a parallel-resonant circuit requires the substitution of a parallel-equivalent resistor for the actual inductor-loss series resistor, as shown in Fig 2.84. Sometimes called the *dynamic resistance* of the parallel-resonant circuit, the parallel-equivalent resistor value will increase with circuit Q, that is, as the series resistance value decreases. To calculate the approximate parallel-equivalent resistance, use the formula:

$$R_P = \frac{X_L^2}{R_S} = \frac{(2 \pi f L)^2}{R_S} = Q_U X_L \quad (126)$$

for $R_S \ll X_C \ll R_P$ and $X_P \approx X_S$ in equations 94 through 97.

Example: What is the parallel-equivalent resistance for a coil with an inductive reactance of 350 Ω and a series resistance of 5.0 Ω at resonance?

$$R_P = \frac{X_L^2}{R_S} = \frac{(350 \Omega)^2}{5.0 \Omega} = \frac{122,500 \Omega^2}{5.0 \Omega} = 24,500 \Omega$$

Since the coil Q_U remains the inductor's reactance divided by its series resistance, the coil Q_U is 70. Multiplying Q_U by the reactance also provides the approximate parallel-equivalent resistance of the coil series resistance.

At resonance, where $X_L = X_C$, R_P defines the impedance of the parallel-resonant circuit. The reactances just equal each other, leaving the voltage and current in phase with each other. In other words, the circuit shows only the parallel resistance. Therefore, equation 126 can be rewritten as:

$$Z = \frac{X_L^2}{R_S} = \frac{(2 \pi f L)^2}{R_S} = Q_U X_L \quad (127)$$

In this example, the circuit impedance at resonance is 24,500 Ω .

At frequencies below resonance the current through the inductor is larger than that through the capacitor, because the reactance of the coil is smaller and that of the capacitor is larger than at resonance. There is only partial cancellation of the two reactive currents, and the total current therefore is larger than the current taken by the resistance alone. At frequencies above resonance the situation is reversed and more current flows through the capacitor than through the inductor, so the total current again increases.

The current at resonance, being determined wholly by R_P , will be small if R_P is large, and large if R_P is small. Fig 2.85 illustrates the relative current flows through a parallel-tuned circuit as the frequency is moved from below

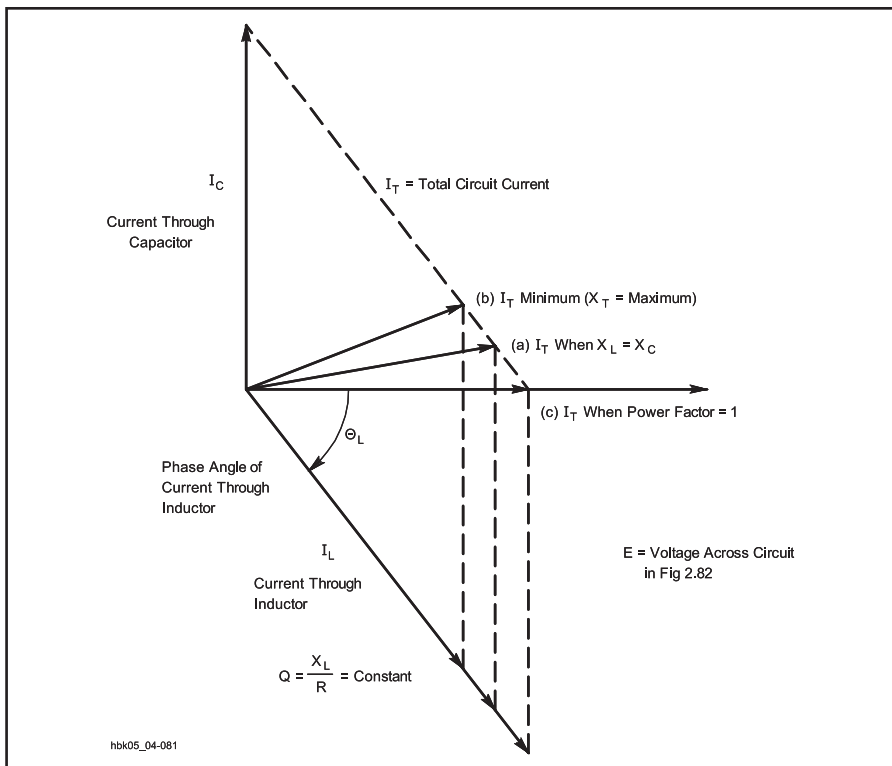

Fig 2.83 — Resonant conditions for a low- Q_U parallel circuit. Resonance may be defined as (a) $X_L = X_C$ (b) minimum current flow and maximum impedance or (c) voltage and current in phase with each other. With the circuit of Fig 2.82 and a Q_U of less than 10, these three definitions may represent three distinct frequencies.

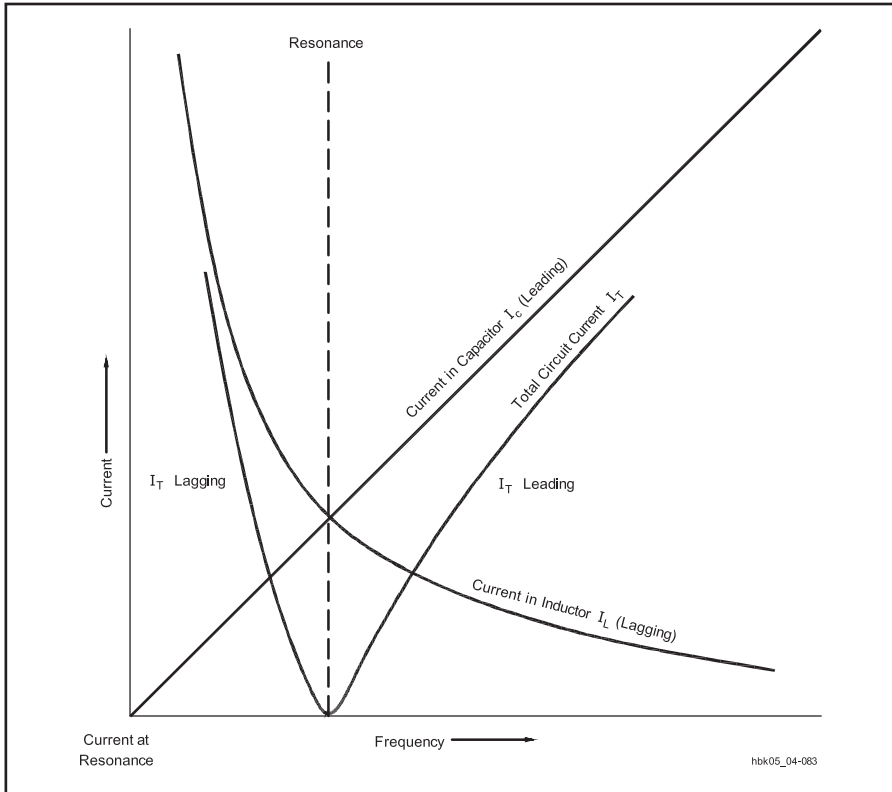

Fig 2.85 — The currents in a parallel-resonant circuit as the frequency moves through resonance. Below resonance, the current lags the voltage; above resonance the current leads the voltage. The base line represents the current level at resonance, which depends on the impedance of the circuit at that frequency.

resonance to above resonance. The base line represents the minimum current level for the particular circuit. The actual current at any frequency off resonance is simply the vector sum of the currents through the parallel equivalent resistance and through the reactive components.

To obtain the impedance of a parallel-tuned circuit either at or off the resonant frequency, apply the general formula:

$$Z = \frac{Z_C Z_L}{Z_S} \quad (128)$$

where

- Z = overall circuit impedance
- Z_C = impedance of the capacitive leg (usually, the reactance of the capacitor),
- Z_L = impedance of the inductive leg (the vector sum of the coil's reactance and resistance), and
- Z_S = series impedance of the capacitor-inductor combination as derived from the denominator of equation 121.

After using vector calculations to obtain Z_L and Z_S , converting all the values to polar form — as described earlier in this chapter — will ease the final calculation. Of course, each impedance may be derived from the resistance and the application of the basic

reactance formulas on the values of the inductor and capacitor at the frequency of interest.

Since the current rises away from resonance, the parallel-resonant-circuit impedance must fall. It also becomes complex, resulting in an ever-greater phase difference between the voltage and the current. The rate at which the impedance falls is a function of Q_U . **Fig 2.86** presents a family of curves showing the impedance drop from resonance for circuit Q ranging from 10 to 100. The curve family for parallel-circuit impedance is essentially the same as the curve family for series-circuit current.

As with series-resonant circuits, the higher the Q of a parallel-tuned circuit, the sharper will be the response peak. Likewise, the lower the Q , the wider the band of frequencies to which the circuit responds. Using the half-power (–3 dB) points as a comparative measure of circuit performance, equations 122 and 123 apply equally to parallel-tuned circuits. That is, $BW = f / Q_U$ and $Q_U = f / BW$, where the resonant frequency and the bandwidth are in the same units. As a handy reminder, **Table 2.12** summarizes the performance of parallel-resonant circuits at high and low Q and above and below resonant frequency.

It is possible to use either series- or parallel-

Fig 2.86 — Relative impedance of parallel-resonant circuits with different values of Q_U . The curves are similar to the series-resonant circuit current level curves of **Fig 2.80**. The effect of Q_U on impedance is most pronounced within 10% of the resonance frequency.

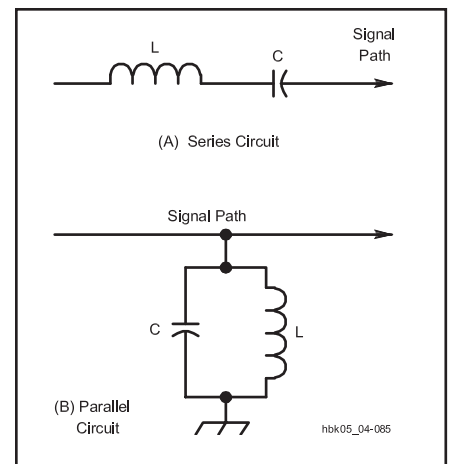

Fig 2.87 — Series- and parallel-resonant circuits configured to perform the same theoretical task: passing signals in a narrow band of frequencies along the signal path. A real design example would consider many other factors.

resonant circuits to do the same work in many circuits, thus giving the designer considerable flexibility. **Fig 2.87** illustrates this general principle by showing a series-resonant circuit in the signal path and a parallel-resonant circuit shunted from the signal path to ground. Assume both circuits are resonant at the same frequency, f , and have the same Q . The series-resonant circuit at A has its lowest impedance at f , permitting the maximum possible current to flow along the signal path. At all other frequencies, the impedance is greater and the current at those frequencies is less. The circuit passes the desired signal and tends to impede

Table 2.12

The Performance of Parallel-Resonant Circuits

A. High- and Low-Q Circuits (in relative terms)

Characteristic	High-Q Circuit	Low-Q Circuit
Selectivity	high	low
Bandwidth	narrow	wide
Impedance	high	low
Total current	low	high
Circulating current	high	low

B. Off-Resonance Performance for Constant Values of Inductance and Capacitance

Characteristic	Above Resonance	Below Resonance
Inductive reactance	increases	decreases
Capacitive reactance	decreases	increases
Circuit resistance	unchanged*	unchanged*
Relative impedance	decreases	decreases
Total current	increases	increases
Circulating current	decreases	decreases
Circuit impedance	capacitive	inductive

*This is true for frequencies near resonance. At distant frequencies, skin effect may alter the resistive losses of the inductor.

signals at undesired frequencies. The parallel circuit at B provides the highest impedance at resonance, f, making the signal path the lowest impedance path for the signal. At frequencies off resonance, the parallel-resonant circuit presents a lower impedance, thus presenting signals with a path to ground and away from the signal path. In theory, the effects will be the same relative to a signal current on the signal path. In actual circuit design exercises, of course, many other variables will enter the design picture to make one circuit preferable to the other.

CIRCULATING CURRENT

In a parallel-resonant circuit, the source voltage is the same for all the circuit elements. The current in each element, however, is a function of the element's reactance. **Fig 2.88** redraws the parallel-resonant circuit to indicate the total current and the current circulating between the coil and the capacitor. The current drawn from the source may be low, because the overall circuit impedance is high. The current through the individual elements may be high, however, because there is little resistive loss as the current circulates through the inductor and capacitor. For parallel-resonant circuits with an unloaded Q of 10 or greater, this *circulating current* is approximately:

$$I_C = Q_U I_T \tag{129}$$

where

- I_C = circulating current in A, mA or μ A,
- Q_U = unloaded circuit Q, and
- I_T = total current in the same units as I_C .

Example: A parallel-resonant circuit permits an ac or RF total current of 30 mA and

has a Q of 100. What is the circulating current through the elements?

$$I_X = Q_U I = 100 \times 30 \text{ mA} = 3000 \text{ mA} = 3 \text{ A}$$

Circulating currents in high-Q parallel-tuned circuits can reach a level that causes component heating and power loss. Therefore, components should be rated for the anticipated circulating currents, and not just the total current.

LOADED Q

In many resonant-circuit applications, the only power lost is that dissipated in the resistance of the circuit itself. At frequencies below 30 MHz, most of this resistance is in the coil. Within limits, increasing the number

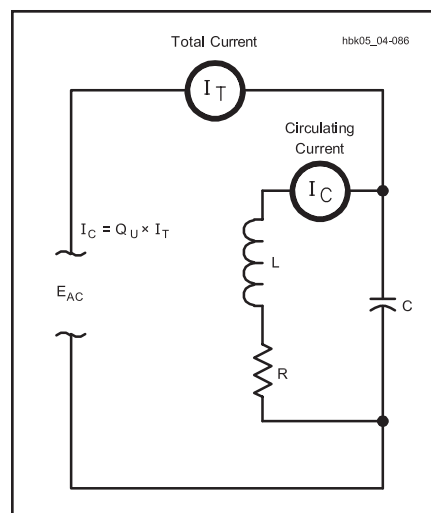

Fig 2.88 — A parallel-resonant circuit redrawn to illustrate both the total current and the circulating current.

of turns in the coil increases the reactance faster than it raises the resistance, so coils for circuits in which the Q must be high are made with relatively large inductances for the frequency.

When the circuit delivers energy to a load (as in the case of the resonant circuits used in transmitters), the energy consumed in the circuit itself is usually negligible compared with that consumed by the load. The equivalent of such a circuit is shown in **Fig 2.89**, where the parallel resistor, R_L , represents the load to which power is delivered. If the power dissipated in the load is at least 10 times as great as the power lost in the inductor and capacitor, the parallel impedance of the resonant circuit itself will be so high compared with the resistance of the load that for all practical purposes the impedance of the combined circuit is equal to the load impedance. Under these conditions, the load resistance replaces the circuit impedance in calculating Q. The Q of a parallel-resonant circuit loaded by a resistive impedance is:

$$Q_L = \frac{R_L}{X} \tag{130}$$

where

- Q_L = circuit loaded Q,
- R_L = parallel load resistance in ohms, and
- X = reactance in ohms of either the inductor or the capacitor.

Example: A resistive load of 3000 Ω is connected across a resonant circuit in which the inductive and capacitive reactances are each 250 Ω . What is the circuit Q?

$$Q_L = \frac{R_L}{X} = \frac{3000 \Omega}{250 \Omega} = 12$$

The effective Q of a circuit loaded by a parallel resistance increases when the reactances are decreased. A circuit loaded with a relatively low resistance (a few thousand ohms) must have low-reactance elements

Fig 2.89 — A loaded parallel-resonant circuit, showing both the inductor-loss resistance and the load, R_L . If smaller than the inductor resistance, R_L will control the loaded Q of the circuit (Q_L).

(large capacitance and small inductance) to have reasonably high Q . Many power-handling circuits, such as the output networks of transmitters, are designed by first choosing a loaded Q for the circuit and then determining component values. See the chapter on **RF Power Amplifiers** for more details.

Parallel load resistors are sometimes added to parallel-resonant circuits to lower the circuit Q and increase the circuit bandwidth. By using a high- Q circuit and adding a parallel resistor, designers can tailor the circuit response to their needs. Since the parallel resistor consumes power, such techniques ordinarily apply to receiver and similar low-power circuits, however.

Example: Specifications call for a parallel-resonant circuit with a bandwidth of 400 kHz at 14.0 MHz. The circuit at hand has a Q_U of 70.0 and its components have reactances of $350\ \Omega$ each. What is the parallel load resistor that will increase the bandwidth to the specified value? The bandwidth of the existing circuit is:

$$BW = \frac{f}{Q_U} = \frac{14.0\ \text{MHz}}{70.0} = 0.200\ \text{MHz}$$

$$= 200\ \text{kHz}$$

The desired bandwidth, 400 kHz, requires a circuit with a Q of:

$$Q = \frac{f}{BW} = \frac{14.0\ \text{MHz}}{0.400\ \text{MHz}} = 35.0$$

Since the desired Q is half the original value, halving the resonant impedance or parallel-resistance value of the circuit is in order. The present impedance of the circuit is:

$$Z = Q_U X_L = 70.0 \times 350\ \Omega = 24500\ \Omega$$

The desired impedance is:

$$Z = Q_U X_L = 35.0 \times 350\ \Omega$$

$$= 12250\ \Omega = 12.25\ \text{k}\Omega$$

or half the present impedance.

A parallel resistor of $24,500\ \Omega$, or the near-

Fig 2.90 — A parallel-resonant circuit with a tapped inductor to effect an impedance match. Although the impedance presented to E_{AC} is very high, the impedance at the connection of the load, R_L , is lower.

est lower value (to guarantee sufficient bandwidth), will produce the required reduction in Q and bandwidth increase. Although this example simplifies the situation encountered in real design cases by ignoring such factors as the shape of the band-pass curve, it illustrates the interaction of the ingredients that determine the performance of parallel-resonant circuits.

IMPEDANCE TRANSFORMATION

An important application of the parallel-resonant circuit is as an impedance matching device. Circuits and antennas often need to be connected to other circuits or feed lines that do not have the same impedance. To transfer power effectively requires a circuit that will convert or “transform” the impedances so that each connected device or system can operate properly.

Fig 2.90 shows such a situation where the source, E_{AC} , operates at a high impedance, but the load, R_L , operates at a low impedance. The technique of impedance transformation shown in the figure is to connect the parallel-resonant circuit, which has a high impedance, across the source, but connect the load across only a portion of the coil. (This is called *tapping the coil* and the connection point is a *tap*.) The coil acts as an *autotransformer*, described in the following section, with the magnetic field of the coil shared between what are ef-

fectively two coils in series, the upper coil having many turns and the lower coil fewer turns. Energy stored in the field induces larger voltages in the many-turn coil than it does in the fewer-turn coil, “stepping down” the input voltage so that energy can be extracted by the load at the required lower voltage-to-current ratio (which is impedance). The correct tap point on the coil usually has to be experimentally determined, but the technique is very effective.

When the load resistance has a very low value (say below $100\ \Omega$) it may be connected in series in the resonant circuit (such as R_S in Fig 2.84A, for example), in which case the series L-R circuit can be transformed to an equivalent parallel L-R circuit as previously described. If the Q is at least 10, the equivalent parallel impedance is:

$$Z_R = \frac{X^2}{R_L} \quad (131)$$

where

Z_R = resistive parallel impedance at resonance,

X = reactance (in ohms) of either the coil or the capacitor, and

R_L = load resistance inserted in series.

If the Q is lower than 10, the reactance will have to be adjusted somewhat — for the reasons given in the discussion of low- Q parallel resonant circuits — to obtain a resistive impedance of the desired value.

These same techniques work in either “direction” — with a high-impedance source and low-impedance load or vice versa. Using a parallel-resonant circuit for this application does have some disadvantages. For instance, the common connection between the input and the output provides no dc isolation. Also, the common ground is sometimes troublesome with regard to ground-loop currents. Consequently, a circuit with only mutual magnetic coupling is often preferable. With the advent of ferrites, constructing impedance transformers that are both broadband and permit operation well up into the VHF portion of the spectrum has become relatively easy. The basic principles of broadband impedance transformers appear in the **RF Techniques** chapter.

2.14 Transformers

When the ac source current flows through every turn of an inductor, the generation of a counter-voltage and the storage of energy during each half cycle is said to be by virtue of self-inductance. If another inductor — not connected to the source of the original current — is positioned so the magnetic field of the first inductor intercepts the turns of the second inductor, coupling the two inductors and creating mutual inductance as described earlier, a voltage will be induced and current will flow in the second inductor. A load such as a resistor may be connected across the second inductor to consume the energy transferred magnetically from the first inductor.

Fig 2.91 illustrates a pair of coupled inductors, showing an ac energy source connected to one, called the *primary inductor*, and a load connected to the other, called the *secondary inductor*. If the inductors are wound tightly on a magnetic core so that nearly all or magnetic flux from the first inductor intersects with the turns of the second inductor, the pair is said to be *tightly coupled*. Inductors not sharing a common core and separated by a distance would be *loosely coupled*.

The signal source for the primary inductor may be household ac power lines, audio or other waveforms at low frequencies, or RF currents. The load may be a device needing power, a speaker converting electrical energy into sonic energy, an antenna using RF energy for communications or a particular circuit set up to process a signal from a preceding circuit. The uses of magnetically coupled energy in electronics are innumerable.

Mutual inductance (M) between inductors is measured in henrys. Two inductors have a mutual inductance of 1 H under the following conditions: as the primary inductor current changes at a rate of 1 A/s, the voltage across the secondary inductor is 1 V. The level of mutual inductance varies with many factors: the size and shape of the inductors, their relative positions and distance from each other, and the permeability of the inductor core material and of the space between them.

If the self-inductance values of two induc-

Fig 2.91 — A basic transformer: two inductors — one connected to an ac energy source, the other to a load — with coupled magnetic fields.

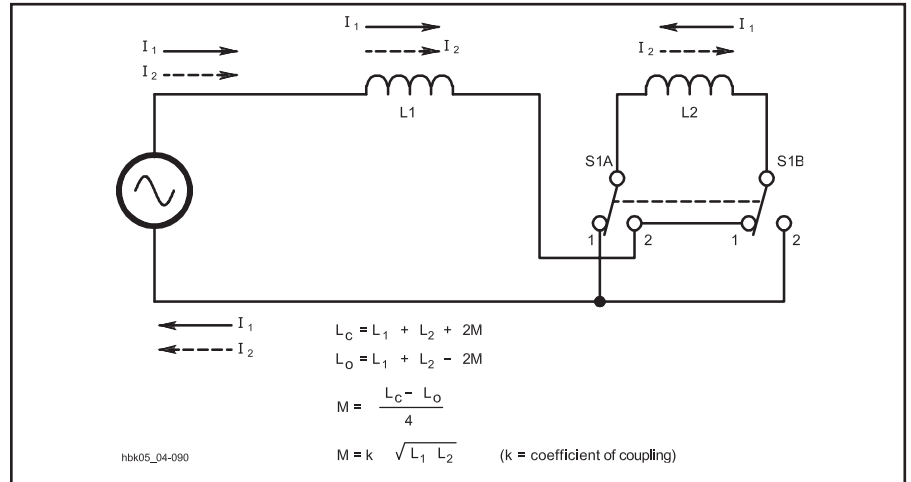

Fig 2.92 — An experimental setup for determining mutual inductance. Measure the inductance with the switch in each position and use the formula in the text to determine the mutual inductance.

Fig 2.93 — A transformer. A is a pictorial diagram. Power is transferred from the primary coil to the secondary by means of the magnetic field. B is a schematic diagram of an iron-core transformer, and C is an air-core transformer.

tors are known (self-inductance is used in this section to distinguish it from the mutual inductance), it is possible to derive the mutual inductance by way of a simple experiment schematically represented in **Fig 2.92**. Without altering the physical setting or position of two inductors, measure the total coupled inductance, L_C , of the series-connected inductors with their windings complementing each other and again with their windings opposing each other. Since, for the two inductors, $L_C = L_1 + L_2 + 2M$, in the complementary case, and $L_O = L_1 + L_2 - 2M$ for the opposing case,

$$M = \frac{L_C - L_O}{4} \quad (132)$$

The ratio of magnetic flux set up by the secondary inductor to the flux set up by the primary inductor is a measure of the extent to which two inductors are coupled, compared to the maximum possible coupling between them. This ratio is the *coefficient of coupling* (k) and is always less than 1. If k were to equal 1, the two inductors would have the maximum possible mutual coupling. Thus:

$$M = k \sqrt{L_1 L_2} \quad (133)$$

where

- M = mutual inductance in henrys,
- L_1 and L_2 = individual coupled inductors, each in henrys, and
- k = the coefficient of coupling.

Using the experiment above, it is possible to solve equation 133 for k with reasonable accuracy.

Any two inductors having mutual inductance comprise a *transformer* having a *primary winding* or inductor and a *secondary winding* or inductor. The word “winding” is generally dropped so that transformers are said to have “primaries” and “secondaries.” **Fig 2.93** provides a pictorial representation of a typical iron-core transformer, along with the schematic symbols for both iron-core and air-core transformers. Conventionally, the term *transformer* is most commonly applied to coupled inductors having a magnetic core material, while coupled air-wound inductors are not called by that name. They

are still transformers, however.

We normally think of transformers as ac devices, since mutual inductance only occurs when magnetic fields are changing. A transformer connected to a dc source will exhibit mutual inductance only at the instants of closing and opening the primary circuit, or on the rising and falling edges of dc pulses, because only then does the primary winding have a changing field. There are three principle uses of transformers: to physically isolate the primary circuit from the secondary circuit, to transform voltages and currents from one level to another, and to transform circuit impedances from one level to another. These functions are not mutually exclusive and have many variations.

2.14.1 Basic Transformer Principles

The primary and secondary windings of a transformer may be wound on a core of magnetic material. The permeability of the magnetic material increases the inductance of the windings so a relatively small number of turns may be used to induce a given voltage value with a small current. A closed core having a continuous magnetic path, such as that shown in Fig 2.93, also tends to ensure that practically all of the field set up by the current in the primary winding will intercept or “cut” the turns of the secondary winding.

For power transformers and impedance-matching transformers used at audio frequencies, cores made of soft iron strips or sheets called *laminations* are most common and generally very efficient. At higher frequencies, ferrite or powdered-iron cores are more frequently used. This section deals with basic transformer operation at audio and power frequencies. RF transformer operation is discussed in the chapter on **RF Techniques**.

The following principles presume a coefficient of coupling (k) of 1, that is, a perfect transformer. The value $k = 1$ indicates that all the turns of both windings link with all the magnetic flux lines, so that the voltage induced per turn is the same with both windings. This condition makes the induced voltage independent of the inductance of the primary and secondary inductors. Iron-core transformers for low frequencies closely approach this ideal condition. **Fig 2.94** illustrates the conditions for transformer action.

VOLTAGE RATIO

For a given varying magnetic field, the voltage induced in an inductor within the field is proportional to the number of turns in the inductor. When the two windings of a transformer are in the same field (which is the case when both are wound on the same closed core), it follows that the induced voltages will

Fig 2.94 — The conditions for transformer action: two coils that exhibit mutual inductance, an ac power source, and a load. The magnetic field set up by the energy in the primary circuit transfers energy to the secondary for use by the load, resulting in a secondary voltage and current.

be proportional to the number of turns in each winding. In the primary, the induced voltage practically equals, and opposes, the applied voltage, as described earlier. Hence:

$$E_S = E_P \left(\frac{N_S}{N_P} \right) \quad (134)$$

where

- E_S = secondary voltage,
- E_P = primary applied voltage,
- N_S = number of turns on secondary, and
- N_P = number of turns on primary.

Example: A transformer has a primary with 400 turns and a secondary with 2800 turns, and a voltage of 120 V is applied to the primary. What voltage appears across the secondary winding?

$$E_S = 120 \text{ V} \left(\frac{2800}{400} \right) = 120 \text{ V} \times 7 = 840 \text{ V}$$

(Notice that the number of turns is taken as a known value rather than a measured quantity, so they do not limit the significant figures in the calculation.) Also, if 840 V is applied to the 2800-turn winding (which then becomes the primary), the output voltage from the 400-turn winding will be 120 V.

Either winding of a transformer can be used as the primary, provided the winding has enough turns (enough inductance) to induce a voltage equal to the applied voltage without requiring an excessive current. The windings must also have insulation with a voltage rating sufficient for the voltages applied or created. Transformers are called *step-up* or *step-down* transformers depending on whether the secondary voltage is higher or lower than the primary voltage, respectively.

CURRENT OR AMPERE-TURNS RATIO

The current in the primary when no current is taken from the secondary is called the *magnetizing current* of the transformer. An ideal transformer, with no internal losses, would consume no power, since the current

through the primary inductor would be 90° out of phase with the voltage. In any properly designed transformer, the power consumed by the transformer when the secondary is open (not delivering power) is only the amount necessary to overcome the losses in the iron core and in the resistance of the wire with which the primary is wound.

When power is transferred from the secondary winding to a load, the secondary current creates a magnetic field that opposes the field established by the primary current. For the induced voltage in the primary to equal the applied voltage, the original magnetizing field must be maintained. Therefore, enough additional current must flow in the primary to create a field exactly equal and opposite to the field set up by the secondary current, leaving the original magnetizing field.

In practical transformer calculations it may be assumed that the entire primary current is caused by the secondary load. This is justifiable because the magnetizing current should be very small in comparison with the primary load current at rated power output.

If the magnetic fields set up by the primary and secondary currents are to be equal, the number of ampere-turns must be equal in each winding. (See the previous discussion of magnetic fields and magnetic flux density.) Thus, primary current multiplied by the primary turns must equal the secondary current multiplied by the secondary turns.

$$I_P N_P = I_S N_S$$

and

$$I_P = I_S \left(\frac{N_S}{N_P} \right) \quad (135)$$

where

- I_P = primary current,
- I_S = secondary current,
- N_P = number of turns in the primary winding, and
- N_S = number of turns in the secondary winding.

Example: Suppose the secondary of the transformer in the previous example is delivering a current of 0.20 A to a load. What will be the primary current?

$$I_P = 0.20 \text{ A} \left(\frac{2800}{400} \right) = 0.20 \text{ A} \times 7 = 1.4 \text{ A}$$

Although the secondary voltage is higher than the primary voltage, the secondary current is lower than the primary current, and by the same ratio. The secondary current in an ideal transformer is 180° out of phase with the primary current, since the field in the secondary just offsets the field in the primary. The phase relationship between the currents in the windings holds true no matter what the phase difference between the current and the voltage of the secondary. In fact, the phase difference,

if any, between voltage and current in the secondary winding will be *reflected* back to the primary as an identical phase difference.

Power Ratio

A transformer cannot create power; it can only transfer it and change the voltage and current ratios. Hence, the power taken from the secondary cannot exceed that taken by the primary from the applied voltage source. There is always some power loss in the resistance of the windings and in the iron core, so in all practical cases the power taken from the source will exceed that taken from the secondary.

$$P_O = \eta P_I \quad (136)$$

where

P_O = power output from secondary,
 P_I = power input to primary, and
 η = efficiency factor.

The efficiency, η , is always less than 1 and is commonly expressed as a percentage: if η is 0.65, for instance, the efficiency is 65%.

Example: A transformer has an efficiency of 85.0% at its full-load output of 150 W. What is the power input to the primary at full secondary load?

$$P_I = \frac{P_O}{\eta} = \frac{150 \text{ W}}{0.850} = 176 \text{ W}$$

A transformer is usually designed to have the highest efficiency at the power output for which it is rated. The efficiency decreases with either lower or higher outputs. On the other hand, the losses in the transformer are relatively small at low output but increase as more power is taken. The amount of power that the transformer can handle is determined by its own losses, because these losses heat the wire and core. There is a limit to the temperature rise that can be tolerated, because too high a temperature can either melt the wire or cause the insulation to break down. A transformer can be operated at reduced output, even though the efficiency is low, because the actual loss will be low under such conditions. The full-load efficiency of small power transformers such as are used in radio receivers and transmitters usually lies between about 60 and 90%, depending on the size and design.

IMPEDANCE RATIO

In an ideal transformer — one without losses or leakage inductance (see Transformer Losses) — the primary power, $P_P = E_P I_P$, and secondary power, $P_S = E_S I_S$, are equal. The relationships between primary and secondary voltage and current are also known (equations 134 and 135). Since impedance is the ratio of voltage to current, $Z = E/I$, the impedances represented in each winding are related as follows:

$$Z_P = Z_S \left(\frac{N_P}{N_S} \right)^2 \quad (137)$$

where

Z_P = impedance at the primary terminals from the power source,
 Z_S = impedance of load connected to secondary, and
 N_P/N_S = turns ratio, primary to secondary.

A load of any given impedance connected to the transformer secondary will thus be transformed to a different value at the primary terminals. The impedance transformation is proportional to the square of the primary-to-secondary turns ratio. (Take care to use the primary-to-secondary turns ratio, since the secondary-to-primary ratio is more commonly used to determine the voltage transformation ratio.)

The term *looking into* is often used to mean the conditions observed from an external perspective at the terminals specified. For example, “impedance looking into” the transformer primary means the impedance measured externally to the transformer at the terminals of the primary winding.

Example: A transformer has a primary-to-secondary turns ratio of 0.6 (the primary has six-tenths as many turns as the secondary) and a load of 3000 Ω is connected to the secondary. What is the impedance looking into the primary of the transformer?

$$Z_P = 3000 \Omega \times (0.6)^2 = 3000 \Omega \times 0.36$$

$$Z_P = 1080 \Omega$$

By choosing the proper turns ratio, the impedance of a fixed load can be transformed to any desired value, within practical limits. If transformer losses can be neglected, the transformed (reflected) impedance has the same phase angle as the actual load impedance. Thus, if the load is a pure resistance, the load presented by the primary to the power source will also be a pure resistance. If the load impedance is complex, that is, if the load current and voltage are out of phase with each other, then the primary voltage and current will have the same phase angle.

Many devices or circuits require a specific value of load resistance (or impedance) for optimum operation. The impedance of the actual load that is to dissipate the power may be quite different from the impedance of the source device or circuit, so an *impedance-matching transformer* is used to change the actual load into an impedance of the desired value. The turns ratio required is:

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}} \quad (138)$$

where

N_P/N_S = required turns ratio, primary to secondary,

Z_P = primary impedance required, and
 Z_S = impedance of load connected to secondary.

Example: A transistor audio amplifier requires a load of 150 Ω for optimum performance, and is to be connected to a loudspeaker having an impedance of 4.0 Ω . What primary-to-secondary turns ratio is required in the coupling transformer?

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}} = \frac{N_P}{N_S} \sqrt{\frac{150 \Omega}{4.0 \Omega}} = \sqrt{38} = 6.2$$

The primary therefore must have 6.2 times as many turns as the secondary.

These relationships may be used in practical circuits even though they are based on an ideal transformer. Aside from the normal design requirements of reasonably low internal losses and low leakage reactance, the only other requirement is that the primary have enough inductance to operate with low magnetizing current at the voltage applied to the primary.

The primary terminal impedance of an iron-core transformer is determined wholly by the load connected to the secondary and by the turns ratio. If the characteristics of the transformer have an appreciable effect on the impedance presented to the power source, the transformer is either poorly designed or is not suited to the voltage and frequency at which it is being used. Most transformers will operate quite well at voltages from slightly above to well below the design figure.

TRANSFORMER LOSSES

In practice, none of the formulas given so far provides truly exact results, although they afford reasonable approximations. Transformers in reality are not simply two coupled inductors, but a network of resistances and reactances, most of which appear in **Fig 2.95**. Since only the terminals numbered 1 through 4 are accessible to the user, transformer ratings and specifications take into account the additional losses created by these complexities.

In a practical transformer not all of the magnetic flux is common to both windings, although in well-designed transformers the amount of flux that cuts one winding and not the other is only a small percentage of the total flux. This *leakage flux* causes a voltage by self-induction in the winding creating the flux. The effect is the same as if a small *leakage inductance* existed independently of the main windings. Leakage inductance acts in exactly the same way as inductance inserted in series with the winding. It has, therefore, a certain reactance, depending on the amount of leakage inductance and the frequency. This reactance is called *leakage reactance* and is shown as X_{L1} and X_{L2} in **Fig 2.95**.

Fig 2.95 — A transformer as a network of resistances, inductances and capacitances. Only L_1 and L_2 contribute to the transfer of energy.

Current flowing through the leakage reactance causes a voltage drop. This voltage drop increases with increasing current (or frequency); hence, it increases as more power is taken from the secondary. The resistances of the transformer windings, R_1 and R_2 , also cause voltage drops when there is current. Although these voltage drops are not in phase with those caused by leakage reactance, together they result in a lower secondary voltage under load than is indicated by the transformer turns ratio. Thus, in a practical transformer, the greater the secondary current, the smaller the secondary terminal voltage becomes.

At ac line frequencies (50 or 60 Hz), the voltage at the secondary, with a reasonably well-designed iron-core transformer, should not drop more than about 10% from open-circuit conditions to full load. The voltage drop may be considerably more than this in a transformer operating at audio frequencies, because the leakage reactance increases with frequency.

In addition to wire resistances and leakage reactances, certain unwanted or “stray” capacitances occur in transformers. The wire forming the separate turns of the windings acts as the plates of a small capacitor, creating a capacitance between turns and between the windings. This *distributed capacitance* appears in Fig 2.95 as C_1 , C_2 , and C_m . Moreover, transformer windings can exhibit capacitance relative to nearby metal, for example, the chassis, the shield and even the core. When current flows through a winding, each turn has a slightly different voltage than its adjacent turns. This voltage causes a small current to flow in these *interwinding* and *winding-to-winding capacitances*.

Although stray capacitances are of little concern with power and audio transformers, they become important as the frequency increases. In transformers for RF use, the stray capacitance can resonate with either the leakage reactance or, at lower frequencies, with the winding reactances, L_1 or L_2 , especially under very light or zero loads. In the frequency region around resonance, transformers no longer exhibit the properties

formulated above or the impedance properties to be described below.

Iron-core transformers also experience losses within the core itself. *Hysteresis losses* include the energy required to overcome the retentivity of the core’s magnetic material. Circulating currents through the core’s resistance are *eddy currents*, which form part of the total core losses. These losses, which add to the required magnetizing current, are equivalent to adding a resistance in parallel with L_1 in Fig 2.95.

CORE CONSTRUCTION

Audio and power transformers usually employ silicon steel as the core material. With permeabilities of 5000 or greater, these cores saturate at flux densities approaching 10^5 (Mx) per square inch of cross section. The cores consist of thin insulated laminations to break up potential eddy current paths.

Each core layer consists of an “E” and an “I” piece butted together, as represented in Fig 2.96. The butt point leaves a small gap. Each layer is reversed from the adjacent layers so that each gap is next to a continuous magnetic path so that the effect of the gaps is minimized. This is different from the air-gapped inductor of Fig 2.49 in which the air gap is maintained for all layers of laminations.

Two core shapes are in common use, as shown in Fig 2.97. In the shell type, both windings are placed on the inner leg, while in the core type the primary and secondary windings may be placed on separate legs, if desired. This is sometimes done when it is necessary to minimize capacitance between the primary and secondary, or when one of the windings must operate at very high voltage.

The number of turns required in the primary for a given applied voltage is determined by the size, shape and type of core material used, as well as the frequency. The number of turns required is inversely proportional to the cross-sectional area of the core. As a rough indication, windings of small power transformers frequently have about six to eight turns per volt on a core of 1-square-inch cross section

Fig 2.96 — A typical transformer iron core. The E and I pieces alternate direction in successive layers to improve the magnetic path while attenuating eddy currents in the core.

Fig 2.97 — Two common transformer constructions: shell and core.

and have a magnetic path 10 or 12 inches in length. A longer path or smaller cross section requires more turns per volt, and vice versa.

In most transformers the windings are wound in layers, with a thin sheet of treated-paper insulation between each layer. Thicker insulation is used between adjacent windings and between the first winding and the core.

SHIELDING

Because magnetic lines of force are continuous loops, shielding requires a complete path for the lines of force of the leakage flux. The high-permeability of iron cores tends to concentrate the field, but additional shielding is often needed. As depicted in Fig 2.98, enclosing the transformer in a good magnetic material can restrict virtually all of the mag-

Fig 2.98 — A shielded transformer cross-section: the core plus an outer shield of magnetic material contain nearly all of the magnetic field.

netic field in the outer case. The nonmagnetic material between the case and the core creates a region of high reluctance, attenuating the field before it reaches the case.

2.14.2 Autotransformers

The transformer principle can be used with only one winding instead of two, as shown in **Fig 2.99A**. The principles that relate voltage, current and impedance to the turns ratio also apply equally well. A one-winding transformer is called an *auto-transformer*. The current in the common section (A) of the winding is the difference between the line (primary) and the load (secondary) currents, since these currents are out of phase. Hence, if the line and load currents are nearly equal, the common section of the winding may be wound with comparatively small wire. The line and load currents will be equal only when the primary

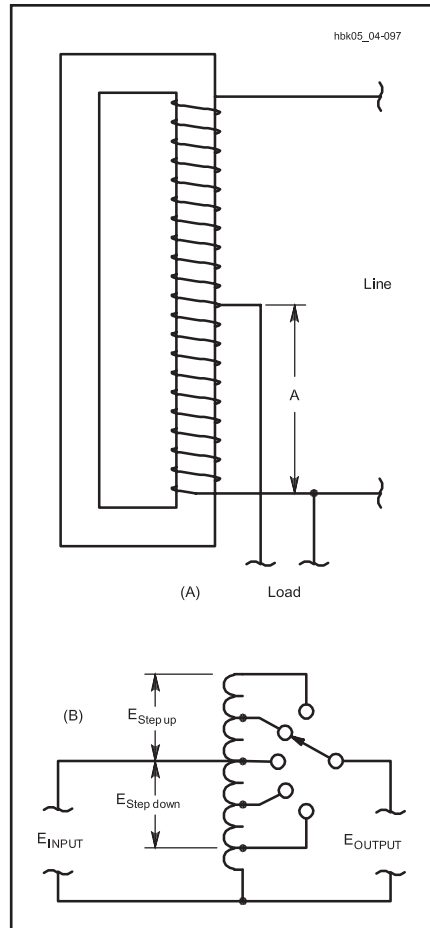

Fig 2.99 — The autotransformer is based on the transformer, but uses only one winding. The pictorial diagram at A shows the typical construction of an autotransformer. The schematic diagram at B demonstrates the use of an autotransformer to step up or step down ac voltage, usually to compensate for excessive or deficient line voltage.

ously variable autotransformers are commercially available under a variety of trade names; Variac and Powerstat are typical examples.

Technically, tapped air-core inductors, such as the one in the network in **Fig 2.90** at the close of the discussion of resonant circuits, are also autotransformers. The voltage from the tap to the bottom of the winding is less than the voltage across the entire winding. Likewise, the impedance of the tapped part of the winding is less than the impedance of the entire winding. Because in this case, leakage reactances are great and the coefficient of coupling is quite low, the relationships that are true in a perfect transformer grow quite unreliable in predicting the exact values. For this reason, tapped inductors are rarely referred to as transformers. The stepped-down situation in **Fig 2.90** is better approximated — at or close to resonance — by the formula

$$R_P = \frac{R_L X_{COM}^2}{X_L} \quad (139)$$

where

- R_P = tuned-circuit parallel-resonant impedance,
- R_L = load resistance tapped across part of the winding,
- X_{COM} = reactance of the portion of the winding common to both the resonant circuit and the load tap, and
- X_L = reactance of the entire winding.

The result is approximate and applies only to circuits with a Q of 10 or greater.

(line) and secondary (load) voltages are not very different.

Autotransformers are used chiefly for boosting or reducing the power-line voltage by relatively small amounts. **Fig 2.99B** illustrates the principle schematically with a switched, stepped autotransformer. Continu-

2.15 Heat Management

While not strictly an electrical fundamental, managing the heat generated by electronic circuits is important in nearly all types of radio equipment. Thus, the topic is included in this chapter. Information on the devices and circuits discussed in this section may be found in other chapters.

Any actual energized circuit consumes electric power because any such circuit contains components that convert electricity into other forms of energy. This dissipated power appears in many forms. For example, a loudspeaker converts electrical energy into sound, the motion of air molecules. An antenna (or a light bulb) converts electricity into electromagnetic radiation. Charging a

battery converts electrical energy into chemical energy (which is then converted back to electrical energy upon discharge). But the most common transformation by far is the conversion, through some form of resistance, of electricity into heat.

Sometimes the power lost to heat serves a useful purpose — toasters and hair dryers come to mind. But most of the time, this heat represents a power loss that is to be minimized wherever possible or at least taken into account. Since all real circuits contain resistance, even those circuits (such as a loudspeaker) whose primary purpose is to convert electricity to some *other* form of energy also convert some part of their input power to heat.

Often, such losses are negligible, but sometimes they are not.

If unintended heat generation becomes significant, the involved components will get warm. Problems arise when the temperature increase affects circuit operation by either

- causing the component to fail, by explosion, melting, or other catastrophic event, or, more subtly,
- causing a slight change in the properties of the component, such as through a temperature coefficient (TC).

In the first case, we can design conservatively, ensuring that components are rated to safely handle two, three or more times the maximum power we expect them to dissipate.

In the second case, we can specify components with low TCs, or we can design the circuit to minimize the effect of any one component. Occasionally we even exploit temperature effects (for example, using a resistor, capacitor or diode as a temperature sensor). Let's look more closely at the two main categories of thermal effects.

Not surprisingly, heat dissipation (more correctly, the efficient removal of generated heat) becomes important in medium- to high-power circuits: power supplies, transmitting circuits and so on. While these are not the only examples where elevated temperatures and related failures are of concern, the techniques we will discuss here are applicable to all circuits.

2.15.1 Thermal Resistance

The transfer of heat energy, and thus the change in temperature, between two ends of a block of material is governed by the following heat flow equation and illustrated in Fig 2.100):

$$P = \frac{kA}{L} \Delta T = \frac{\Delta T}{\theta} \quad (140)$$

where

P = power (in the form of heat) conducted between the two points

k = *thermal conductivity*, measured in $W/(m \text{ } ^\circ C)$, of the material between the two points, which may be steel, silicon, copper, PC board material and so on

L = length of the block

A = area of the block, and

ΔT = *difference* in temperature between the two points.

Thermal conductivities of various common materials at room temperature are given in Table 2.13.

The form of equation 140 is the same as the variation of Ohm's Law relating current flow to the ratio of a difference in potential to resistance; $I = E/R$. In this case, what's flowing is heat (P), the difference in potential is a temperature difference (ΔT), and what's resisting the flow of heat is the *thermal resistance*;

$$\theta = \frac{L}{kA} \quad (141)$$

with units of $^\circ C/W$. (The units of resistance are equivalent to V/A .) The analogy is so apt that the same principles and methods apply to heat flow problems as circuit problems. The following correspondences hold:

- Thermal conductivity $W/(m \text{ } ^\circ C) \leftrightarrow$ Electrical conductivity (S/m).

- Thermal resistance ($^\circ C/W$) \leftrightarrow Electrical resistance (Ω).

- Thermal current (heat flow) (W) \leftrightarrow Electrical current (A).

Table 2.13

Thermal Conductivities of Various Materials

Gases at 0 $^\circ C$, Others at 25 $^\circ C$; from *Physics*, by Halliday and Resnick, 3rd Ed.

Material	k in units of $W/m^\circ C$
Aluminum	200
Brass	110
Copper	390
Lead	35
Silver	410
Steel	46
Silicon	150
Air	0.024
Glass	0.8
Wood	0.08

Fig 2.100 — Physical and "circuit" models for the heat-flow equation.

- Thermal potential (T) \leftrightarrow Electrical potential (V).

- Heat source \leftrightarrow Power source.

For example, calculate the temperature of a 2-inch (0.05 m) long piece of #12 copper wire at the end that is being heated by a 25 W (input power) soldering iron, and whose other end is clamped to a large metal vise (assumed to be an infinite heat sink), if the ambient temperature is 25 $^\circ C$ (77 $^\circ F$).

First, calculate the thermal resistance of the copper wire (diameter of #12 wire is 2.052 mm, cross-sectional area is $3.31 \times 10^{-6} m^2$)

$$\theta = \frac{L}{kA} = \frac{(0.05 \text{ m})}{(390 \text{ W}/(m \text{ } ^\circ C)) \times (3.31 \times 10^{-6} m^2)}$$

$$= 38.7 \text{ } ^\circ C/W$$

Then, rearranging the heat flow equation above yields (after assuming the heat energy actually transferred to the wire is around 10 W)

$$\Delta T = P \theta = (10 \text{ W}) \times (38.7 \text{ } ^\circ C / W) = 387 \text{ } ^\circ C$$

So the wire temperature at the hot end is $25 \text{ } ^\circ C + \Delta T = 412 \text{ } ^\circ C$ (or 774 $^\circ F$). If this sounds

a little high, remember that this is for the steady state condition, where you've been holding the iron to the wire for a long time.

From this example, you can see that things can get very hot even with application of moderate power levels. For this reason, circuits that generate sufficient heat to alter, not necessarily damage, the components must employ some method of cooling, either active or passive. Passive methods include heat sinks or careful component layout for good ventilation. Active methods include forced air (fans) or some sort of liquid cooling (in some high-power transmitters).

2.15.2 Heat Sink Selection and Use

The purpose of a heat sink is to provide a high-power component with a large surface area through which to dissipate heat. To use the models above, it provides a low thermal-resistance path to a cooler temperature, thus allowing the hot component to conduct a large "thermal current" away from itself.

Power supplies probably represent one of the most common high-power circuits amateurs are likely to encounter. Everyone has certainly noticed that power supplies get warm or even hot if not ventilated properly. Performing the thermal design for a properly cooled power supply is a very well-defined process and is a good illustration of heat-flow concepts.

This material was originally prepared by ARRL Technical Advisor Dick Jansson, KD1K, during the design of a 28-V, 10-A power supply. (The chapter **Analog Basics** discusses semiconductor diodes, rectifiers, and transistors. The **Power Sources** chapter has more information on power supply design.) An outline of the design procedure shows the logic applied:

1. Determine the expected power dissipation (P_{in}).
2. Identify the requirements for the dissipating elements (maximum component temperature).
3. Estimate heat-sink requirements.
4. Rework the electronic device (if necessary) to meet the thermal requirements.
5. Select the heat exchanger (from heat sink data sheets).

The first step is to estimate the filtered, unregulated supply voltage under full load. Since the transformer secondary output is 32 V ac (RMS) and feeds a full-wave bridge rectifier, let's estimate 40 V as the filtered dc output at a 10-A load.

The next step is to determine our critical components and estimate their power dissipations. In a regulated power supply, the pass transistors are responsible for nearly all the power lost to heat. Under full load, and allowing for some small voltage drops in the

Fig 2.101 — Resistive model of thermal conduction in a power transistor and associated heat sink. See text for calculations.

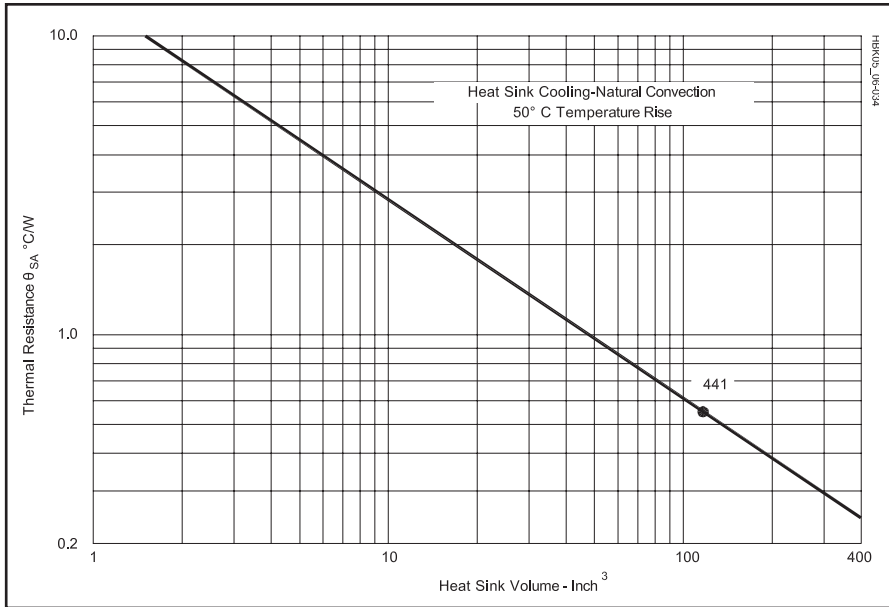

Fig 2.102 — Thermal resistance vs heat-sink volume for natural convection cooling and 50 °C temperature rise. The graph is based on engineering data from Wakefield Thermal Solutions, Inc.

power-transistor emitter circuitry, the output of the series pass transistors is about 29 V for a delivered 28 V under a 10-A load. With an unregulated input voltage of 40 V, the total energy heat dissipated in the pass transistors is $(40\text{ V} - 29\text{ V}) \times 10\text{ A} = 110\text{ W}$. The heat sink for this power supply must be able to handle that amount of dissipation and still keep the transistor junctions below the specified safe operating temperature limits. It is a good rule of thumb to select a transistor that has a maximum power dissipation of twice the desired output power.

Now, consider the ratings of the pass transistors to be used. This supply calls for 2N3055s as pass transistors. The data sheet shows that a 2N3055 is rated for 15-A service and 115-W dissipation. But the design uses *four* in parallel. Why? Here we must look past the big, bold type at the top of the data sheet to such subtle characteristics as the junction-to-case thermal resistance, θ_{jc} , and the maximum allowable junction temperature, T_j .

The 2N3055 data sheet shows $\theta_{jc} = 1.52\text{ }^\circ\text{C/W}$, and a maximum allowable case (and junction) temperature of 220 °C. While it seems that one 2N3055 could barely, on paper

at least, handle the electrical requirements — at what temperature would it operate?

To answer that, we must model the entire “thermal circuit” of operation, starting with the transistor junction on one end and ending at some point with the ambient air. A reasonable model is shown in **Fig 2.101**. The ambient air is considered here as an infinite heat sink; that is, its temperature is assumed to be a constant 25 °C (77 °F). θ_{jc} is the thermal resistance from the transistor junction to its case. θ_{cs} is the resistance of the mounting interface between the transistor case and the heat sink. θ_{sa} is the thermal resistance between the heat sink and the ambient air. In this “circuit,” the generation of heat (the “thermal current source”) occurs in the transistor at P_{in} .

Proper mounting of most TO-3 package power transistors such as the 2N3055 requires that they have an electrical insulator between the transistor case and the heat sink. However, this electrical insulator must at the same time exhibit a low thermal resistance. To achieve a quality mounting, use thin polyimide or mica formed washers and a suitable thermal compound to exclude air from the interstitial space. “Thermal greases” are commonly

available for this function. Any silicone grease may be used, but filled silicone oils made specifically for this purpose are better.

Using such techniques, a conservatively high value for θ_{cs} is 0.50 °C/W. Lower values are possible, but the techniques needed to achieve them are expensive and not generally available to the average amateur. Furthermore, this value of θ_{cs} is already much lower than θ_{jc} , which cannot be lowered without going to a somewhat more exotic pass transistor.

Finally, we need an estimate of θ_{sa} .

Fig 2.102 shows the relationship of heat-sink volume to thermal resistance for natural-convection cooling. This relationship presumes the use of suitably spaced fins (0.35 inch or greater) and provides a “rough order-of-magnitude” value for sizing a heat sink. For a first calculation, let’s assume a heat sink of roughly $6 \times 4 \times 2$ inch (48 cubic inches). From **Fig 2.102**, this yields a θ_{sa} of about 1 °C/W.

Returning to **Fig 2.101**, we can now calculate the approximate temperature increase of a single 2N3055:

$$\begin{aligned} \delta T &= P \theta_{total} \\ &= 110\text{ W} \times (1.52\text{ }^\circ\text{C/W} + 0.5\text{ }^\circ\text{C/W} + 1.0\text{ }^\circ\text{C/W}) \\ &= 332\text{ }^\circ\text{C} \end{aligned}$$

Given the ambient temperature of 25 °C, this puts the junction temperature T_j of the 2N3055 at $25 + 332 = 357\text{ }^\circ\text{C}$! This is clearly too high, so let’s work backward from the air end and calculate just how many transistors we need to handle the heat.

First, putting more 2N3055s in parallel means that we will have the thermal model illustrated in **Fig 2.103**, with several identical θ_{jc} and θ_{cs} in parallel, all funneled through the same θ_{as} (we have one heat sink).

Keeping in mind the physical size of the project, we could comfortably fit a heat sink of approximately 120 cubic inches ($6 \times 5 \times 4$ inches), well within the range of commercially available heat sinks. Furthermore, this application can use a heat sink where only “wire access” to the transistor connections is required. This allows the selection of a more efficient design. In contrast, RF designs require the transistor mounting surface to be completely exposed so that the PC board can be mounted close to the transistors to minimize parasitics. Looking at **Fig 2.102**, we see that a 120-cubic-inch heat sink yields a θ_{sa} of 0.55 °C/W. This means that the temperature of the heat sink when dissipating 110 W will be $25\text{ }^\circ\text{C} + (110\text{ W} \times 0.55\text{ }^\circ\text{C/W}) = 85.5\text{ }^\circ\text{C}$.

Industrial experience has shown that silicon transistors suffer substantial failure when junctions are operated at highly elevated temperatures. Most commercial and military specifications will usually not permit design junction temperatures to exceed 125 °C. To arrive at a safe figure for our maximum

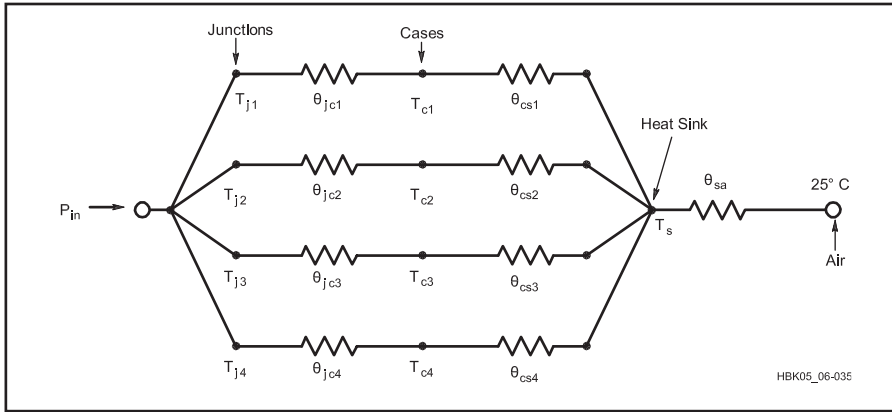

Fig 2.103 — Thermal model for multiple power transistors mounted on a common heat sink.

allowed T_j , we must consider the intended use of the power supply. If we are using it in a 100% duty-cycle transmitting application such as RTTY or FM, the circuit will be dissipating 110 W continuously. For a lighter duty-cycle load such as CW or SSB, the “key-down” temperature can be slightly higher as long as the average is less than 125 °C. In this intermittent type of service, a good conservative figure to use is $T_j = 150$ °C.

Given this scenario, the temperature rise across each transistor can be $150 - 85.5 = 64.5$ °C. Now, referencing Fig 2.103, remembering the total θ for each 2N3055 is $1.52 + 0.5 = 2.02$ °C/W, we can calculate the maximum power each 2N3055 can safely dissipate:

$$P = \frac{\delta T}{\theta} = \frac{64.5 \text{ °C}}{2.02 \text{ °C/W}} = 31.9 \text{ W}$$

Thus, for 110 W full load, we need four 2N3055s to meet the thermal requirements of the design. Now comes the big question:

What is the “right” heat sink to use? We have already established its requirements: it must be capable of dissipating 110 W, and have a θ_{sa} of 0.55 °C/W (see above).

A quick consultation with several manufacturer’s catalogs reveals that Wakefield Thermal Solutions, Inc. model nos. 441 and 435 heat sinks meet the needs of this application. A Thermalloy model no. 6441 is suitable as well. Data published in the catalogs of these manufacturers show that in natural-convection service, the expected temperature rise for 100 W dissipation would be just under 60 °C, an almost perfect fit for this application. Moreover, the no. 441 heat sink can easily mount four TO-3-style 2N3055 transistors as shown in Fig 2.104. Remember: heat sinks should be mounted with the fins and transistor mounting area vertical to promote convection cooling.

The design procedure just described is applicable to any circuit where heat buildup is a potential problem. By using the thermal-

Fig 2.104 — A Wakefield 441 heat sink with four 2N3055 transistors mounted.

resistance model, we can easily calculate whether or not an external means of cooling is necessary, and if so, how to choose it. Aside from heat sinks, forced air cooling (fans) is another common method. In commercial transceivers, heat sinks with forced-air cooling are common.

2.15.3 Transistor Derating

Maximum ratings for power transistors are usually based on a case temperature of 25 °C. These ratings will decrease with increasing operating temperature. Manufacturer’s data sheets usually specify a *derating* figure or curve that indicates how the maximum ratings change per degree rise in temperature. If such information is not available (or even if it is!), it is a good rule of thumb to select a power transistor with a maximum power dissipation of at least twice the desired output power.

2.15.4 Rectifiers

Diodes are physically quite small, and they operate at high current densities. As a result their heat-handling capabilities are somewhat limited. Normally, this is not a problem in high-voltage, low-current supplies in which rectifiers in axial-lead DO-type packages are used. (See the **Component Data and References** chapter for information on device packages.) The use of high-current (2 A or greater) rectifiers at or near their maximum ratings, however, requires some form of heat sinking. The average power dissipated by a rectifier is

$$P = I_{AVG} \times V_F \tag{142}$$

where

I_{AVG} is the average current, and V_F is the forward voltage drop.

Average current must account for the conduction duty cycle and the forward voltage drop must be determined at the average current level.

Rectifiers intended for such high-current applications are available in a variety of packages suitable for mounting to flat surfaces. Frequently, mounting the rectifier on the main chassis (directly, or with thin mica insulating washers) will suffice. If the diode is insulated from the chassis, thin layers of thermal compound or thermal insulating washers should be used to ensure good heat conduction. Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling is sometimes used as a further aid.

2.15.5 RF Heating

RF current often causes component heating problems where the same level of dc current may not. An example is the tank circuit of

an RF oscillator. If several small capacitors are connected in parallel to achieve a desired capacitance, skin effect will be reduced and the total surface area available for heat dissipation will be increased, thus significantly reducing the RF heating effects as compared to a single large capacitor. This technique can be applied to any similar situation; the general idea is to divide the heating among as many components as possible.

2.15.6 Forced-Air and Water Cooling

In Amateur Radio today, forced-air cooling is most commonly found in vacuum-tube circuits or in power supplies built in small enclosures, such as those in solid-state transceivers or computers. Fans or blowers are commonly specified in cubic feet per minute (CFM). While the nomenclature and specifications differ from those used for heat sinks, the idea remains the same: to offer a low thermal resistance between the inside of the enclosure and the (ambient) exterior.

For forced air cooling, we basically use the “one resistor” thermal model of Fig 2.100. The important quantity to be determined is heat generation, P_{in} . For a power supply, this can be easily estimated as the difference between the input power, measured at the transformer primary, and the output power at full load. For variable-voltage supplies, the worst-case output condition is minimum voltage with maximum current. A discussion of forced-air cooling for vacuum tube equipment appears in the **RF Power Amplifiers** chapter.

Dust build-up is a common problem for forced-air cooling systems, even with powerful blowers and fans. If air intake grills and vents are not kept clean and free of lint and debris, air flow can be significantly reduced, leading to excessive equipment temperature and premature failure. Cleaning of air passageways should be included in regular equipment maintenance for good performance and maximum equipment life.

Water cooling systems are much less common in amateur equipment, used primarily for high duty cycle operating, such as RTTY, and at frequencies where the efficiency of the amplifier is relatively low, such as UHF and microwaves. In these situations, water cooling is used because water can absorb and transfer more than 3000 times as much heat as the same volume of air!

The main disadvantage of water cooling is that it requires pumps, hoses, and reservoirs whereas a fan or blower is all that is required for forced-air cooling. For high-voltage circuits, using water cooling also requires special insulation techniques and materials to allow water to circulate in close contact with the heat source while remaining electrically isolated.

Nevertheless, the technique can be effective.

The increased availability of inexpensive materials designed for home sprinkler and other low-pressure water distribution systems make water-cooling less difficult to implement. It is recommended that the interested reader review articles and projects in the amateur literature to observe the successful implementation of water cooling systems.

2.15.7 Heat Pipe Cooling

A heat pipe is a device containing a *working fluid* in a reservoir where heat is absorbed and a channel to a second reservoir where heat is dissipated. Heat pipes work by *evaporative cooling*. The heat-absorbing reservoir is placed in thermal contact with the heat source which transfers heat to the working fluid, usually a liquid substance with a boiling point just above room temperature. The working fluid vaporizes and the resulting vapor pressure pushes the hot vapor through the channel to the cooling reservoir.

In the cooling reservoir, the working fluid gives up its heat of vaporization, returning to the fluid state. The cooled fluid then flows back through the channel to the heat-absorbing reservoir where the process is repeated.

Heat pipes require no fans or pumps — movement of the working fluid is driven entirely from the temperature difference between the two reservoirs. The higher the temperature difference between the absorbing and dissipating reservoirs, the more effective the heat pump becomes, up to the limit of the dissipating reservoir to dissipate heat.

The principle application for heat pipes is for space operations. Heat pipe applications in terrestrial applications are limited due to the gravity gradient sensitivity of heat pipes. At present, the only amateur equipment making use of heat pipes are computers and certain amplifier modules. Nevertheless, as more general-purpose products become available, this technique will become more common.

2.15.8 Thermoelectric Cooling

Thermoelectric cooling makes use of the *Peltier effect* to create heat flow across the junction of two different types of materials. This process is related to the *thermoelectric effect* by which thermocouples generate voltages based on the temperature of a similar junction. A *thermoelectric cooler* or *TEC* (also known as a *Peltier cooler*) requires only a source of dc power to cause one side of the device to cool and the other side to warm. TECs are available with different sizes and power ratings for different applications.

TECs are not available with sufficient heat transfer capabilities that they can be used in high-power applications, such as RF ampli-

fiers. However, they can be useful in lowering the temperature of sensitive receiver circuits, such as preamplifiers used at UHF and microwave frequencies, or imaging devices, such as charge-coupled devices (CCDs). Satellites use TECs as *radiative coolers* that dissipate heat directly as thermal or infrared radiation. TECs are also found in some computing equipment where they are used to remove heat from microprocessors and other large integrated circuits.

2.15.9 Temperature Compensation

Aside from catastrophic failure, temperature changes may also adversely affect circuits if the temperature coefficient (TC) of one or more components is too large. If the resultant change is not too critical, adequate temperature stability can often be achieved simply by using higher-precision components with low TCs (such as NPO/COG capacitors or metal-film resistors). For applications where this is impractical or impossible (such as many solid-state circuits), we can minimize temperature sensitivity by *compensation* or *matching* — using temperature coefficients to our advantage.

Compensation is accomplished in one of two ways. If we wish to keep a certain circuit quantity constant, we can interconnect pairs of components that have equal but opposite TCs. For example, a resistor with a negative TC can be placed in series with a positive TC resistor to keep the total resistance constant. Conversely, if the important point is to keep the *difference* between two quantities constant, we can use components with the *same* TC so that the pair “tracks.” That is, they both change by the same amount with temperature.

An example of this is a Zener reference circuit. Since a diode is strongly affected by operating temperature, circuits that use diodes or transistors to generate stable reference voltages must use some form of temperature compensation. Since, for a constant current, a reverse-biased PN junction has a negative voltage TC while a forward-biased junction has a positive voltage TC, a good way to temperature-compensate a Zener reference diode is to place one or more forward-biased diodes in series with it.

2.15.10 Thermistors

Thermistors can be used to control temperature and improve circuit behavior or protect against excessive temperatures, hot or cold. Circuit temperature variations can affect gain, distortion or control functions like receiver AGC or transmitter ALC. Thermistors can be used in circuits that compensate for temperature changes.

A *thermistor* is a small bit of intrinsic (no N or P doping) metal-oxide semiconductor compound material between two wire leads. As temperature increases, the number of

liberated hole/electron pairs increases exponentially, causing the resistance to decrease exponentially. You can see this in the resistance equation:

$$R(T) = R(T_0)e^{-\beta(1/T_0 - 1/T)} \quad (143)$$

where T is some temperature in Kelvins and T₀ is a reference temperature, usually 298 K (25°C), at which the manufacturer specifies R(T₀).

The constant β is experimentally determined by measuring resistance at various tem-

peratures and finding the value of β that best agrees with the measurements. A simple way to get an approximate value of β is to make two measurements, one at room temperature, say 25 °C (298 K) and one at 100 °C (373 K) in boiling water. Suppose the resistances are 10 kΩ and 938 Ω. Eq 143 is solved for β

$$\beta = \frac{\ln\left(\frac{R(T)}{R(T_0)}\right)}{\frac{1}{T} - \frac{1}{T_0}} = \frac{\ln\left(\frac{938}{1000}\right)}{\frac{1}{373} - \frac{1}{298}} = 3507 \quad (144)$$

With the behavior of the thermistor known — either by equation or calibration table — its change in resistance can be used to create an electronic circuit whose behavior is controlled by temperature in a known fashion. Such a circuit can be used for controlling temperature or detecting specific temperatures.

See “Thermistors in Homebrew Projects” by Bill Sabin, WØIYH, and “Thermistor Based Temperature Controller” by Bill Sabin, WØIYH on this book’s CD-ROM for practical projects using thermistors.

Analog Basics

The first section of this chapter discusses a variety of techniques for working with analog signals, called signal processing. These basic functions are combined to produce useful systems that become radios, instruments, audio recorders and so on.

Subsequent sections present several types of active components and circuits that can be used to manipulate analog signals. (An active electronic component is one that requires a power source to function; passive components such as resistors, capacitors and inductors are described in the **Electrical Fundamentals** chapter.)

The chapter concludes with a discussion of analog-digital conversion by which analog signals are converted into digital signals and vice versa.

Material in this chapter was updated by Ward Silver, NØAX, and Courtney Duncan, N5BF, building on material from previous editions by Greg Lapin, N9GL, and Leonard Kay, K1NU.

The section “Poles and Zeroes” was adapted from material contributed by David Stockton, GM4ZNX and Fred Telewski, WA7TZY.

3.1 Analog Signal Processing

The term *analog signal* refers to voltages, currents and waves that make up ac radio and audio signals, dc measurements, even power. The essential characteristic of an analog signal is that the information or energy it carries is continuously variable. Even small variations of an analog signal affect its value or the information it carries. This stands in contrast to *digital signals* (described in the **Digital Basics** chapter) that have values only within well-defined and separate ranges called *states*. To be sure, at the fundamental level all circuits and signals are analog: Digital signals are created by designing circuits that restrict the values of analog signals to those discrete states.

Analog signal processing involves various electronic stages to perform functions on analog signals such as amplifying, filtering, modulation and demodulation. A piece of electronic equipment, such as a radio, is constructed by combining a number of these circuits. How these stages interact with each other and how they affect the signal individually and in tandem is the subject of sections later in the chapter.

3.1.1 Linearity

The premier properties of analog signals are *superposition* and *scaling*. Superposition is the property by which signals are combined, whether in a circuit, in a piece of wire, or even in air, as the sum of the individual signals. This is to say that at any one point in time, the voltage of the combined signal is the sum of the voltages of the original signals at the same time. In a *linear system* any number of signals will add in this way to give a single combined signal. (Mathematically, this is a *linear combination*.) For this reason, analog signals and components are often referred to as *linear signals* or *linear components*. A linear system whose characteristics do not change, such as a resistive voltage divider, is called *time-invariant*. If the system changes with time, it is *time-varying*. The variations may be random, intermittent (such as being adjusted by an operator) or periodic.

One of the more important features of superposition, for the purposes of signal processing, is that signals that have been combined by superposition can be separated back into the original signals. This is what allows multiple signals that have been received by an antenna to be separated back into individual signals by a receiver.

3.1.2 Linear Operations

Any operation that modifies a signal and obeys the rules of superposition and scaling is a *linear operation*. The following sections explain the basic linear operations from which linear systems are made.

AMPLIFICATION AND ATTENUATION

Amplification and *attenuation* scale signals to be larger and smaller, respectively. The operation of *scaling* is the same as multiplying the signal at each point in time by a constant value; if the constant is greater than one then the signal is amplified, if less than one then the signal is attenuated.

An *amplifier* is a circuit that increases the amplitude of a signal. Schematically, a generic

amplifier is signified by a triangular symbol, its input along the left face and its output at the point on the right (see Fig 3.1). The linear amplifier multiplies every value of a signal by a constant value. Amplifier gain is often expressed as a multiplication factor ($\times 5$, for example).

$$\text{Gain} = \frac{V_o}{V_i} \quad (1)$$

where V_o is the output voltage from an amplifier when an input voltage, V_i , is applied. (Gain is often expressed in decibels (dB) as explained in the chapter on **Electrical Fundamentals**.)

Certain types of amplifiers for which currents are the input and output signals have *current gain*. Most amplifiers have both voltage and current gain. *Power gain* is the ratio of output power to input power.

Ideal linear amplifiers have the same gain for all parts of a signal. Thus, a gain of 10 changes 10 V to 100 V, 1 V to 10 V and -1 V to -10 V. (Gain can also be less than one.) The ability of an amplifier to change a signal's level is limited by the amplifier's *dynamic range*, however. An amplifier's dynamic range is the range of signal levels over which the amplifier produces the required gain without distortion. Dynamic range is limited for small signals by noise, distortion and other nonlinearities.

Dynamic range is limited for large signals because an amplifier can only produce out-

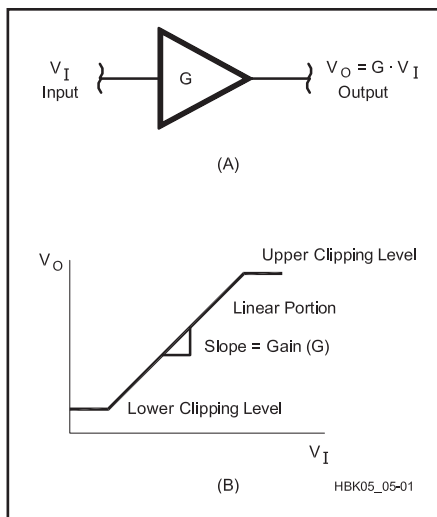

Fig 3.1 — Generic amplifier. (A) Symbol. For the linear amplifier, gain is the constant value, G , and the output voltage is equal to the input voltage times G ; (B) Transfer function, input voltage along the x-axis is converted to the output voltage along the y-axis. The linear portion of the response is where the plot is diagonal; its slope is equal to the gain, G . Above and below this range are the clipping limits, where the response is not linear and the output signal is clipped.

Obtaining a Frequency Response

With the computer tools such as spreadsheets, it's easy to do the calculations and make a graph of frequency response. If you don't have a spreadsheet program, then use semi-log graph paper with the linear axis used for dB or phase and the logarithmic axis for frequency. An Excel spreadsheet set up to calculate and display frequency response is available on the CD that comes with this book. You can modify it to meet your specific needs.

Follow these rules whether using a spreadsheet or graph paper:

- Measure input and output in the same units, such as volts, and use the same conventions, such as RMS or peak-to-peak.
 - Measure phase shift from the input to the output. (The **Test Equipment and Measurements** chapter discusses how to make measurements of amplitude and phase.)
 - Use $10 \log (P_o/P_i)$ for power ratios and $20 \log (V_o/V_i)$ for voltage or current.
- To make measurements that are roughly equally spaced along the logarithmic frequency axis, follow the "1-2-5 rule." Dividing a range this way, for example 1-2-5-10-20-50-100-200-500 Hz, creates steps in approximately equal ratios that then appear equally spaced on a logarithmic axis.

put voltages (and currents) that are within the range of its power supply. (Power-supply voltages are also called the *rails* of a circuit.) As the amplified output approaches one of the rails, the output can not exceed a given voltage near the rail and the operation of the amplifier becomes nonlinear as described below in the section on Clipping and Rectification.

Another similar limitation on amplifier lin-

earity is called *slew rate*. Applied to an amplifier, this term describes the maximum rate at which a signal can change levels and still be accurately amplified in a particular device. *Input slew rate* is the maximum rate of change to which the amplifier can react linearly. *Output slew rate* refers to the maximum rate at which the amplifier's output circuit can change. Slew rate is an important concept, because there is

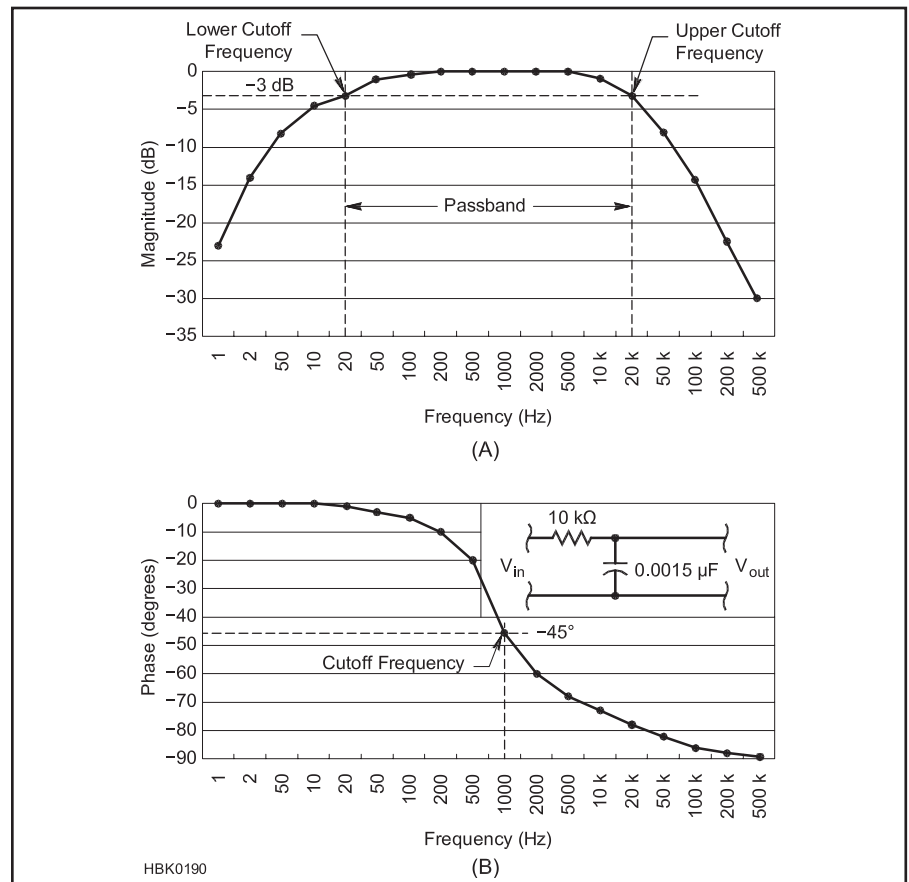

Fig 3.2 — Bode plot of (A) band-pass filter magnitude response and (B) an RC low-pass filter phase response.

a direct correlation between a signal level's rate of change and the frequency content of that signal. The amplifier's ability to react to or reproduce that rate of change affects its frequency response and dynamic range.

An *attenuator* is a circuit that reduces the amplitude of a signal. Attenuators can be constructed from passive circuits, such as the attenuators built using resistors, described in the chapter on **Test Equipment and Measurements**. Active attenuator circuits include amplifiers whose gain is less than one or circuits with adjustable resistance in the signal path, such as a PIN diode attenuator or amplifier with gain is controlled by an external voltage.

FREQUENCY RESPONSE AND BODE PLOTS

Another important characteristic of a circuit is its *frequency response*, a description of how it modifies a signal of any frequency. Frequency response can be stated in the form of a mathematical equation called a *transfer function*, but it is more conveniently presented as a graph of gain vs frequency. The ratio of output amplitude to input amplitude is often called the circuit's *magnitude* or *amplitude response*. Plotting the circuit's magnitude response in dB versus frequency on a logarithmic scale, such as in **Fig 3.2A**, is called a *Bode plot* (after Henrik Wade Bode). The combination of decibel and log-frequency scales is used because the behavior of most circuits depends on ratios of amplitude and frequency and thus appears linear on a graph in which both the vertical and horizontal scales are logarithmic.

Most circuits also affect a signal's phase along with its amplitude. This is called *phase shift*. A plot of phase shift from the circuit's input to its output is called the *phase response*, seen in **Fig 3.2B**. Positive phase greater than 0° indicates that the output signal *leads* the input signal, while *lagging* phase shift has a negative phase. The combination of an amplitude and phase response plot gives a good picture of what effect the circuit has on signals passing through it.

TRANSFER CHARACTERISTICS

Transfer characteristics are the ratio of an output parameter to an input parameter, such as output current divided by input current, h_{FE} . There are different families of transfer characteristics, designated by letters such as h, s, y or z. Each family compares parameters in specific ways that are useful in certain design or analysis methods. The most common transfer characteristics used in radio are the h-parameter family (used in transistor models) and the s-parameter family (used in RF design, particularly at VHF and above). See the **RF Techniques** chapter for more discussion of transfer characteristics.

COMPLEX FREQUENCY

We are accustomed to thinking of frequency as a real number — so many cycles per second — but frequency can also be a complex number, s , with both a real part, designated by σ , and an imaginary part, designated by $j\omega$. (ω is also equal to $2\pi f$.) The resulting complex frequency is written as $s = \sigma + j\omega$. At the lower left of **Fig 3.3** a pair of real and imaginary axes are used to plot values of s . This is called the *s-plane*. Complex frequency is used in Laplace transforms, a mathematical technique used for circuit and signal analysis. (Thorough treatments of the application of complex frequency can be found in college-level textbooks on circuit and signal analysis.)

When complex frequency is used, a sinusoidal signal is described by Ae^{st} , where A is the amplitude of the signal and t is time. Because s is complex, $Ae^{st} = Ae^{(\sigma + j\omega)t} = A(e^{\sigma t})(e^{j\omega t})$. The two exponential terms describe independent characteristics of the signal. The second term, $e^{j\omega t}$, is the sine

wave with which we are familiar and that has frequency f , where $f = \omega/2\pi$. The first term, $e^{\sigma t}$, represents the rate at which the signal increases or decreases. If σ is negative, the exponential term decreases with time and the signal gets smaller and smaller. If σ is positive, the signal gets larger and larger. If $\sigma = 0$, the exponential term equals 1, a constant, and the signal amplitude stays the same.

Complex frequency is very useful in describing a circuit's stability. If the response to an input signal is at a frequency on the right-hand side of the s -plane for which $\sigma > 0$, the system is *unstable* and the output signal will get larger until it is limited by the circuit's power supply or some other mechanism. If the response is on the left-hand side of the s -plane, the system is *stable* and the response to the input signal will eventually die out. The larger the absolute value of σ , the faster the response changes. If the response is precisely on the $j\omega$ axis where $\sigma = 0$, the response will persist indefinitely.

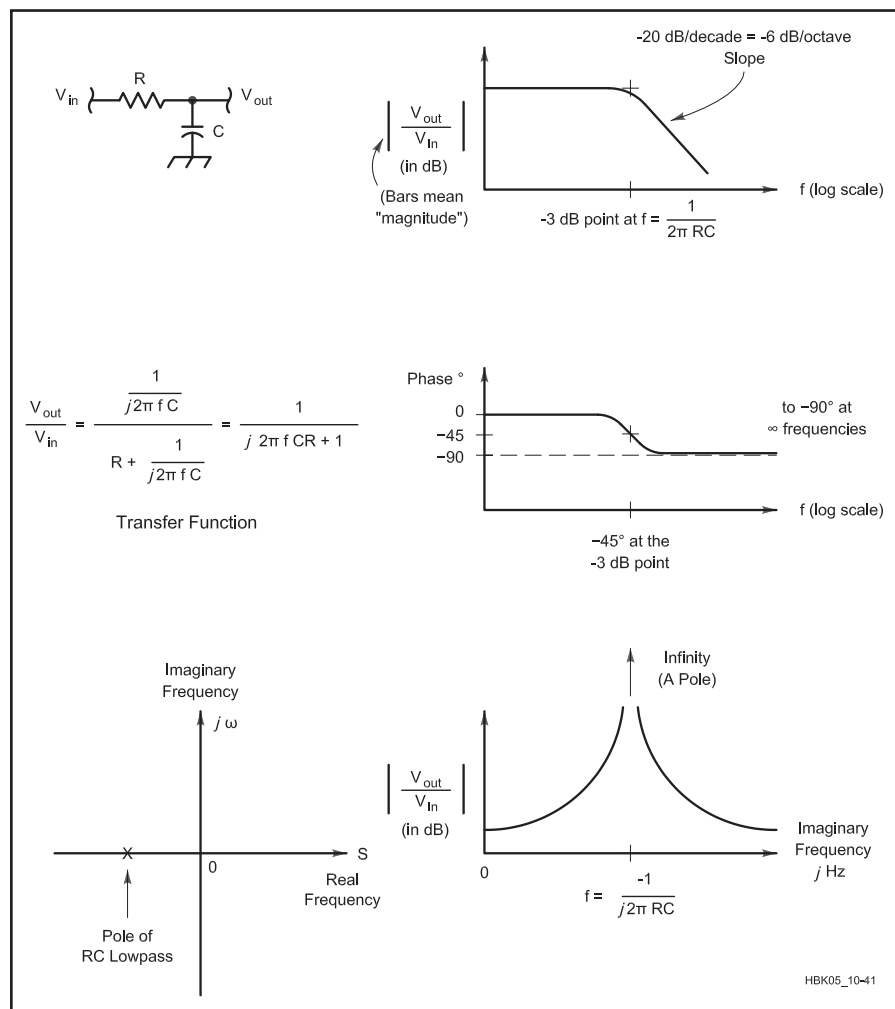

Fig 3.3 — The transfer function for a circuit describes both the magnitude and phase response of a circuit. The RC circuit shown at the upper left has a pole at $f = 2\pi RC$, the filter's -3 dB or cutoff frequency, at which the phase response is a 45° lagging phase shift. Poles cause an infinite response on the imaginary frequency axis.

In Fig 3.3 the equation for the simple RC-circuit's transfer function is shown at the left of the figure. It describes the circuit's behavior at real-world frequencies as well as imaginary frequencies whose values contain j . Because complex numbers are used for f , the transfer function describes the circuit's phase response, as well as amplitude. At one such frequency, $f = -j/2\pi RC$, the denominator of the transfer function is zero, and the gain is infinite! Infinite gain is a pretty amazing thing to achieve with a passive circuit — but because this can only happen at an imaginary frequency, it does not happen in the real world.

The practical effects of complex frequency can be experienced in a narrow CW crystal or LC filter. The poles of such a filter are just to the left of the $j\omega$ axis, so the input signal causes the filters to “ring”, or output a damped sine wave along with the desired signal. Similarly, the complex frequency of an oscillator's output at power-up must have $\sigma > 0$ or the oscillation would never start! The output amplitude continues to grow until limiting takes place, reducing gain until $\sigma = 1$ for a steady output.

POLES AND ZEROES

Frequencies that cause the transfer function to become infinite are called *poles*. This is shown at the bottom right of Fig 3.3 in the graph of the circuit's amplitude response for imaginary frequencies shown on the horizontal axis. (The pole causes the graph to extend up “as a pole under a tent,” thus the name.) Similarly, circuits can have *zeroes* which occur at imaginary frequencies that cause the transfer function to be zero, a less imaginative name, but quite descriptive.

A circuit can also have poles and zeroes at frequencies of zero and infinity. For example, the circuit in Fig 3.3 has a zero at infinity because the capacitor's reactance is zero at infinity and the transfer function is zero, as well. If the resistor and capacitor were exchanged, so that the capacitor was in series with the output, then at zero frequency (dc), the output would be zero because the capacitor's reactance was infinite, creating a zero.

Complex circuits can have multiple poles or multiple zeroes at the same frequency. Poles and zeroes can also occur at frequencies that are combinations of real and imaginary numbers. The poles and zeroes of a circuit form a pattern in the complex plane that corresponds to certain types of circuit behavior. (The relationships between the pole-zero pattern and circuit behavior is beyond the scope of this book, but are covered in textbooks on circuit theory.)

What is a Pole?

Poles cause a specific change in the circuit's amplitude and phase response for real-world

frequencies, even though we can't experience imaginary frequencies directly. A pole is associated with a bend in a magnitude response plot that changes the slope of the response downward with increasing frequency by 6 dB per octave (20 dB per decade; an octave is a 2:1 frequency ratio, a decade is a 10:1 frequency ratio).

There are four ways to identify the existence and frequency of a pole as shown in Fig 3.3:

1. For a downward bend in the magnitude versus frequency plot, the pole is at the -3 dB frequency for a single pole. If the bend causes a change in slope of more than 6 dB/octave, there must be multiple poles at this frequency.

2. A 90° lagging change on a phase versus frequency plot, where the lag increases with frequency. The pole is at the point of 45° added lag on the S-shaped transition. Multiple poles will add their phase lags, as above.

3. On a circuit diagram, a single pole looks like a simple RC low-pass filter. The pole is at the -3 dB frequency ($f = 1/2\pi RC$ Hz). Any other circuit with the same response has a pole at the same frequency.

4. In an equation for the transfer function of a circuit, a pole is a theoretical value of frequency that would result in infinite gain. This is clearly impossible, but as the value of frequency will either be absolute zero, or will have an imaginary component, it is impossible to make an actual real-world signal at a pole frequency.

For example, comparing the amplitude responses at top and bottom of Fig 3.3 shows that the frequency of the pole is equal to the circuit's -3 dB cutoff frequency ($1/2\pi fC$) multiplied by j , which is also the frequency at which the circuit causes a -45° (lagging) phase shift from input to output.

What Is a Zero?

A zero is the complement of a pole. In math, it is a frequency at which the transfer function equation of a circuit is zero. This is not impossible in the real world (unlike the pole), so zeroes can be found at real-number frequencies as well as complex-number frequencies.

Each zero is associated with an *upward* bend of 6 dB per octave in a magnitude response. Similarly to a pole, the frequency of the zero is at the $+3$ dB point. Each zero is associated with a transition on a phase-versus-frequency plot that reduces the lag by 90° . The zero is at the 45° leading phase point. Multiple zeroes add their phase shifts just as poles do.

In a circuit, a zero creates gain that increases with frequency forever above the zero frequency. This requires active circuitry that would inevitably run out of gain at some frequency, which implies one or more poles up there. In real-world circuits, zeroes are usu-

ally not found by themselves, making the magnitude response go up, but rather paired with a pole of a different frequency, resulting in the magnitude response having a slope between two frequencies but flat above and below them.

Real-world circuit zeroes are only found accompanied by a greater or equal number of poles. Consider a classic RC high-pass filter, such as if the resistor and capacitor in Fig 3.3 were exchanged. The response of such a circuit increases at 6 dB per octave from 0 Hz (so there must be a zero at 0 Hz) and then levels off at $1/2\pi RC$ Hz. This leveling off is due to the presence of a pole adding its 6 dB-per-octave roll-off to cancel the 6 dB-per-octave roll-off of the zero. The transfer function for such a circuit would equal zero at zero frequency and infinity at the imaginary pole frequency.

FEEDBACK AND OSCILLATION

The *stability* of an amplifier refers to its ability to provide gain to a signal without tending to oscillate. For example, an amplifier just on the verge of oscillating is not generally considered to be “stable.” If the output of an amplifier is fed back to the input, the feedback can affect the amplifier stability. If the amplified output is added to the input, the output of the sum will be larger. This larger output, in turn, is also fed back. As this process continues, the amplifier output will continue to rise until the amplifier cannot go any higher (clamps). Such *positive feedback* increases the amplifier gain, and is called *regeneration*. (The chapter on **Oscillators and Synthesizers** includes a discussion of positive feedback.)

Most practical amplifiers have some intrinsic and unavoidable feedback either as part of the circuit or in the amplifying device(s) itself. To improve the stability of an amplifier, *negative feedback* can be added to counteract any unwanted positive feedback. Negative feedback is often combined with a phase-shift *compensation* network to improve the amplifier stability.

Although negative feedback reduces amplifier or stage gain, the advantages of *stable* gain, freedom from unwanted oscillations and the reduction of distortion are often key design objectives and advantages of using negative feedback.

The design of feedback networks depends on the desired result. For amplifiers, which should not oscillate, the feedback network is customized to give the desired frequency response without loss of stability. For oscillators, the feedback network is designed to create a steady oscillation at the desired frequency.

SUMMING

In a linear system, nature does most of

the work for us when it comes to adding signals; placing two signals together naturally causes them to add according to the principle of superposition. When processing signals, we would like to control the summing operation so the signals do not distort or combine in a nonlinear way. If two signals come from separate stages and they are connected together directly, the circuitry of the stages may interact, causing distortion of either or both signals.

Summing amplifiers generally use a resistor in series with each stage, so the resistors connect to the common input of the following stage. This provides some *isolation* between the output circuits of each stage. Fig 3.4 illustrates the resistors connecting to a summing amplifier. Ideally, any time we wanted to combine signals (for example, combining an audio signal with a sub-audible tone in a 2 meter FM transmitter prior to modulating the RF signal) we could use a summing amplifier.

FILTERING

A *filter* is a common linear stage in radio equipment. Filters are characterized by their ability to selectively attenuate certain frequencies in the filter's *stop band*, while passing or amplifying other frequencies in the *passband*. If the filter's passband extends to or near dc, it is a *low-pass* filter, and if to infinity (or at least very high frequencies for the circuitry involved), it is a *high-pass* filter. Filters that pass a range of frequencies are *band-pass* filters. *All-pass* filters are designed to affect only the phase of a signal without changing the signal amplitude. The range of frequencies between a band-pass circuit's low-pass and high-pass regions is its *mid-band*.

Fig 3.2A is the amplitude response for a typical band-pass audio filter. It shows that the input signal is passed to the output with no loss (0 dB) between 200 Hz and 5 kHz. This is the filter's *mid-band response*. Above and below those frequencies the response of the filter begins to drop. By 20 Hz and 20 kHz, the amplitude response has been reduced to one-

half of (-3 dB) the mid-band response. These points are called the circuit's *cutoff* or *corner* or *half-power frequencies*. The range between the cutoff frequencies is the filter's passband. Outside the filter's passband, the amplitude response drops to 1/200th of (-23 dB) mid-band response at 1 Hz and only 1/1000th (-30 dB) at 500 kHz. The steepness of the change in response with frequency is the filter's *roll-off* and it is usually specified in dB/octave (an octave is a doubling or halving of frequency) or dB/decade (a decade is a change to 10 times or 1/10th frequency).

Fig 3.2B represents the phase response of a different filter — the simple RC low-pass filter shown at the upper right. As frequency increases, the reactance of the capacitor becomes smaller, causing most of the input signal to appear across the fixed-value resistor instead. At low frequencies, the capacitor has little effect on phase shift. As the signal frequency rises, however, there is more and more phase shift until at the cutoff frequency, there is 45° of lagging phase shift, plotted as a negative number. Phase shift then gradually approaches 90°.

Practical passive and active filters are described in the **RF and AF Filters** chapter. Filters implemented by digital computation (*digital filters*) are discussed in the chapter on **DSP and Software Radio Design**. Filters at RF may also be created by using transmission lines as described in the **Transmission Lines** chapter. All practical amplifiers are in effect either low-pass filters or band-pass filters, because their magnitude response decreases as the frequency increases beyond their gain-bandwidth products.

AMPLITUDE MODULATION/ DEMODULATION

Voice and data signals can be transmitted over the air by using *amplitude modulation* (AM) to combine them with higher frequency *carrier* signals (see the **Modulation** chapter). The process of amplitude modulation can be mathematically described as the multiplication (product) of the voice signal and the carrier signal. Multiplication is a linear process — amplitude modulation by the sum of two audio signals produces the same signal as the sum of amplitude modulation by each audio signal individually. Another aspect of the linear behavior of amplitude modulation is that amplitude-modulated signals can be demodulated exactly to their original form. Amplitude demodulation is the converse of amplitude modulation, and is represented as division, also a linear operation.

In the linear model of amplitude modulation, the signal that performs the modulation (such as the audio signal in an AM transmitter) is shifted in frequency by multiplying it with the carrier. The modulated waveform is considered to be a linear function of the signal.

The carrier is considered to be part of a time-varying linear system and not a second signal.

A curious trait of amplitude modulation (and demodulation) is that it can be performed nonlinearly, as well. Accurate analog multipliers (and dividers) are difficult and expensive to fabricate, so less-expensive nonlinear methods are often employed. Each nonlinear form of amplitude modulation generates the desired linear combination of signals, called *products*, in addition to other unwanted products that must then be removed. Both linear and nonlinear modulators and demodulators are discussed in the chapter on **Mixers, Modulators, and Demodulators**.

3.1.3 Nonlinear Operations

All signal processing doesn't have to be linear. Any time that we treat various signal levels differently, the operation is called *nonlinear*. This is not to say that all signals must be treated the same for a circuit to be linear. High-frequency signals are attenuated in a low-pass filter while low-frequency signals are not, yet the filter can be linear. The distinction is that the amount of attenuation at different frequencies is always the same, regardless of the amplitude of the signals passing through the filter.

What if we do not want to treat all voltage levels the same way? This is commonly desired in analog signal processing for clipping, rectification, compression, modulation and switching.

CLIPPING AND RECTIFICATION

Clipping is the process of limiting the range of signal voltages passing through a circuit (in other words, *clipping* those voltages outside the desired range from the signals). There are a number of reasons why we would like to do this. As shown in Fig 3.1, clipping is the process of limiting the positive and negative peaks of a signal. (Clipping is also called *clamping*.)

Clamping might be used to prevent a large audio signal from causing excessive deviation in an FM transmitter that would interfere with communications on adjacent channels. Clipping circuits are also used to protect sensitive inputs from excessive voltages. Clipping distorts the signal, changing it so that the original signal waveform is lost.

Another kind of clipping results in *rectification*. A *rectifier* circuit clips off all voltages of one polarity (positive or negative) and passes only voltages of the other polarity, thus changing ac to pulsating dc (see the **Power Sources** chapter). Another use of rectification is in a *peak detection* circuit that measures the peak value of a waveform. Only one polarity of the ac voltage needs to be measured and so a rectifier clips the unwanted polarity.

Fig 3.4 — Summing amplifier. The output voltage is equal to the sum of the input voltages times the amplifier gain, **G**. As long as the resistance values, **R**, are equal and the amplifier input impedance is much higher, the actual value of **R** does not affect the output signal.

LIMITING

Another type of clipping occurs when an amplifier is intentionally operated with so much gain that the input signals result in an output that is clipped at the limits of its power supply voltages (or some other designated voltages). The amplifier is said to be driven into *limiting* and an amplifier designed for this behavior is called a *limiter*. Limiters are

used in FM receivers to amplify the signal until all amplitude variations in the signal are removed and the only characteristic of the original signal that remains is the frequency.

LOGARITHMIC AMPLIFICATION

It is sometimes desirable to amplify a signal logarithmically, which means amplifying low

levels more than high levels. This type of amplification is often called *signal compression*. Speech compression is sometimes used in audio amplifiers that feed modulators. The voice signal is compressed into a small range of amplitudes, allowing more voice energy to be transmitted without overmodulation (see the **Modulation** chapter).

3.2 Analog Devices

There are several different kinds of components that can be used to build circuits for analog signal processing. Bipolar semiconductors, field-effect semiconductors and integrated circuits comprise a wide spectrum of active devices used in analog signal processing. (Vacuum tubes are discussed in the chapter on **RF Power Amplifiers**, their primary application in Amateur Radio.) Several different devices can perform the same function, each with its own advantages and disadvantages based on the physical characteristics of each type of device.

Understanding the specific characteristics of each device allows you to make educated decisions about which device would be best for a particular purpose when designing analog circuitry, or understanding why an existing circuit was designed in a particular way.

3.2.1 Terminology

A similar terminology is used when describing active electronic devices. The letter V or v stands for voltages and I or i for currents. Capital letters are often used to denote dc or bias values (bias is discussed later in this chapter). Lower-case often denotes instantaneous or ac values.

Voltages generally have two subscripts indicating the terminals between which the voltage is measured (V_{BE} is the dc voltage between the base and the emitter of a bipolar transistor). Currents have a single subscript indicating the terminal into which the current flows (I_C is the dc current into the collector of a bipolar transistor). If the current flows out of the device, it is generally treated as a negative value.

Resistance is designated with the letter R or r, and impedance with the letter Z or z. For example, r_{DS} is resistance between drain and source of an FET and Z_i is input impedance. For some parameters, values differ for dc and ac signals. This is indicated by using capital letters in the subscripts for dc and lower-case subscripts for ac. For example, the common-emitter dc current gain for a bipolar transistor is designated as h_{FE} , and h_{fe} is the ac current

gain. (See the section on transistor amplifiers later in this chapter for a discussion of the common-emitter circuit.) Qualifiers are sometimes added to the subscripts to indicate certain operating modes of the device. SS for saturation, BR for breakdown, ON and OFF are all commonly used.

Power supply voltages have two subscripts that are the same, indicating the terminal to which the voltage is applied. V_{DD} would represent the power supply voltage applied to the drain of a field-effect transistor.

Since integrated circuits are collections of semiconductor components, the abbreviations for the type of semiconductor used also apply to the integrated circuit. For example, V_{CC} is a power supply voltage for an integrated circuit made with bipolar transistor technology in which voltage is applied to transistor collectors.

3.2.2 Gain and Transconductance

The operation of an amplifier is specified by its *gain*. Gain in this sense is defined as the change (Δ) in the output parameter divided by the corresponding change in the input parameter. If a particular device measures its input and output as currents, the gain is called a *current gain*. If the input and output are voltages, the amplifier is defined by its *voltage gain*. *Power gain* is often used, as well. Gain is technically unit-less, but is often given in V/V. Decibels are often used to specify gain, particularly power gain.

If an amplifier's input is a voltage and the output is a current, the ratio of the change in output current to the change in input voltage is called *transconductance*, g_m .

$$g_m = \frac{\Delta I_o}{\Delta V_i} \quad (2)$$

Transconductance has the same units as conductance and admittance, Siemens (S), but is only used to describe the operation of active devices, such as transistors or vacuum tubes.

3.2.3 Characteristic Curves

Analog devices are described most completely with their *characteristic curves*. The characteristic curve is a plot of the interrelationships between two or three variables. The vertical (y) axis parameter is the output, or

Fig 3.5 — Characteristic curves. A forward voltage vs forward current characteristic curve for a semiconductor diode is shown at (A). (B) shows a set of characteristic curves for a bipolar transistor in which the collector current vs collector-to-emitter voltage curve is plotted for five different values of base current.

result of the device being operated with an input parameter on the horizontal (x) axis. Often the output is the result of two input values. The first input parameter is represented along the x-axis and the second input parameter by several curves, each for a different value.

Almost all devices of concern are nonlinear over a wide range of operating parameters. We are often interested in using a device only in the region that approximates a linear response. Characteristic curves are used to graphically describe a device's operation in both its linear and nonlinear regions.

Fig 3.5A shows the characteristic curve for a semiconductor diode with the y-axis showing the forward current, I_F , flowing through the diode and the x-axis showing forward voltage, V_F , across the diode. This curve shows the relationship between current and voltage in the diode when it is conducting current. Characteristic curves showing voltage and current in two-terminal devices such as diodes are often called *I-V curves*. Characteristic curves may include all four quadrants of operation in which both axes include positive and negative values. It is also common for different scales to be used in the different quadrants, so inspect the legend for the curves carefully.

The parameters plotted in a characteristic curve depend on how the device will be used so that the applicable design values can be obtained from the characteristic curve. The slope of the curve is often important because it relates changes in output to changes in input. To determine the slope of the curve, two closely-spaced points along that portion of the curve are selected, each defined by its location along the x and y axes. If the two points are defined by (x_1, y_1) and (x_2, y_2) , the slope, m , of the curve (which can be a gain, a resistance or a conductance, for example) is calculated as:

$$m = \frac{\Delta y}{\Delta x} = \frac{y_1 - y_2}{x_1 - x_2} \quad (3)$$

It is important to pick points that are close together or the slope will not reflect the actual behavior of the device. A device whose characteristic curve is not a straight line will not have a linear response to inputs because the slope changes with the value of the input parameter.

For a device in which three parameters interact, such as a transistor, sets of characteristic curves can be drawn. **Fig 3.5B** shows a set of characteristic curves for a bipolar transistor where collector current, I_C , is shown on the y axis and collector-to-emitter voltage, V_{CE} , is shown on the x axis. Because the amount of collector current also depends on base current, I_B , the curve is repeated several times for different values of I_B . From this set of curves, an amplifier circuit using this transistor can be designed to have specific values of gain.

BIASING

The operation of an analog signal-processing device is greatly affected by which portion of the characteristic curve is used to do the processing. The device's *bias point* is its set of operating parameters when no input signal is applied. The bias point is also known as the *quiescent point* or *Q-point*. By changing the bias point, the circuit designer can affect the relationship between the input and output signal. The bias point can also be considered as a dc offset of the input signal. Devices that perform analog signal processing require appropriate input signal biasing.

As an example, consider the characteristic curve shown in **Fig 3.6**. (The exact types of device and circuit are unimportant.) The characteristic curve shows the relationship between an input voltage and an output current. Increasing input voltage results in an increase in output current so that an input signal is reproduced at the output. The characteristic curve is linear in the middle, but is quite nonlinear in its upper and lower regions.

In the circuit described by the figure, bias points are established by adding one of the three voltages, V_1 , V_2 or V_3 to the input signal. Bias voltage V_1 results in an output current of I_1 when no input signal is present. This is shown as Bias Point 1 on the characteristic curve. When an input signal is applied, the input voltage varies around V_1 and the output current varies around I_1 as shown. If the dc

value of the output current is subtracted, a reproduction of the input signal is the result.

If Bias Point 2 is chosen, we can see that the input voltage is reproduced as a changing output current with the same shape. In this case, the device is operating linearly. If either Bias Point 1 or Bias Point 3 is chosen, however, the shape of the output signal is distorted because the characteristic curve of the device is nonlinear in this region. Either the increasing portion of the input signal results in more variation than the decreasing portion (Bias Point 1) or vice versa (Bias Point 3). Proper biasing is crucial to ensure that a device operates linearly.

3.2.4 Manufacturer's Data Sheets

Manufacturer's data sheets list device characteristics, along with the specifics of the part type (polarity, semiconductor type), identity of the pins and leads (*pinouts*), and the typical use (such as small signal, RF, switching or power amplifier). The pin identification is important because, although common package pinouts are normally used, there are exceptions. Manufacturers may differ slightly in the values reported, but certain basic parameters are listed. Different batches of the same devices are rarely identical, so manufacturers specify the guaranteed limits for the parameters of their device. There are

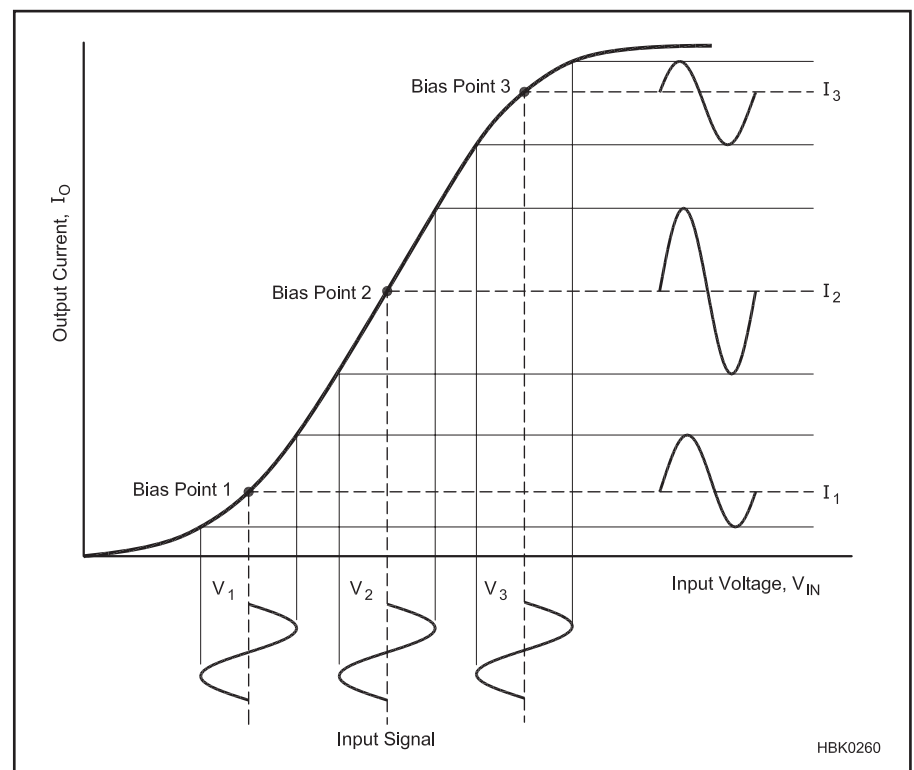

Fig 3.6 — Effect of biasing. An input signal may be reproduced linearly or nonlinearly depending on the choice of bias points.

usually three values listed in the data sheet for each parameter: guaranteed minimum value, the guaranteed maximum value, and/or the typical value.

Another section of the data sheet lists ABSOLUTE MAXIMUM RATINGS, beyond which device damage may result. For example, the parameters listed in the ABSOLUTE MAXIMUM RATINGS section for a solid-state device are typically voltages, continuous currents, total device power dissipation (P_D) and operating- and storage-temperature ranges.

Rather than plotting the characteristic curves for each device, the manufacturer often selects key operating parameters that describe the device operation for the configurations and parameter ranges that are most commonly used. For example, a bipolar transistor data sheet might include an OPERATING PARAMETERS section. Parameters are listed in an OFF CHARACTERISTICS subsection and an ON CHARACTERISTICS subsection that describe the conduction properties of the device for dc voltages. The SMALL-SIGNAL CHARACTERISTICS section might contain a minimum Gain-Bandwidth Product (f_T or GBW), maximum output capacitance, maximum input capacitance, and the range of the transfer parameters applicable to a given device. Finally, the SWITCHING CHARACTERISTICS section might list absolute maximum ratings for Delay Time (t_d), Rise Time (t_r), Storage Time (t_s), and Fall Time (t_f). Other types of devices list characteristics important to operation of that specific device.

When selecting equivalent parts for replacement of specified devices, the data sheet provides the necessary information to tell if a given part will perform the functions of another. Lists of *cross-references* and *substitution guides* generally only specify devices that have nearly identical parameters. There are usually a large number of additional devices that can be chosen as replacements. Knowledge of the circuit requirements adds even more to the list of possible replacements. The device parameters should be compared individually to make sure that the replacement part meets or exceeds the parameter values of the original part required by the circuit. Be aware that in some applications a far superior part may fail as a replacement, however. A transistor with too much gain could easily oscillate if there were insufficient negative feedback to ensure stability.

3.2.5 Physical Electronics of Semiconductors

In a conductor, such as a metal, some of the outer, or *valence*, electrons of each atom are free to move about between atoms. These *free electrons* are the constituents of electrical current. In a good conductor, the concentration of these free electrons is very high, on the order

of 10^{22} electrons/cm³. In an insulator, nearly all the electrons are tightly held by their atoms and the concentration of free electrons is very small — on the order of 10 electrons/cm³.

Between the classes of materials considered to be conductors and insulators is a class of elements called *semiconductors*, materials with conductivity much poorer than metals and much better than insulators. (In electronics, “semiconductor” means a device made from semiconductor elements that have been chemically manipulated as described below, leading to interesting properties that create useful applications.)

Semiconductor atoms (silicon, Si, is the most widely used) share their valence electrons in a chemical bond that holds adjacent atoms together, forming a three-dimensional *lattice* that gives the material its physical characteristics. A lattice of pure semiconductor material (one type of atom or molecule) can form a crystal, in which the lattice structure and orientation is preserved throughout the material. *Monocrystalline* or “single-crystal” is the type of material used in electronic semiconductor devices. *Polycrystalline* material is made of up many smaller crystals with their own individual lattice orientations.

Crystals of pure semiconductor material are called *intrinsic* semiconductors. When energy, generally in the form of heat, is added to a semiconductor crystal lattice, some electrons are liberated from their bonds and move freely throughout the lattice. The bond that loses an electron is then unbalanced and the space that the electron came from is referred to as a *hole*. In these materials the number of free electrons is equal to the number of holes.

Electrons from adjacent bonds can leave their positions to fill the holes, thus leaving behind a hole in their old location. As a consequence of the electron moving, two opposite movements can be said to occur: negatively charged electrons move from bond to bond in one direction and positively charged holes move from bond to bond in the opposite direction. Both of these movements represent forms of electrical current, but this is very different from the current in a conductor. While a conductor has free electrons that flow independently from the bonds of the crystalline lattice, the current in a pure semiconductor is constrained to move from bond to bond.

Impurities can be added to intrinsic semiconductors (by a process called *doping*) to enhance the formation of electrons or holes and thus improve conductivity. These materials are *extrinsic* semiconductors. Since the additional electrons and holes can move, their movement is current and they are called *carriers*. The type of carrier that predominates in the material is called the *majority carrier*. In N-type material the majority carriers are electrons and in P-type material, holes.

There are two types of impurities that can be added: a *donor impurity* with five valence

electrons donates free electrons to the crystalline structure; this is called an *N-type* impurity, for the negative charge of the majority carriers. Some examples of donor impurities are antimony (Sb), phosphorus (P) and arsenic (As). N-type extrinsic semiconductors have more electrons and fewer holes than intrinsic semiconductors. *Acceptor impurities* with three valence electrons accept free electrons from the lattice, adding holes to the overall structure. These are called P-type impurities, for the positive charge of the majority carriers; some examples are boron (B), gallium (Ga) and indium (In).

It is important to note that even though N-type and P-type material have different numbers of holes and free electrons than intrinsic material, they are still electrically neutral. When an electron leaves an atom, the positively-charged atom that remains in place in the crystal lattice electrically balances the roaming free electron. Similarly, an atom gaining an electron acquires a negative charge that balances the positively-charged atom it left. At no time does the material acquire a net electrical charge, positive or negative.

Compound semiconductor material can be formed by combining equal amounts of N-type and P-type impurity materials. Some examples of this include gallium-arsenide (GaAs), gallium-phosphate (GaP) and indium-phosphide (InP). To make an N-type compound semiconductor, a slightly higher amount of N-type material is used in the mixture. A P-type compound semiconductor has a little more P-type material in the mixture.

Impurities are introduced into intrinsic semiconductors by diffusion, the same physical process that lets you smell cookies baking from several rooms away. (Molecules diffuse through air much faster than through solids.) Rates of diffusion are proportional to temperature, so semiconductors are doped with impurities at high temperature to save time. Once the doped semiconductor material is cooled, the rate of diffusion of the impurities is so low that they are essentially immobile for many years to come. If an electronic device made from a structure of N- and P-type materials is raised to a high temperature, such as by excessive current, the impurities can again migrate and the internal structure of the device may be destroyed. The maximum operating temperature for semiconductor devices is specified at a level low enough to limit additional impurity diffusion.

The conductivity of an extrinsic semiconductor depends on the charge density (in other words, the concentration of free electrons in N-type, and holes in P-type, semiconductor material). As the energy in the semiconductor increases, the charge density also increases. This is the basis of how all semiconductor devices operate: the major difference is the way in which the energy level is increased. Variations include: The *transistor*, where con-

ductivity is altered by injecting current into the device via a wire; the *thermistor*, where the level of heat in the device is detected by its conductivity, and the *photoconductor*, where light energy that is absorbed by the semiconductor material increases the conductivity.

3.2.6 The PN Semiconductor Junction

If a piece of N-type semiconductor material is placed against a piece of P-type semiconductor material, the location at which they join is called a *PN junction*. The junction has characteristics that make it possible to develop diodes and transistors. The action of the junction is best described by a diode operating as a rectifier.

Initially, when the two types of semiconductor material are placed in contact, each type of material will have only its majority carriers: P-type will have only holes and N-type will have only free electrons. The presence of the positive charges (holes) in the P-type material attracts free electrons from the N-type material immediately across the junction. The opposite is true in the N-type material.

These attractions lead to diffusion of some of the majority carriers across the junction, which combine with and neutralize the majority carriers immediately on the other side (a process called *recombination*). As distance from the junction increases, the attraction quickly becomes too small to cause the carriers to move. The region close to the junction is then *depleted* of carriers, and so is named the *depletion region* (also the *space-charge region* or the *transition region*). The width of the depletion region is very small, on the order of 0.5 μm .

If the N-type material (the *cathode*) is placed at a more negative voltage than the P-type material (the *anode*), current will pass through the junction because electrons are attracted from the lower potential to the higher potential and holes are attracted in the opposite direction. This *forward bias* forces the majority carriers toward the junction where recombination occurs with the opposite type of majority carrier. The source of voltage supplies replacement electrons to the N-type material and removes electrons from the P-type material so that the majority carriers are continually replenished. Thus, the net effect is a *forward current* flowing through the semiconductor, across the PN junction. The *forward resistance* of a diode conducting current is typically very low and varies with the amount of forward current.

When the polarity is reversed, majority carriers are attracted away from the junction, not toward it. Very little current flows across the PN junction — called *reverse leakage current* — in this case. Allowing only unidirectional current flow is what allows a

semiconductor diode to act as rectifier.

3.2.7 Junction Semiconductors

Semiconductor devices that operate using the principles of a PN junction are called *junction semiconductors*. These devices can have one or several junctions. The properties of junction semiconductors can be tightly controlled by the characteristics of the materials used and the size and shape of the junctions.

SEMICONDUCTOR DIODES

Diodes are commonly made of silicon and occasionally germanium. Although they act similarly, they have slightly different characteristics. The *junction threshold voltage*, or *junction barrier voltage*, is the forward bias voltage (V_F) at which current begins to pass through the device. This voltage is different for the two kinds of diodes. In the diode response curve of Fig 3.7, V_F corresponds to the voltage at which the positive portion of the curve begins to rise sharply from the x-axis. Most silicon diodes have a junction threshold voltage of about 0.7 V, while the voltage for germanium diodes is typically 0.3 V. Reverse leakage current is much lower for silicon diodes than for germanium diodes.

The characteristic curve for a semiconductor diode junction is given by the following equation (slightly simplified) called the *Fundamental Diode Equation* because it describes the behavior of all semiconductor PN junctions.

$$I = I_S \left(e^{\frac{V}{\eta V_t}} - 1 \right) \quad (4)$$

where

I = diode current

V = diode voltage

I_S = reverse-bias saturation current

$V_t = kT/q$, the thermal equivalent of voltage (about 25 mV at room temperature)

η = emission coefficient.

The value of I_S varies with the type of semiconductor material, with the value of 10^{-12} used for silicon. η also varies from 1 to 2 with the type of material and method of fabrication. (η is close to 1 for silicon at normal current values, increasing to 2 at high currents.) This curve is shown in Fig 3.8B.

The obvious differences between Fig 3.8A and B are that the semiconductor diode has a finite *turn-on* voltage — it requires a small but nonzero forward bias voltage before it begins conducting. Furthermore, once conducting, the diode voltage continues to increase very slowly with increasing current, unlike a true short circuit. Finally, when the applied voltage is negative, the reverse current is not exactly zero but very small (microamperes).

Fig 3.7 — Semiconductor diode (PN junction) characteristic curve. (A) Forward-biased (anode voltage higher than cathode) response for Germanium (Ge) and Silicon (Si) devices. Each curve breaks away from the x-axis at its junction threshold voltage. The slope of each curve is its forward resistance. (B) Reverse-biased response. Very small reverse current increases until it reaches the reverse saturation current (I_0). The reverse current increases suddenly and drastically when the reverse voltage reaches the reverse breakdown voltage, V_{BR} .

The reverse current flow rapidly reaches a level that varies little with the reverse bias voltage. This is the *reverse-bias saturation current*, I_S .

For bias (dc) circuit calculations, a useful model for the diode that takes these two effects into account is shown by the artificial I-V curve in Fig 3.8C. This model neglects the negligible reverse bias current I_S .

When converted into an equivalent circuit, the model in Fig 3.8C yields the circuit in Fig 3.8D. The ideal voltage source V_a represents the turn-on voltage and R_f represents the effective resistance caused by the small increase in diode voltage as the diode current increases. The turn-on voltage is material-dependent: approximately 0.3 V for germanium diodes and 0.7 for silicon. R_f is typically on the order of 10 Ω , but it can vary according to the specific component. R_f can often be completely neglected in comparison to the other

Figure 3.8 — Circuit models for rectifying switches (diodes). A: I-V curve of the ideal rectifier. B: I-V curve of a typical semiconductor diode showing the typical small leakage current in the reverse direction. Note the different scales for forward and reverse current. C shows a simplified diode I-V curve for dc-circuit calculations (at a much larger scale than B). D is an equivalent circuit for C.

resistances in the circuit. This very common simplification leaves only a pure *voltage drop* for the diode model.

BIPOLAR TRANSISTOR

A bipolar transistor is formed when two PN junctions are placed next to each other. If N-type material is surrounded by P-type material, the result is a PNP transistor. Alternatively, if P-type material is in the middle of two layers of N-type material, the NPN transistor is formed (Fig 3.9).

Physically, we can think of the transistor as two PN junctions back-to-back, such as two diodes connected at their *anodes* (the positive terminal) for an NPN transistor or two diodes connected at their *cathodes* (the negative terminal) for a PNP transistor. The connection point is the base of the transistor. (You can't actually make a transistor this way — this is a representation for illustration only.)

A transistor conducts when the base-emitter junction is forward biased and the base-collector is reverse biased. Under these conditions, the emitter region emits majority carriers into the base region, where they be-

come minority carriers because the materials of the emitter and base regions have opposite polarity. The excess minority carriers in the base are then attracted across the very thin base to the base-collector junction, where they are collected and are once again considered majority carriers before they can flow to the base terminal.

The flow of majority carriers from emitter to collector can be modified by the application of a bias current to the base terminal. If the bias current causes majority carriers to be injected into the base material (electrons flowing into an N-type base or out of a P-type base) the emitter-collector current increases. In this way, a transistor allows a small base current to control a much larger collector current.

As in a semiconductor diode, the forward biased base-emitter junction has a threshold voltage (V_{BE}) that must be exceeded before the emitter current increases. As the base-emitter current continues to increase, the point is reached at which further increases in base-emitter current cause no additional change in collector current. This is the condition of

Fig 3.9 — Bipolar transistors. (A) A layer of N-type semiconductor sandwiched between two layers of P-type semiconductor makes a PNP device. The schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing in toward the base. (B) A layer of P-type semiconductor sandwiched between two layers of N-type semiconductor makes an NPN device. The schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing out away from the base.

saturation. Conversely, when base-emitter current is reduced to the point at which collector current ceases to flow, that is the situation of *cutoff*.

THYRISTORS

Thyristors are semiconductors made with four or more alternating layers of P- and N-type semiconductor material. In a four-layer thyristor, when the anode is at a higher potential than the cathode, the first and third junctions are forward biased and the center junction reverse biased. In this state, there is little current, just as in the reverse-biased diode. The different types of thyristor have different ways in which they turn on to conduct current and in how they turn off to interrupt current flow.

PNPN Diode

The simplest thyristor is a PNPN (usually pronounced like *pinpin*) diode with three junctions (see Fig 3.10). As the forward bias voltage is increased, the current through the device increases slowly until the *breakover* (or *firing*) voltage, V_{BO} , is reached and the flow of current abruptly increases. The PNPN diode is often considered to be a switch that is off below V_{BO} and on above it.

Bilateral Diode Switch (Diac)

A semiconductor device similar to two

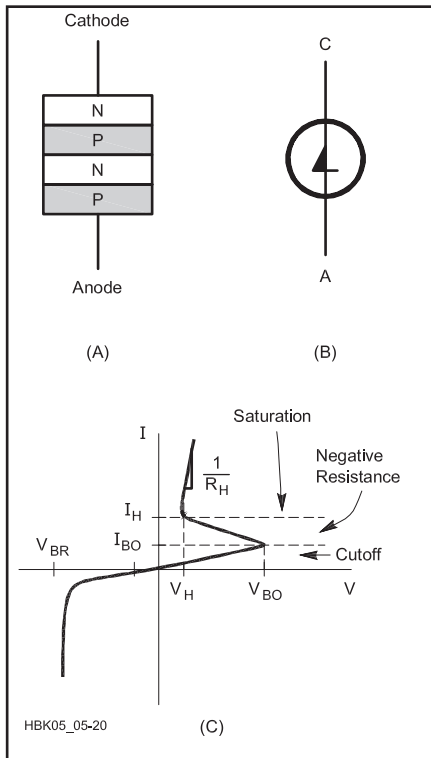

Fig 3.10 — PNP diode. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol with cathode (C) and anode (A) leads. (C) I-V curve. Reverse-biased response is the same as normal PN junction diodes. Forward biased response acts as a hysteresis switch. Resistance is very high until the bias voltage reaches V_{BO} (where the center junction breaks over) and exceeds the cutoff current, I_{BO} . The device exhibits a negative resistance when the current increases as the bias voltage decreases until a voltage of V_H and saturation current of I_H is reached. After this, the resistance is very low, with large increases in current for small voltage increases.

PNPN diodes facing in opposite directions and attached in parallel is the *bilateral diode switch* or *diac*. This device has the characteristic curve of the PNP diode for both positive and negative bias voltages. Its construction, schematic symbol and characteristic curve are shown in **Fig 3.11**.

Silicon Controlled Rectifier (SCR)

Another device with four alternate layers of P-type and N-type semiconductor is the *silicon controlled rectifier (SCR)*. (Some sources refer to an SCR as a thyristor, as well.) In addition to the connections to the outer two layers, two other terminals can be brought out for the inner two layers. The connection to the P-type material near the cathode is called the *cathode gate* and the N-type material near

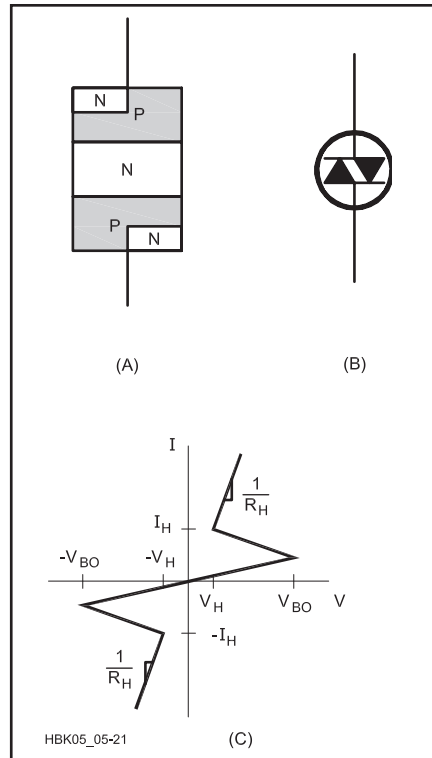

Fig 3.11 — Bilateral switch. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol. (C) I-V curve. The right-hand side of the curve is identical to the PNP diode response in Fig 3.10. The device responds identically for both forward and reverse bias so the left-hand side of the curve is symmetrical with the right-hand side.

the anode is called the *anode gate*. In nearly all commercially available SCRs, only the cathode gate is connected (**Fig 3.12**).

Like the PNP diode switch, the SCR is used to abruptly start conducting when the voltage exceeds a given level. By biasing the gate terminal appropriately, the breakover voltage can be adjusted.

Triac

A five-layered semiconductor whose operation is similar to a bidirectional SCR is the *triac* (**Fig 3.13**). This is also similar to a bidirectional diode switch with a bias control gate. The gate terminal of the triac can control both positive and negative breakover voltages and the devices can pass both polarities of voltage.

Thyristor Applications

The SCR is highly efficient and is used in power control applications. SCRs are available that can handle currents of greater than

Fig 3.12 — SCR. (A) Alternating layers of P-type and N-type semiconductor. This is similar to a PNP diode with gate terminals attached to the interior layers. (B) Schematic symbol with anode (A), cathode (C), anode gate (G_A) and cathode gate (G_C). Many devices are constructed without G_A . (C) I-V curve with different responses for various gate currents. $I_G = 0$ has a similar response to the PNP diode.

100 A and voltage differentials of greater than 1000 V, yet can be switched with gate currents of less than 50 mA. Because of their high current-handling capability, SCRs are used as “crowbars” in power supply circuits, to short the output to ground and blow a fuse when an overvoltage condition exists.

SCRs and triacs are often used to control ac power sources. A sine wave with a given RMS value can be switched on and off at preset points during the cycle to decrease the RMS voltage. When conduction is delayed until after the peak (as **Fig 3.14** shows) the peak-to-peak voltage is reduced. If conduction starts before the peak, the RMS voltage is reduced, but the peak-to-peak value remains the same. This method is used to operate light dimmers and 240 V ac to 120 V ac converters. The sharp switching transients created when these devices turn on are common sources of RF interference. (See the chapter on **RF Interference** for information on dealing with interference from thyristors.)

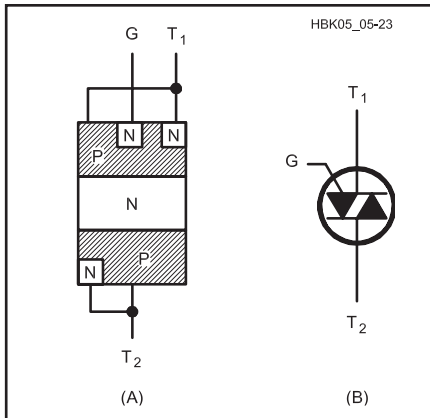

Fig 3.13 — Triac. (A) Alternating layers of P-type and N-type semiconductor. This behaves as two SCR devices facing in opposite directions with the anode of one connected to the cathode of the other and the cathode gates connected together. (B) Schematic symbol.

Fig 3.14 — Triac operation on sine wave. The dashed line is the original sine wave and the solid line is the portion that conducts through the triac. The relative delay and conduction period times are controlled by the amount or timing of gate current, I_G . The response of an SCR is the same as this for positive voltages (above the x-axis) and with no conduction for negative voltages.

3.2.8 Field-Effect Transistors (FET)

The *field-effect transistor (FET)* controls the current between two points but does so differently than the bipolar transistor. The FET operates by the effects of an electric field on the flow of electrons through a single type of semiconductor material. This is why the FET is sometimes called a *unipolar* transistor. Unlike bipolar semiconductors that can be arranged in many configurations to provide diodes, transistors, photoelectric devices, temperature sensitive devices and so on, the field effect technique is usually only used to make transistors, although FETs are also available as special-purpose diodes, for use as constant current sources.

FET devices are constructed on a *substrate* of doped semiconductor material. The channel is formed within the substrate and has the

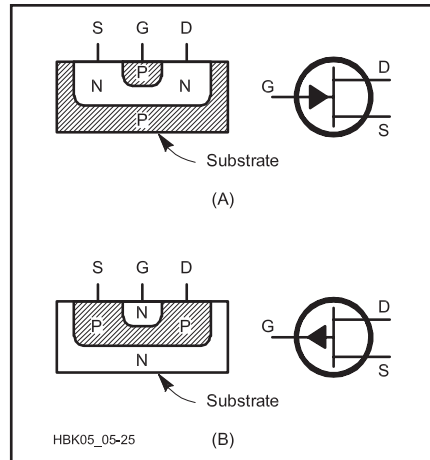

Fig 3.15 — JFET devices with terminals labeled: source (S), gate (G) and drain (D). A) Pictorial of N-type channel embedded in P-type substrate and schematic symbol. B) P-channel embedded in N-type substrate and schematic symbol.

opposite polarity (a P-channel FET has N-type substrate). Most FETs are constructed with silicon.

Within the FET, current moves in a *channel* as shown in Fig 3.15. The channel is made of either N-type or P-type semiconductor material; an FET is specified as either an N-channel or P-channel device. Current flows from the *source* terminal (where majority carriers are injected) to the *drain* terminal (where majority carriers are removed). A *gate* terminal generates an electric field that controls the current in the channel.

In N-channel devices, the drain potential must be higher than that of the source ($V_{DS} > 0$) for electrons (the majority carriers) to flow in channel. In P-channel devices, the flow of holes requires that $V_{DS} < 0$. The polarity of the electric field that controls current in the channel is determined by the majority carriers of the channel, ordinarily positive for P-channel FETs and negative for N-channel FETs.

Variations of FET technology are based on different ways of generating the electric field. In all of these, however, electrons at the gate are used only for their charge in order to create an electric field around the channel. There is a minimal flow of electrons through the gate. This leads to a very high dc input resistance in devices that use FETs for their input circuitry. There may be quite a bit of capacitance between the gate and the other FET terminals, however, causing the input impedance to be quite low at high frequencies.

The current through an FET only has to pass through a single type of semiconductor material. Depending on the type of material and the construction of the FET, drain-source resistance when the FET is conduct-

ing ($r_{DS(ON)}$) may be anywhere from a few hundred ohms to much less than an ohm. The output impedance of devices made with FETs is generally quite low. If a gate bias voltage is added to operate the transistor near cutoff, the circuit output impedance may be much higher.

In order to achieve a higher gain-bandwidth product, other materials have been used. Gallium-arsenide (GaAs) has *electron mobility* and *drift velocity* (both are measures of how easily electrons are able to move through the crystal lattice) far higher than the standard doped silicon. Amplifiers designed with GaAsFET devices operate at much higher frequencies and with a lower noise factor at VHF and UHF than those made with silicon FETs (although silicon FETs have improved dramatically in recent years).

JFET

One of two basic types of FET, the *junction FET (JFET)* gate material is made of the opposite polarity semiconductor to the channel material (for a P-channel FET the gate is made of N-type semiconductor material). The gate-channel junction is similar to a diode's PN junction with the gate material in direct contact with the channel. JFETs are used with the junction reverse-biased, since any current in the gate is undesirable. The reverse bias of the junction creates an electric field that "pinches" the channel. Since the magnitude of the electric field is proportional to the reverse-bias voltage, the current in the channel is reduced for higher reverse gate bias voltages. When current in the channel is completely halted by the electric field, this is called *pinch-off* and it is analogous to cutoff in a bipolar transistor. The channel in a JFET is at its maximum conductivity when the gate and source voltages are equal ($V_{GS} = 0$).

Because the gate-channel junction in a JFET is similar to a bipolar junction diode, this junction must never be forward biased; otherwise large currents will pass through the gate and into the channel. For an N-channel JFET, the gate must always be at a lower potential than the source ($V_{GS} < 0$). The prohibited condition is for $V_{GS} > 0$. For P-channel JFETs these conditions are reversed (in normal operation $V_{GS} > 0$ and the prohibited condition is for $V_{GS} < 0$).

MOSFET

Placing an insulating layer between the gate and the channel allows for a wider range of control (gate) voltages and further decreases the gate current (and thus increases the device input resistance). The insulator is typically made of an oxide (such as silicon dioxide, SiO_2). This type of device is called a *metal-oxide-semiconductor FET (MOSFET)* or *insulated-gate FET (IGFET)*.

The substrate is often connected to the source internally. The insulated gate is on the

opposite side of the channel from the substrate (see Fig 3.16). The bias voltage on the gate terminal either attracts or repels the majority carriers of the substrate across its PN-junction with the channel. This narrows (*depletes*) or widens (*enhances*) the channel, respectively, as V_{GS} changes polarity. For example, in the N-channel enhancement-mode MOSFET, positive gate voltages with respect to the substrate and the source ($V_{GS} > 0$) repel holes from the channel into the substrate, thereby widening the channel and decreasing channel resistance. Conversely, $V_{GS} < 0$ causes holes to be attracted from the substrate, narrowing the channel and increasing the channel resistance. Once again, the polarities discussed in this example are reversed for P-channel devices. The common abbreviation for an N-channel MOSFET is *NMOS*, and for a P-channel MOSFET, *PMOS*.

Because of the insulating layer next to the gate, input resistance of a MOSFET is usually greater than $10^{12} \Omega$ (a million megohms). Since MOSFETs can both deplete the channel, like the JFET, and also enhance it, the construction of MOSFET devices differs based on the channel size in the quiescent state, $V_{GS} = 0$.

A *depletion mode device* (also called a *normally-on MOSFET*) has a channel in the quiescent state that gets smaller as a reverse bias is applied; this device conducts current with no bias applied (see Fig 3.16A and B). An *enhancement mode device* (also called a *normally-off MOSFET*) is built without a channel and does not conduct current when $V_{GS} = 0$; increasing forward bias forms a temporary channel that conducts current (see Fig 3.16C and D).

Complementary Metal Oxide Semiconductors (CMOS)

Power dissipation in a circuit can be reduced to very small levels (on the order of a few nanowatts) by using MOSFET devices in complementary pairs (CMOS). Each amplifier is constructed of a series circuit of MOSFET devices, as in Fig 3.17. The gates are tied together for the input signal, as are the drains for the output signal. In saturation and cutoff, only one of the devices conducts. The current drawn by the circuit under no load is equal to the OFF leakage current of either device and the voltage drop across the pair is equal to V_{DD} , so the steady-state power used by the circuit is always equal to $V_{DD} \times I_{D(OFF)}$. Power is only consumed during the switching process, so for ac signals, power consumption is proportional to frequency.

CMOS circuitry could be built with discrete components, but the number of extra parts and the need for the complementary components to be matched has made that an unusual design technique. The low power consumption and ease of fabrication has made CMOS the most

Fig 3.16 — MOSFET devices with terminals labeled: source (S), gate (G) and drain (D). N-channel devices are pictured. P-channel devices have the arrows reversed in the schematic symbols and the opposite type semiconductor material for each of the layers. (A) N-channel depletion mode device schematic symbol and (B) pictorial of P-type substrate, diffused N-type channel, SiO₂ insulating layer and aluminum gate region and source and drain connections. The substrate is connected to the source internally. A negative gate potential narrows the channel. (C) N-channel enhancement mode device schematic and (D) pictorial of P-type substrate, N-type source and drain wells, SiO₂ insulating layer and aluminum gate region and source and drain connections. Positive gate potential forms a channel between the two N-type wells by repelling the P-carriers away from the channel region in the substrate.

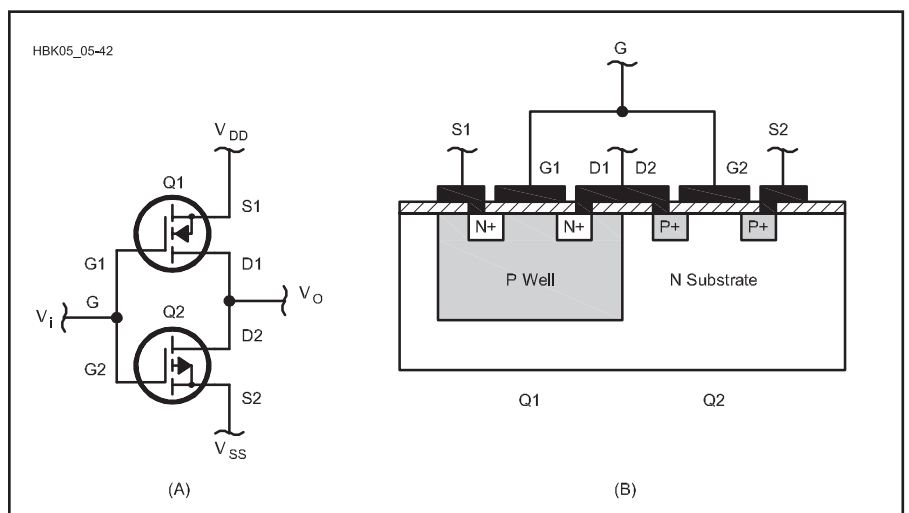

Fig 3.17 — Complementary metal oxide semiconductor (CMOS). (A) CMOS device is made from a pair of enhancement mode MOS transistors. The upper is an N-channel device, and the lower is a P-channel device. When one transistor is biased on, the other is biased off; therefore, there is minimal current from V_{DD} to ground. (B) Implementation of a CMOS pair as an integrated circuit.

common of all IC technologies. Although CMOS is most commonly used in digital integrated circuitry, its low power consumption has also been put to work by manufacturers of analog ICs, as well as digital ICs.

3.2.9 Semiconductor Temperature Effects

The number of excess holes and electrons in semiconductor material is increased as the temperature of a semiconductor increases. Since the conductivity of a semiconductor is related to the number of excess carriers, this also increases with temperature. With respect to resistance, semiconductors have a negative temperature coefficient. The resistance of silicon *decreases* by about 8% per °C and by about 6% per °C for germanium. Semiconductor temperature properties are the opposite of most metals, which *increase* their resistance by about 0.4% per °C. These opposing temperature characteristics permit the design of circuits with opposite temperature coefficients that cancel each other out, making a temperature insensitive circuit.

Semiconductor devices can experience an effect called *thermal runaway* as the current causes an increase in temperature. (This is primarily an issue with bipolar transistors.) The increased temperature decreases resistance and may lead to a further increase in current (depending on the circuit) that leads to an additional temperature increase. This sequence of events can continue until the semiconductor destroys itself, so circuit design must include measures that compensate for the effects of temperature.

Semiconductor Failure Caused by Heat

There are several common failure modes

for semiconductors that are related to heat. The semiconductor material is connected to the outside world through metallic *bonding leads*. The point at which the lead and the semiconductor are connected is a common place for the semiconductor device to fail. As the device heats up and cools down, the materials expand and contract. The rate of expansion and contraction of semiconductor material is different from that of metal. Over many cycles of heating and cooling the bond between the semiconductor and the metal can break. Some experts have suggested that the lifetime of semiconductor equipment can be extended by leaving the devices powered on all the time, but this requires removal of the heat generated during normal operation.

A common failure mode of semiconductors is caused by the heat generated during semiconductor use. If the temperatures of the PN junctions remain at high enough levels for long enough periods of time, the impurities resume their diffusion across the PN junctions. When enough of the impurity atoms cross the depletion region, majority carrier recombination stops functioning properly and the semiconductor device fails permanently.

Excessive temperature can also cause failure anywhere in the semiconductor from heat generation within any current-carrying conductor, such as an FET channel or the bonding leads. Integrated circuits with more than one output may have power dissipation limits that depend on how many of the outputs are active at one time. The high temperature can cause localized melting or cracking of the semiconductor material, causing a permanent failure.

Another heat-driven failure mode, usually not fatal to the semiconductor, is excessive leakage current or a shift in operating point that causes the circuit to operate improperly. This is a particular problem in complex integrated

circuits — analog and digital — dissipating significant amounts of heat under normal operating conditions. Computer microprocessors are a good example, often requiring their own cooling systems. Once the device cools, normal operation is usually restored.

To reduce the risk of thermal failures, the designer must comply with the limits stated in the manufacturer's data sheet, devising an adequate heat removal system. (Thermal issues are discussed in the **Electrical Fundamentals** chapter.)

3.2.10 Safe Operating Area (SOA)

Devices intended for use in circuits handling high currents or voltages are specified to have a *safe operating area (SOA)*. This refers to the area drawn on the device's characteristic curve containing combinations of voltage and current that the device can be expected to control without damage under specific conditions. The SOA combines a number of limits — voltage, current, power, temperature and various breakdown mechanisms — in order to simplify the design of protective circuitry. The SOA is also specified to apply to specific durations of use — steady-state, long pulses, short pulses and so forth. The device may have separate SOAs for resistive and inductive loads.

You may also encounter two specialized types of SOA for turning the device on and off. *Reverse bias safe operating area (RBSOA)* applies when the device is turning off. *Forward bias safe operating area (FBSOA)* applies when turning the device on. These SOAs are used because the high rate-of-change of current and voltage places additional stresses on the semiconductor.

3.3 Practical Semiconductors

3.3.1 Semiconductor Diodes

Although many types of semiconductor diodes are available, they share many common characteristics. The different types of diodes have been developed to optimize particular characteristics for one type of application. You will find many examples of diode applications throughout this book.

The diode symbol is shown in **Fig 3.18**. Forward current flows in the direction from anode to cathode, in the direction of the arrow. Reverse current flows from cathode to anode. (Current is considered to be conventional current as described in the **Electrical Fundamentals** chapter.) The anode of a semiconductor junction diode is made of P-type material and the cathode is made of N-type

material, as indicated in **Fig 3.18**. Most diodes are marked with a band on the cathode end (**Fig 3.18**).

DIODE RATINGS

Five major characteristics distinguish standard junction diodes from one another: current handling capacity, maximum voltage rating, response speed, reverse leakage current and junction forward voltage. Each of these characteristics can be manipulated during manufacture to produce special purpose diodes.

Current Capacity

The ideal diode would have zero resistance in the forward direction and infinite resistance

in the reverse direction. This is not the case for actual devices, which behave as shown in the plot of a diode response in **Fig 3.7**. Note that the scales of the two graphs are drastically different. The inverse of the slope of the line (the change in voltage between two points on a straight portion of the line divided by the corresponding change in current) on the upper right is the resistance of the diode in the forward direction, R_F .

The range of voltages is small and the range of currents is large since the forward resistance is very small (in this example, about 2Ω). Nevertheless, this resistance causes heat dissipation according to $P = I_F^2 \times R_F$.

In addition, there is a forward voltage, V_F , whenever the forward current is flowing. This

Fig 3.18 — Practical semiconductor diodes. All devices are aligned with anode on the left and cathode on the right. (A) Standard PN junction diode. (B) Point-contact or “cat’s whisker” diode. (C) PIN diode formed with heavily doped P-type (P+), undoped (intrinsic) and heavily doped N-type (N+) semiconductor material. (D) Diode schematic symbol. (E) Diode package with marking stripe on the cathode end.

also results in heat dissipation as $P = I \times V_F$. In power applications where the average forward current is high, heating from forward resistance and the forward voltage drop can be significant. Since forward current determines the amount of heat dissipation, the diode’s power rating is stated as a *maximum average current*. Exceeding the current rating in a diode will cause excessive heating that leads to PN junction failure as described earlier.

Peak Inverse Voltage (PIV)

In Fig 3.7, the lower left portion of the curve illustrates a much higher resistance that increases from tens of kilohms to thousands of megohms as the reverse voltage gets larger, and then decreases to near zero (a nearly vertical line) very suddenly. This sudden change occurs because the diode enters *reverse breakdown* or when the reverse voltage becomes high enough to push current across the junction. The voltage at which this occurs is the *reverse breakdown voltage*. Unless the current is so large that the diode fails from overheating, breakdown is not destructive and the diode will again behave normally when the bias is removed. The maximum reverse voltage that the diode can withstand under normal use is the *peak inverse voltage (PIV)* rating. A related effect is *avalanche breakdown* in which the voltage across a device is greater than its ability to control or block current flow.

Response Speed

The speed of a diode’s response to a change in voltage polarity limits the frequency of ac current that the diode can rectify. The diode response in Fig 3.7 shows how that diode will act at dc. As the frequency increases, the diode

may not be able to turn current on and off as fast as the changing polarity of the signal.

Diode response speed mainly depends on *charge storage* in the depletion region. When forward current is flowing, electrons and holes fill the region near the junction to recombine. When the applied voltage reverses, these excess charges move away from the junction so that no recombination can take place. As reverse bias empties the depletion region of excess charge, it begins to act like a small capacitor formed by the regions containing majority carriers on either side of the junction and the depletion region acting as the dielectric. This *junction capacitance* is inversely proportional to the width of the depletion region and directly proportional to the cross-sectional surface area of the junction.

The effect of junction capacitance is to allow current to flow for a short period after the applied voltage changes from positive to negative. To halt current flow requires that the junction capacitance be charged. Charging this capacitance takes some time; a few μs for regular rectifier diodes and a few hundred nanoseconds for *fast-recovery* diodes. This is the diode’s *charge-storage time*. The amount of time required for current flow to cease is the diode’s *recovery time*.

Reverse Leakage Current

Because the depletion region is very thin, reverse bias causes a small amount of reverse leakage or reverse saturation current to flow from cathode to anode. This is typically $1 \mu\text{A}$ or less until reverse breakdown voltage is reached. Silicon diodes have lower reverse leakage currents than diodes made from other materials with higher carrier mobility, such as germanium.

The reverse saturation current I_s is not constant but is affected by temperature, with higher temperatures increasing the mobility of the majority carriers so that more of them cross the depletion region for a given amount of reverse bias. For silicon diodes (and transistors) near room temperature, I_s increases by a factor of 2 every 4.8°C . This means that for every 4.8°C rise in temperature, either the current doubles (if the voltage across it is constant), or if the current is held constant by other resistances in the circuit, the diode voltage will *decrease* by $V_T \times \ln 2 = 18 \text{ mV}$. For germanium, the current doubles every 8°C and for gallium-arsenide (GaAs), 3.7°C . This dependence is highly reproducible and may actually be exploited to produce temperature-measuring circuits.

While the change resulting from a rise of several degrees may be tolerable in a circuit design, that from 20 or 30 degrees may not. Therefore it’s a good idea with diodes, just as with other components, to specify power ratings conservatively (2 to 4 times margin) to prevent self-heating.

While component derating does reduce self-heating effects, circuits must be designed for the expected operating environment. For example, mobile radios may face temperatures from -20° to $+140^\circ\text{F}$ (-29° to 60°C).

Forward Voltage

The amount of voltage required to cause majority carriers to enter the depletion region and recombine, creating full current flow, is called a diode’s *forward voltage*, V_F . It depends on the type of material used to create the junction and the amount of current. For silicon diodes at normal currents, $V_F = 0.7 \text{ V}$, and for germanium diodes, $V_F = 0.3 \text{ V}$. As you saw earlier, V_F also affects power dissipation in the diode.

POINT-CONTACT DIODES

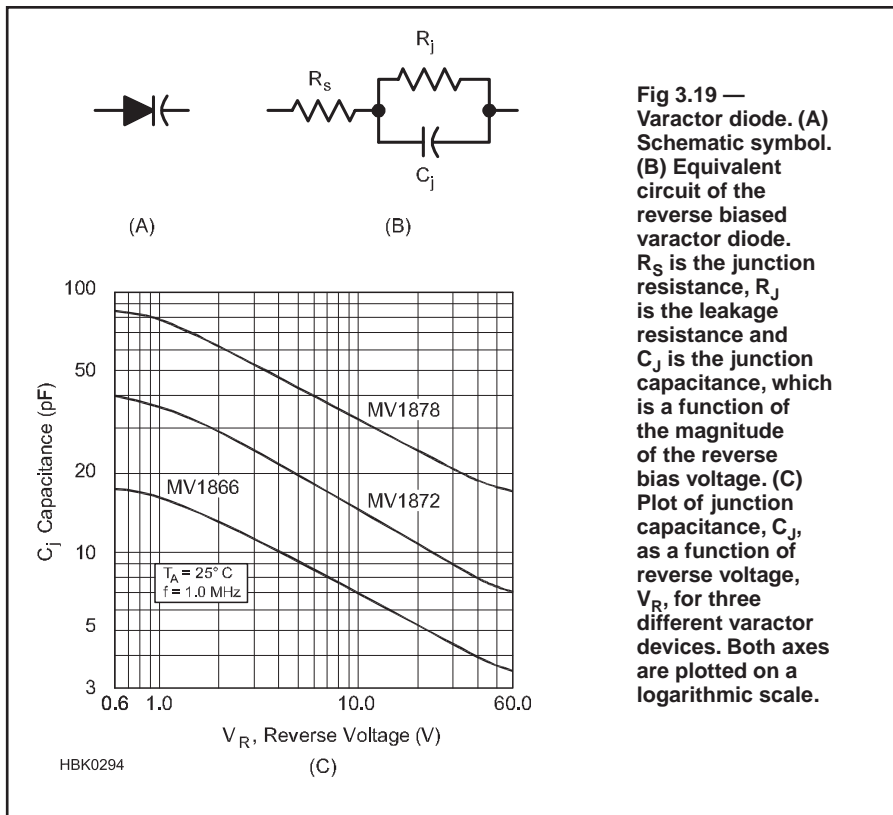

One way to decrease charge storage time in the depletion region is to form a metal-semiconductor junction for which the depletion is very thin. This can be accomplished with a *point-contact diode*, where a thin piece of aluminum wire, often called a *whisker*, is placed in contact with one face of a piece of lightly doped N-type material. In fact, the original diodes used for detecting radio signals (“cat’s whisker diodes”) were made with a steel wire in contact with a crystal of impure lead (galena). Point-contact diodes have high response speed, but poor PIV and current-handling ratings. The 1N34 germanium point-contact diode is the best-known example of point-contact diode still in common use.

SCHOTTKY DIODES

An improvement to point-contact diodes, the *hot-carrier diode* is similar to a point-contact diode, but with more ideal characteristics attained by using more efficient metals, such as platinum and gold, that act to lower forward resistance and increase PIV. This type of contact is known as a *Schottky barrier*, and diodes made this way are called *Schottky diodes*. The junctions of Schottky diodes, being smaller, store less charge and as a result, have shorter switching times and junction capacitances than standard PN-junction diodes. Their forward voltage is also lower, typically 0.3 to 0.4 V. In most other respects they behave similarly to PN diodes.

PIN DIODES

The PIN diode, shown in Fig 3.18C is a *slow response* diode that is capable of passing RF and microwave signals when it is forward biased. This device is constructed with a layer of intrinsic (undoped) semiconductor placed between very highly doped P-type and N-type material (called P+ type and N+ type material to indicate the extra amount of doping), creating a *PIN junction*. These devices provide very effective switches for RF signals and are often used in transmit-receive switches

in transceivers and amplifiers. The majority carriers in PIN diodes have longer than normal lifetimes before recombination, resulting in a slow switching process that causes them to act more like resistors than diodes at high radio frequencies. The amount of resistance can be controlled by the amount of forward bias applied to the PIN diode and this allows them to act as current-controlled attenuators. (For additional discussion of PIN diodes and projects in which they are used, see the chapters on **Transmitters and Transceivers**, **RF Power Amplifiers**, and **Test Equipment and Measurements**.)

VARACTOR DIODES

Junction capacitance can be used as a circuit element by controlling the reverse bias voltage across the junction, creating a small variable capacitor. Junction capacitances are small, on the order of pF. As the reverse bias voltage on a diode increases, the width of the depletion region increases, decreasing its capacitance. A *varactor* (also known by the trade name Varicap diode) is a diode with a junction specially formulated to have a relatively large range of capacitance values for a modest range of reverse bias voltages (Fig 3.19).

As the reverse bias applied to a diode changes, the width of the depletion layer, and therefore the capacitance, also changes. The diode junction capacitance (C_j) under a reverse bias of V volts is given by

$$C_j = \frac{C_{j0}}{\sqrt{V_{on} - V}} \quad (5)$$

where C_{j0} = measured capacitance with zero applied voltage.

Note that the quantity under the radical is a large *positive* quantity for reverse bias. As seen from the equation, for large reverse biases C_j is inversely proportional to the square root of the voltage.

Although special forms of varactors are available from manufacturers, other types of diodes may be used as inexpensive varactor diodes, but the relationship between reverse voltage and capacitance is not always reliable.

When designing with varactor diodes, the reverse bias voltage must be absolutely free of noise since any variations in the bias voltage will cause changes in capacitance. For example, if the varactor is used to tune an oscillator, unwanted frequency shifts or instability will result if the reverse bias voltage is noisy. It is possible to frequency modulate a signal by adding the audio signal to the reverse bias on a varactor diode used in the carrier oscillator. (For examples of the use of varactors in oscillators and modulators, see the chapters on **Mixers, Modulators, and Demodulators** and **Oscillators and Synthesizers**.)

ZENER DIODES

When the PIV of a reverse-biased diode is exceeded, the diode begins to conduct current

Fig 3.20 — Zener diode. (A) Schematic symbol. (B) Basic voltage regulating circuit. V_Z is the Zener reverse breakdown voltage. Above V_Z , the diode draws current until $V_I - I_1 R = V_Z$. The circuit design should select R so that when the maximum current is drawn, $R < (V_I - V_Z) / I_O$. The diode should be capable of passing the same current when there is no output current drawn.

as it does when it is forward biased. This current will not destroy the diode if it is limited to less than the device's maximum allowable value. By using heavy levels of doping during manufacture, a diode's PIV can be precisely controlled to be at a specific level, called the *Zener voltage*, creating a type of voltage reference. These diodes are called Zener diodes after their inventor, American physicist Clarence Zener.

When the Zener voltage is reached, the reverse voltage across the Zener diode remains constant even as the current through it changes. With an appropriate series current-limiting resistor, the Zener diode provides an accurate voltage reference (see Fig 3.20).

Zener diodes are rated by their reverse-breakdown voltage and their power-handling capacity, where $P = V_Z \times I_Z$. Since the same current must always pass through the resistor to drop the source voltage down to the reference voltage, with that current divided between the Zener diode and the load, this type of power source is very wasteful of current.

The Zener diode does make an excellent and efficient voltage reference in a larger voltage regulating circuit where the load current is provided from another device whose voltage is set by the reference. (See the **Power Sources** chapter for more information about using Zener diodes as voltage regulators.) When operating in the breakdown region, Zener diodes can be modeled as a simple voltage source.

The primary sources of error in Zener-diode-derived voltages are the variation with load current and the variation due to heat. Temperature-compensated Zener diodes are available with temperature coefficients as low as 5 parts per million per °C. If this is unacceptable, voltage reference integrated circuits based on Zener diodes have been developed

that include additional circuitry to counteract temperature effects.

A variation of Zener diodes, *transient voltage suppressor (TVS)* diodes are designed to dissipate the energy in short-duration, high-voltage transients that would otherwise damage equipment or circuits. TVS diodes have large junction cross-sections so that they can handle large currents without damage. These diodes are also known as TransZorbs. Since the polarity of the transient can be positive, negative, or both, transient protection circuits can be designed with two devices connected with opposite polarities.

RECTIFIERS

The most common application of a diode is to perform rectification; that is, permitting current flow in only one direction. Power rectification converts ac current into pulsating dc current. There are three basic forms of power rectification using semiconductor diodes: half wave (1 diode), full-wave center-tapped (2 diodes) and full-wave bridge (4 diodes). These applications are shown in **Fig 3.21A**, B and C and are more fully described in the **Power Sources** chapter.

The most important diode parameters to consider for power rectification are the PIV and current ratings. The peak negative voltages that are blocked by the diode must be smaller in magnitude than the PIV and the peak current through the diode when it is forward biased must be less than the maximum average forward current.

Rectification is also used at much lower current levels in modulation and demodulation and other types of analog signal processing circuits. For these applications, the diode's response speed and junction forward voltage are the most important ratings.

3.3.2 Bipolar Junction Transistors (BJT)

The bipolar transistor is a *current-controlled device* with three basic terminals; *emitter*, *collector* and *base*. The current between the emitter and the collector is controlled by the current between the base and emitter. The convention when discussing transistor operation is that the three currents into the device are positive (I_c into the collector, I_b into the base and I_e into the emitter). Kirchhoff's Current Law (see the **Electrical Fundamentals** chapter) applies to transistors just as it does to passive electrical networks: the total current entering the device must be zero. Thus, the relationship between the currents into a transistor can be generalized as

$$I_c + I_b + I_e = 0 \quad (6)$$

which can be rearranged as necessary. For

Fig 3.21 — Diode rectifier circuits. (A) Half wave rectifier circuit. Only when the ac voltage is positive does current pass through the diode. Current flows only during half of the cycle. (B) Full-wave center-tapped rectifier circuit. Center-tap on the transformer secondary is grounded and the two ends of the secondary are 180° out of phase. (C) Full-wave bridge rectifier circuit. In each half of the cycle two diodes conduct.

example, if we are interested in the emitter current,

$$I_e = -(I_c + I_b) \quad (7)$$

The back-to-back diode model shown in Fig 3.9 is appropriate for visualization of transistor construction. In actual transistors,

however, the relative sizes of the collector, base and emitter regions differ. A common transistor configuration that spans a distance of 3 mm between the collector and emitter contacts typically has a base region that is only 25 μm across.

The operation of the bipolar transistor is described graphically by characteristic curves as shown in **Fig 3.22**. These are similar to the I-V characteristic curves for the two-terminal devices described in the preceding sections. The parameters shown by the curves depend on the type of circuit in which they are measured, such as common emitter or common collector. The output characteristic shows a set of curves for either collector or emitter current versus collector-emitter voltage at various values of input current (either base or emitter). The input characteristic shows the voltage between the input and common terminals (such as base-emitter) versus the input current for different values of output voltage.

CURRENT GAIN

Two parameters describe the relationships between the three transistor currents at low frequencies:

$$\alpha \approx -\frac{\Delta I_C}{\Delta I_E} \approx 1 \quad (8)$$

$$\beta = \frac{\Delta I_C}{\Delta I_B} \quad (9)$$

The relationship between α and β is defined as

$$\alpha = -\frac{\beta}{1 + \beta} \quad (10)$$

Another designation for β is often used: h_{FE} , the *forward dc current gain*. (The “h” refers to “h parameters,” a set of transfer parameters for describing a two-port network and described in more detail in the **RF Techniques** chapter.) The symbol, h_{fe} , in which the subscript is in lower case, is used for the forward current gain of ac signals.

OPERATING REGIONS

Current conduction between collector and emitter is described by *regions* of the transistor's characteristic curves in Fig 3.22. (References such as *common-emitter* or *common-base* refer to the configuration of the circuit in which the parameter is measured.) The transistor is in its *active* or *linear region* when the base-collector junction is reverse biased and the base-emitter junction is forward biased. The slope of the output current, I_O , versus the output voltage, V_O , is virtually flat, indicating that the output current is nearly independent of the output voltage. In this region, the output circuit of the transistor can be modeled as a constant-current source controlled by

Fig 3.22 — Transistor response curve output characteristics. The x-axis is the output voltage, and the y-axis is the output current. Different curves are plotted for various values of input current. The three regions of the transistor are its cutoff region, where no current flows in any terminal, its active region, where the output current is nearly independent of the output voltage and there is a linear relationship between the input current and the output current, and the saturation region, where the output current has large changes for small changes in output voltage.

the input current. The slight slope that does exist is due to base-width modulation (known as the *Early effect*).

When both the junctions in the transistor are forward biased, the transistor is said to be in its *saturation region*. In this region, V_O is nearly zero and large changes in I_O occur for very small changes in V_O . Both junctions in the transistor are reverse-biased in the *cutoff region*. Under this condition, there is very little current in the output, only the nanoamperes or microamperes that result from the very small leakage across the input-to-output junction. Finally, if V_O is increased to very high values, avalanche breakdown begins as in a PN-junction diode and output current increases rapidly. This is the *breakdown region*, not shown in Fig 3.22.

These descriptions of junction conditions are the basis for the use of transistors. Various configurations of the transistor in circuitry make use of the properties of the junctions to serve different purposes in analog signal processing.

OPERATING PARAMETERS

A typical general-purpose bipolar-transistor data sheet lists important device specifications. Parameters listed in the ABSOLUTE MAXIMUM RATINGS section are the three junction voltages (V_{CEO} , V_{CBO} and V_{EBO}), the continuous collector current (I_C), the total device power dissipation (P_D) and the operating and storage temperature range. Exceeding any of these parameters is likely to cause the transistor to be destroyed. (The “O” in the suffixes of the junction voltages indicates that the remaining terminal is not connected, or open.)

In the OPERATING PARAMETERS section, three guaranteed minimum junction breakdown voltages are listed $V_{(BR)CEO}$, $V_{(BR)CBO}$ and $V_{(BR)EBO}$. Exceeding these voltages is likely to cause the transistor to enter avalanche breakdown, but if current is limited, permanent damage may not result.

Under ON CHARACTERISTICS are the guaranteed minimum dc current gain (β or h_{FE}), guaranteed maximum collector-emitter saturation voltage, $V_{CE(SAT)}$, and the guaranteed maximum base-emitter on voltage, $V_{BE(ON)}$. Two guaranteed maximum collector cutoff currents, I_{CEO} and I_{CBO} , are listed under OFF CHARACTERISTICS.

The next section is SMALL-SIGNAL CHARACTERISTICS, where the guaranteed minimum current gain-bandwidth product, BW or f_T , the guaranteed maximum output capacitance, C_{obo} , the guaranteed maximum input capacitance, C_{ibo} , the guaranteed range of input impedance, h_{ie} , the small-signal current gain, h_{fe} , the guaranteed maximum voltage feedback ratio, h_{re} and output admittance, h_{oe} are listed.

Finally, the SWITCHING CHARACTERISTICS section lists absolute maximum ratings for delay time, t_d ; rise time, t_r ; storage time, t_s ; and fall time, t_f .

3.3.3 Field-Effect Transistors (FET)

FET devices are controlled by the voltage level of the input rather than the input current, as in the bipolar transistor. FETs have three basic terminals, the *gate*, the *source* and the *drain*. They are analogous to bipolar transistor terminals: the gate to the base, the source

Fig 3.23—FET schematic symbols.

to the emitter, and the drain to the collector. Symbols for the various forms of FET devices are pictured in Fig 3.23.

The FET gate has a very high impedance, so the input can be modeled as an open circuit. The voltage between gate and source, V_{GS} , controls the resistance of the drain-source

Fig 3.24 — JFET input leakage curves for common source amplifier configuration. Input voltage (V_{GS}) on the x-axis versus input current (I_G) on the y-axis, with two curves plotted for different operating temperatures, 25 °C and 125 °C. Input current increases greatly when the gate voltage exceeds the junction breakpoint voltage.

channel, r_{DS} , and so the output of the FET is modeled as a current source, whose output current is controlled by the input voltage.

The action of the FET channel is so nearly ideal that, as long as the JFET gate does not become forward biased and inject current from the base into the channel, the drain and source currents are virtually identical. For JFETs the *gate leakage current*, I_G , is a function of V_{GS} and this is often expressed with an *input curve* (see **Fig 3.24**). The point at which there is a significant increase in I_G is called the *junction breakpoint voltage*. Because the gate of MOSFETs is insulated from the channel, gate leakage current is insignificant in these devices.

The dc channel resistance, r_{DS} , is specified in data sheets to be less than a maximum value when the device is biased on ($r_{DS(on)}$). When the gate voltage is maximum ($V_{GS} = 0$ for a

JFET), $r_{DS(on)}$ is minimum. This describes the effectiveness of the device as an analog switch. Channel resistance is approximately the same for ac and dc signals until at high frequencies the capacitive reactances inherent in the FET structure become significant.

FETs also have strong similarities to vacuum tubes in that input voltage between the grid and cathode controls an output current between the plate and cathode. (See the chapter on **RF Power Amplifiers** for more information on vacuum tubes.)

FORWARD TRANSCONDUCTANCE

The change in FET drain current caused by a change in gate-to-source voltage is called *forward transconductance*, g_m .

$$g_m = \frac{\Delta I_{DS}}{\Delta V_{GS}}$$

or

$$\Delta I_{DS} = g_m \Delta V_{GS} \quad (11)$$

The input voltage, V_{GS} , is measured between the FET gate and source and drain current, I_{DS} , flows from drain to source. Analogous to a bipolar transistor's current gain, the units of transconductance are Siemens (S) because it is the ratio of current to voltage. (Both g_m and g_{fs} are used interchangeably to indicate transconductance. Some sources specify g_{fs} as the *common-source forward transconductance*. This chapter uses g_m , the most common convention in the reference literature.)

OPERATING REGIONS

The most useful relationships for FETs are the output and transconductance response characteristic curves in **Fig 3.25**. (References such as *common-source* or *common-gate* refer

Fig 3.26 — JFET operating regions. At the left, I_D is increasing rapidly with V_{GS} and the JFET can be treated as resistance (R_{DS}) controlled by V_{GS} . In the saturation region, drain current, I_D , is relatively independent of V_{GS} . As V_{DS} increases further, avalanche breakdown begins and I_D increases rapidly.

to the configuration of the circuit in which the parameter is measured.) Transconductance curves relate the drain current, I_D , to gate-to-source voltage, V_{GS} , at various drain-source voltages, V_{DS} . The FET's forward transconductance, g_m , is the slope of the lines in the forward transconductance curve. The same parameters are interrelated in a different way in the output characteristic, in which I_D is shown versus V_{DS} for different values of V_{GS} .

Like the bipolar transistor, FET operation can be characterized by regions. The *ohmic region* is shown at the left of the FET output characteristic curve in **Fig 3.26** where I_D is increasing nearly linearly with V_{DS} and the FET is acting like a resistance controlled by V_{GS} . As V_{DS} continues to increase, I_D saturates and becomes nearly constant. This is the FET's *saturation region* in which the channel of the FET can be modeled as a constant-current source. V_{DS} can become so large that V_{GS} no longer controls the conduction of the device and avalanche breakdown occurs as in bipolar transistors and PN-junction diodes. This is the *breakdown region*, shown in **Fig 3.26** where the curves for I_D break sharply upward. If V_{GS} is less than V_P , so that transconductance is zero, the FET is in the *cutoff region*.

OPERATING PARAMETERS

A typical FET data sheet gives ABSOLUTE MAXIMUM RATINGS for V_{DS} , V_{DG} , V_{GS} and I_D , along with the usual device dissipation (P_D) and storage temperature range. Exceeding these limits usually results in destruction of the FET.

Under OPERATING PARAMETERS the OFF CHARACTERISTICS list the gate-source breakdown voltage, $V_{GS(BR)}$, the reverse gate current, I_{GSS} and the gate-source cutoff voltage,

Fig 3.25 — JFET output and transconductance response curves for common source amplifier configuration. (A) Output voltage (V_{DS}) on the x-axis versus output current (I_D) on the y-axis, with different curves plotted for various values of input voltage (V_{GS}). (B) Transconductance curve with the same three variables rearranged: V_{GS} on the x-axis, I_D on the y-axis and curves plotted for different values of V_{DS} .

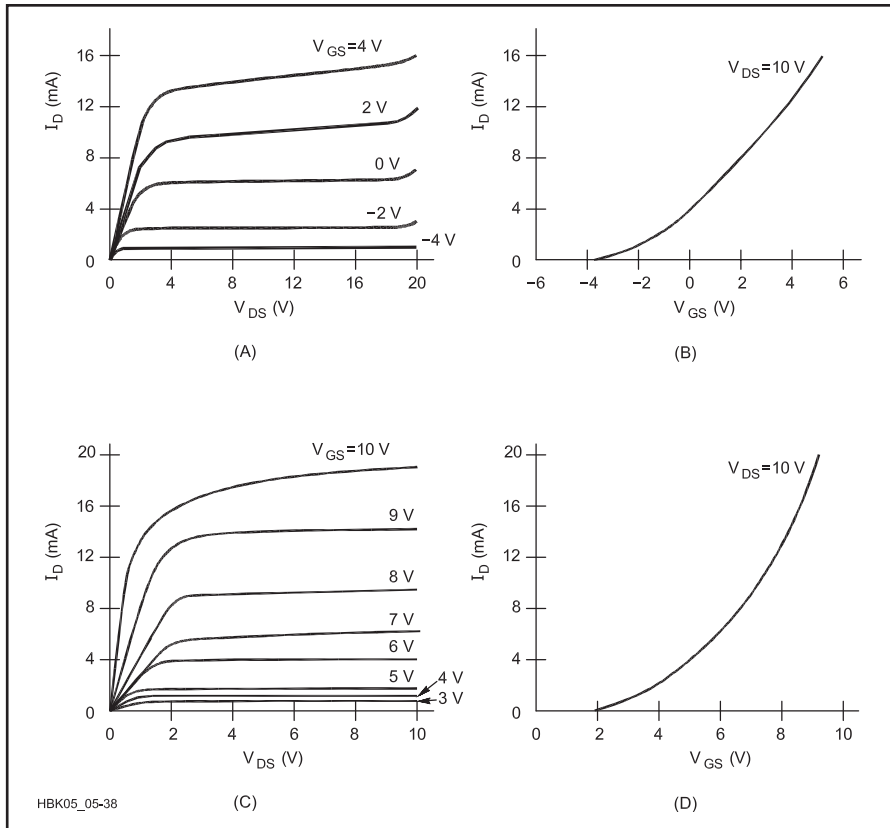

Fig 3.27 — MOSFET output [(A) and (C)] and transconductance [(B) and (D)] response curves. Plots (A) and (B) are for an N-channel depletion mode device. Note that V_{GS} varies from negative to positive values. Plots (C) and (D) are for an N-channel enhancement mode device. V_{GS} has only positive values.

$V_{GS(OFF)}$. Exceeding $V_{GS(BR)}$ will not permanently damage the device if current is limited. The primary ON CHARACTERISTIC parameters are the channel resistance, r_{DS} , and the zero-gate-voltage drain current (I_{DSS}). An FET's dc channel resistance, r_{DS} , is specified in data sheets to be less than a maximum value when the device is biased on ($r_{DS(on)}$). For ac signals, $r_{ds(on)}$ is not necessarily the same as $r_{DS(on)}$, but it is not very different as long as the frequency is not so high that capacitive reactance in the FET becomes significant.

The SMALL SIGNAL CHARACTERISTICS include the forward transfer admittance, y_{fs} , the output admittance, y_{os} , the static drain-source on resistance, $r_{ds(on)}$ and various capacitances such as input capacitance, C_{iss} , reverse transfer capacitance, C_{rss} , the drain-substrate capacitance, $C_{d(sub)}$. FUNCTIONAL CHARACTERISTICS include the noise figure, NF, and the common source power gain, G_{ps} .

MOSFETS

As described earlier, the MOSFET's gate is insulated from the channel by a thin layer of nonconductive oxide, doing away with any appreciable gate leakage current. Because of this isolation of the gate, MOSFETs do not

need input and reverse transconductance curves. Their output curves (Fig 3.27) are similar to those of the JFET. The gate acts as a small capacitance between the gate and both the source and drain.

The output and transconductance curves in Fig 3.27A and 3.27B show that the depletion-mode N-channel MOSFET's transconductance is positive at $V_{GS} = 0$, like that of the N-channel JFET. Unlike the JFET, however, increasing V_{GS} does not forward-bias the gate-source junction and so the device can be operated with $V_{GS} > 0$.

In the enhancement-mode MOSFET, transconductance is zero at $V_{GS} = 0$. As V_{GS} is increased, the MOSFET enters the ohmic region. If V_{GS} increases further, the saturation region is reached and the MOSFET is said to be *fully-on*, with r_{DS} at its minimum value. The behavior of the enhancement-mode MOSFET is similar to that of the bipolar transistor in this regard.

The relatively flat regions in the MOSFET output curves are often used to provide a constant current source. As is plotted in these curves, the drain current, I_D , changes very little as the drain-source voltage, V_{DS} , varies in this portion of the curve. Thus, for a fixed

gate-source voltage, V_{GS} , the drain current can be considered to be constant over a wide range of drain-source voltages.

Multiple gate MOSFETs are also available. Due to the insulating layer, the two gates are isolated from each other and allow two signals to control the channel simultaneously with virtually no loading of one signal by the other. A common application of this type of device is an automatic gain control (AGC) amplifier. The signal is applied to one gate and a rectified, low-pass filtered form of the output (the AGC voltage) is fed back to the other gate. Another common application is as a mixer in which the two input signals are applied to the pair of gates.

MOSFET Gate Protection

The MOSFET is constructed with a very thin layer of SiO_2 for the gate insulator. This layer is extremely thin in order to improve the transconductance of the device but this makes it susceptible to damage from high voltage levels, such as *electrostatic discharge* (ESD) from static electricity. If enough charge accumulates on the gate terminal, it can *punch through* the gate insulator and destroy it. The insulation of the gate terminal is so good that virtually none of this potential is eased by leakage of the charge into the device. While this condition makes for nearly ideal input impedance (approaching infinity), it puts the device at risk of destruction from even such seemingly innocuous electrical sources as static electrical discharges from handling.

Some MOSFET devices contain an internal Zener diode with its cathode connected to the gate and its anode to the substrate. If the voltage at the gate rises to a damaging level the Zener diode junction conducts, bleeding excess charges off to the substrate. When voltages are within normal operating limits the Zener has little effect on the signal at the gate, although it may decrease the input impedance of the MOSFET.

This solution will not work for all MOSFETs. The Zener diode must always be reverse biased to be effective. In the enhancement-mode MOSFET, $V_{GS} > 0$ for all valid uses of the part, keeping the Zener reverse biased. In depletion mode devices however, V_{GS} can be both positive and negative; when negative, a gate-protection Zener diode would be forward biased and the MOSFET gate would not be driven properly. In some depletion mode MOSFETs, back-to-back Zener diodes are used to protect the gate.

MOSFET devices are at greatest risk of damage from static electricity when they are out of circuit. Even though an electrostatic discharge is capable of delivering little energy, it can generate thousands of volts and high peak currents. When storing MOSFETs, the leads should be placed into conductive foam. When working with MOSFETs, it is a good

idea to minimize static by wearing a grounded wrist strap and working on a grounded workbench or mat. A humidifier may help to decrease the static electricity in the air. Before inserting a MOSFET into a circuit board it helps to first touch the device leads with your hand and then touch the circuit board. This serves to equalize the excess charge so that little excess charge flows when the device is inserted into the circuit board.

Power MOSFETs

Power MOSFETs are designed for use as switches, with extremely low values of $r_{DS(on)}$; values of 50 milliohms ($m\Omega$) are common. The largest devices of this type can switch tens of amps of current with V_{DS} voltage ratings of hundreds of volts. The **Component Data and References** chapter includes a table of Power FET ratings. The schematic symbol for power MOSFETs (see Fig 3.23) includes a *body diode* that allows the FET to conduct in the reverse direction, regardless of V_{GS} . This is useful in many high-power switching applications. Power MOSFETs used for RF amplifiers are discussed in more detail in the **RF Power Amplifiers** chapter.

While the maximum ratings for current and voltage are high, the devices cannot withstand both high drain current and high drain-to-source voltage at the same time because of the power dissipated; $P = V_{DS} \times I_D$. It is important to drive the gate of a power MOSFET such that the device is fully on or fully off so that either V_{DS} or I_D is at or close to zero. When switching, the device should spend as little time as possible in the linear region where both current and voltage are nonzero because their product (P) can be substantial. This is not a big problem if switching only takes place occasionally, but if the switching is repetitive (such as in a switching power supply) care should be taken to drive the gate properly and remove excess heat from the device.

Because the gate of a power MOSFET is capacitive (up to several hundred pF for large devices), charging and discharging the gate quickly results in short current peaks of more than 100 mA. Whatever circuit is used to drive the gate of a power MOSFET must be able to handle that current level, such as an integrated circuit designed for driving the capacitive load an FET gate presents.

The gate of a power MOSFET should not be left open or connected to a high-impedance circuit. Use a pull-down or pull-up resistor connected between the gate and the appropriate power supply to ensure that the gate is placed at the right voltage when not being driven by the gate drive circuit.

GaAsFETs

FETs made from gallium-arsenide (GaAs) material are used at UHF and microwave frequencies because they have gain at these

frequencies and add little noise to the signal. The reason GaAsFETs have gain at these frequencies is the high mobility of the electrons in GaAs material. Because the electrons are more mobile than in silicon, they respond to the gate-source input signal more quickly and strongly than silicon FETs, providing gain at higher frequencies (f_T is directly proportional to electron mobility). The higher electron mobility also reduces thermally-generated noise generated in the FET, making the GaAsFET especially suitable for weak-signal preamps.

Because electron mobility is always higher than hole mobility, N-type material is used in GaAsFETs to maximize high-frequency gain. Since P-type material is not used to make a gate-channel junction, a metal Schottky junction is formed by depositing metal directly on the surface of the channel. This type of device is also called a *MESFET* (metal-semiconductor field-effect transistor).

3.3.4 Optical Semiconductors

In addition to electrical energy and heat energy, light energy also affects the behavior of semiconductor materials. If a device is made to allow photons of light to strike the surface of the semiconductor material, the energy absorbed by electrons disrupts the bonds between atoms, creating free electrons and holes. This increases the conductivity of the material (*photoconductivity*). The photon can also transfer enough energy to an electron

to allow it to cross a PN junction's depletion region as current flow through the semiconductor (*photoelectricity*).

PHOTOCONDUCTORS

In commercial *photoconductors* (also called *photoresistors*) the resistance can change by as much as several kilohms for a light intensity change of 100 ft-candles. The most common material used in photoconductors is cadmium sulfide (CdS), with a resistance range of more than 2 M Ω in total darkness to less than 10 Ω in bright light. Other materials used in photoconductors respond best at specific colors. Lead sulfide (PbS) is most sensitive to infrared light and selenium (Se) works best in the blue end of the visible spectrum.

PHOTODIODES

A similar effect is used in some diodes and transistors so that their operation can be controlled by light instead of electrical current biasing. These devices, shown in Fig 3.28, are called *photodiodes* and *phototransistors*. The flow of minority carriers across the reverse biased PN junction is increased by light falling on the doped semiconductor material. In the dark, the junction acts the same as any reverse biased PN junction, with a very low current, I_{SC} , (on the order of 10 μA) that is nearly independent of reverse voltage. The presence of light not only increases the current but also provides a resistance-like relationship

Fig 3.28 — The photodiode (A) is used to detect light. An amplifier circuit changes the variations in photodiode current to a change in output voltage. At (B), a phototransistor conducts current when its base is illuminated. This causes the voltage at the collector to change causing the amplifier's output to switch between ON and OFF.

Fig 3.29 — Photodiode I-V curve. Reverse voltage is plotted on the x-axis and current through diode is plotted on the y-axis. Various response lines are plotted for different illumination. Except for the zero illumination line, the response does not pass through the origin since there is current generated at the PN junction by the light energy. A load line is shown for a 50-k Ω resistor in series with the photodiode.

(reverse current increases as reverse voltage increases). See **Fig 3.29** for the characteristic response of a photodiode. Even with no reverse voltage applied, the presence of light causes a small reverse current, as indicated by the points at which the lines in **Fig 3.29** intersect the left side of the graph.

Photoconductors and photodiodes are generally used to produce light-related analog signals that require further processing. For example, a photodiode is used to detect infrared light signals from remote control devices as in **Fig 3.28A**. The light falling on the reverse-biased photodiode causes a change in I_{SC} that is detected as a change in output voltage.

Light falling on the phototransistor acts as base current to control a larger current

between the collector and emitter. Thus the phototransistor acts as an amplifier whose input signal is light and whose output is current. Phototransistors are more sensitive to light than the other devices. Phototransistors have lots of light-to-current gain, but photodiodes normally have less noise, so they make more sensitive detectors. The phototransistor in **Fig 3.28B** is being used as a detector. Light falling on the phototransistor causes collector current to flow, dropping the collector voltage below the voltage at the amplifier's + input and causing a change in V_{OUT} .

PHOTOVOLTAIC CELLS

When illuminated, the reverse-biased photodiode has a reverse current caused by excess

minority carriers. As the reverse voltage is reduced, the potential barrier to the forward flow of majority carriers is also reduced. Since light energy leads to the generation of both majority and minority carriers, when the resistance to the flow of majority carriers is decreased these carriers form a forward current. The voltage at which the forward current equals the reverse current is called the *photovoltaic potential* of the junction. If the illuminated PN junction is not connected to a load, a voltage equal to the photovoltaic potential can be measured across it as the *terminal voltage*, V_T or *open-circuit voltage*, V_{OC} .

Devices that use light from the sun to produce electricity in this way are called *photovoltaic (PV)* or *solar cells* or *solar batteries*. The symbol for a photovoltaic cell is shown in **Fig 3.30A**. The electrical equivalent circuit of the cell is shown in **Fig 3.30B**. The cell is basically a large, flat diode junction exposed to light. Metal electrodes on each side of the junction collect the current generated.

When illuminated, the cell acts like a current source, with some of the current flowing through a diode (made of the same material as the cell), a shunt resistance for leakage current and a series resistor that represents the resistance of the cell. Two quantities define the electrical characteristics of common silicon photovoltaic cells. These are an open-circuit voltage, V_{OC} of 0.5 to 0.6 V and the output *short-circuit current*, I_{SC} as above, that depends on the area of the cell exposed to light and the degree of illumination. A measure of the cell's effectiveness at converting light into current is the *conversion efficiency*. Typical silicon solar cells have a conversion efficiency of 10 to 15% although special cells with stacked junctions or using special light-absorbing materials have shown efficiencies as high as 40%.

Solar cells are primarily made from single-crystal slices of silicon, similar to diodes and transistors, but with a much greater area. *Polycrystalline silicon* and *thin-film* cells are less expensive, but have lower conversion efficiency. Technology is advancing rapidly in the field of photovoltaic energy and there are a number of different types of materials and fabrication techniques that have promise in surpassing the effectiveness of the single-junction silicon cells.

Solar cells are assembled into arrays called *solar panels*, shown in **Fig 3.30C**. Cells are connected in series so that the combined output voltage is a more useful voltage, such as 12 V. Several strings of cells are then connected in parallel to increase the available output current. Solar panels are available with output powers from a few watts to hundreds of watts. Note that unlike batteries, strings of solar cells can be connected directly in parallel because they act as sources of constant current instead

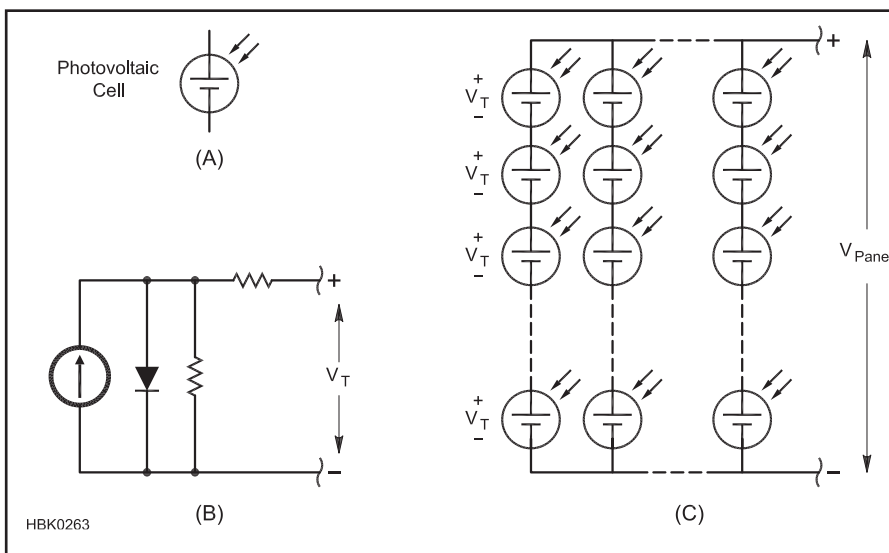

Fig 3.30 — A photovoltaic cell's symbol (A) is similar to a battery. Electrically, the cell can be modeled as the equivalent circuit at (B). Solar panels (C) consist of arrays of cells connected to supply power at a convenient voltage.

of voltage. (More information on the use of solar panels for powering radio equipment can be found in the chapter on **Power Sources**.)

LIGHT EMITTING DIODES AND LASER DIODES

In the photodiode, energy from light falling on the semiconductor material is absorbed to create additional electron-hole pairs. When the electrons and holes recombine, the same amount of energy is given off. In normal diodes the energy from recombination of carriers is given off as heat. In certain forms of semiconductor material, the recombination energy is given off as light with a mechanism called *electroluminescence*. Unlike the incandescent light bulb, electroluminescence is a cold (non-thermal) light source that typically operates with low voltages and currents (such as 1.5 V and 10 mA). Devices made for this purpose are called *light emitting diodes (LEDs)*. They have the advantages of low power requirements, fast switching times (on the order of 10 ns) and narrow spectra (relatively pure color).

The LED emits light when it is forward biased and excess carriers are present. As the carriers recombine, light is produced with a color that depends on the properties of the semiconductor material used. Gallium-arsenide (GaAs) generates light in the infrared region, gallium-phosphide (GaP) gives off red light when doped with oxygen or green light when doped with nitrogen. Orange light is attained with a mixture of GaAs and GaP (GaAsP). Silicon-carbide (SiC) creates a blue LED.

White LEDs are made by coating the inside of the LED lens with a white-light emitting phosphor and illuminating the phosphor with light from a single-color LED. White LEDs are currently approaching the cost of cold-florescent (CFL) bulbs and will eventually displace CFL technology for lighting, just as CFL is replacing the incandescent bulb.

The LED, shown in **Fig 3.31**, is very simple to use. It is connected across a voltage source

Fig 3.31 — A light-emitting diode (LED) emits light when conducting forward current. A series current-limiting resistor is used to set the current through the LED according to the equation.

(V) with a series resistor (R) that limits the current to the desired level (I_F) for the amount of light to be generated.

$$R = \frac{V - V_F}{I_F} \quad (12)$$

where V_F is the forward voltage of the LED.

The cathode lead is connected to the lower potential, and is specially marked as shown in the manufacturer's data sheet. LEDs may be connected in series for additional light, with the same current flowing in all of the diodes. Diodes connected in parallel without current-limiting resistors for each diode are likely to share the current unequally, thus the series connection is preferred.

The laser diode operates by similar principles to the LED except that all of the light produced is *monochromatic* (of the same color and wavelength) and it is *coherent*, meaning that all of the light waves emitted by the device are in phase. Laser diodes generally require higher current than an LED and will not emit light until the *lasing current* level is reached. Because the light is monochromatic and coherent, laser diodes can be used for applications requiring precise illumination and modulation, such as high-speed data links, and in data storage media such as CD-ROM and DVD. LEDs are not used for high-speed or high-frequency analog modulation because of recovery time limitations, just as in regular rectifiers.

OPTOISOLATORS

An interesting combination of optoelectronic components proves very useful in many analog signal processing applications. An *optoisolator* consists of an LED optically coupled to a phototransistor, usually in an enclosed package (see **Fig 3.32**). The optoisolator, as its name suggests, isolates different circuits from each other. Typically, isolation resistance is on the order of $10^{11} \Omega$ and isolation capacitance is less than 1 pF. Maximum voltage isolation varies from 1000 to 10,000 V ac. The most common optoisolators are available in 6-pin DIP packages.

Optoisolators are primarily used for voltage level shifting and signal isolation. Voltage level shifting allows signals (usually digital signals) to pass between circuits operating at greatly different voltages. The isolation has two purposes: to protect circuitry (and operators) from excessive voltages and to isolate noisy circuitry from noise-sensitive circuitry.

Optoisolators also cannot transfer signals with high power levels. The power rating of the LED in a 4N25 device is 120 mW. Optoisolators have a limited frequency response due to the high capacitance of the LED. A typical bandwidth for the 4N25 series is 300 kHz. Optoisolators with bandwidths of several MHz are available, but are

Fig 3.32 — The optoisolator consists of an LED (input) that illuminates the base of a phototransistor (output). The phototransistor then conducts current in the output circuit. CTR is the optoisolator's current transfer ratio.

somewhat expensive.

As an example of voltage level shifting, an optoisolator can be used to allow a low-voltage, solid-state electronic Morse code keyer to activate a vacuum-tube grid-block keying circuit that operates at a high negative voltage (typically about -100 V) but low current. No common ground is required between the two pieces of equipment.

Optoisolators can act as input protection for circuits that are exposed to high voltages or transients. For example, a short 1000-V transient that can destroy a semiconductor circuit will only saturate the LED in the optoisolator, preventing damage to the circuit. The worst that will happen is the LED in the optoisolator will be destroyed, but that is usually quite a bit less expensive than the circuit it is protecting.

Optoisolators are also useful for isolating different ground systems. The input and output signals are totally isolated from each other, even with respect to the references for each signal. A common application for optoisolators is when a computer is used to control radio equipment. The computer signal, and even its ground reference, typically contains considerable wide-band noise caused by the digital circuitry. The best way to keep this noise out of the radio is to isolate both the signal and its reference; this is easily done with an optoisolator.

The design of circuits with optoisolators is not greatly different from the design of circuits with LEDs and with transistors. On the input side, the LED is forward-biased and driven with a series current-limiting resistor whose value limits current to less than the maximum value for the device (for example, 60 mA is the maximum LED current for a 4N25). This is identical to designing with standalone LEDs.

On the output side, instead of current gain for a transistor, the optoisolator's *current transfer ratio (CTR)* is used. CTR is a ratio

given in percent between the amount of current through the LED to the output transistor's maximum available collector current. For example, if an optoisolator's $CTR = 25\%$, then an LED current of 20 mA results in the output transistor being able to conduct up to $20 \times 0.25 = 5$ mA of current in its collector circuit.

If the optoisolator is to be used for an analog signal, the input signal must be appropriately dc shifted so that the LED is always forward biased. A phototransistor with all three leads available for connection (as in Fig 3.32) is required. The base lead is used for biasing, allowing the optical signal to create variations above and below the transistor's operating point. The collector and emitter leads are used as they would be in any transistor amplifier circuit. (There are also linear optoisolators that include built-in linearizing circuitry.) The use of linear optoisolators is not common.

FIBER OPTICS

An interesting variation on the optoisolator is the *fiber-optic* connection. Like the optoisolator, the input signal is used to drive an LED or laser diode that produces modulated light (usually light pulses). The light is transmitted in a fiber optic cable, an extruded glass fiber that efficiently carries light over long distances and around fairly sharp bends. The signal is recovered by a photo detector (photoresistor, photodiode or phototransistor). Because the fiber optic cable is nonconductive, the transmitting and receiving systems are electrically isolated.

Fiber optic cables generally have far less loss than coaxial cable transmission lines. They do not leak RF energy, nor do they pick up electrical noise. Fiber optic cables are virtually immune to electromagnetic interference! Special forms of LEDs and phototransistors are available with the appropriate optical couplers for connecting to fiber optic cables. These devices are typically designed for higher frequency operation with gigahertz bandwidth.

3.3.5 Linear Integrated Circuits

If you look inside a transistor, the actual size of the semiconductor is quite small compared to the size of the packaging. For most semiconductors, the packaging takes considerably more space than the actual semiconductor device. Thus, an obvious way to reduce the physical size of circuitry is to combine more of the circuit inside a single package.

HYBRID INTEGRATED CIRCUITS

It is easy to imagine placing several small semiconductor chips in the same package. This is known as *hybrid circuitry*, a technology in which several semiconductor chips

are placed in the same package and miniature wires are connected between them to make complete circuits.

Hybrid circuits miniaturize analog electronic circuits by replacing much of the packaging that is inherent in discrete electronics. The term *discrete* refers to the use of individual components to make a circuit, each in its own package. The individual components are attached together on a small circuit board or with bonding wires.

Once widespread in electronics, hybrid ICs have largely been displaced by fully integrated devices with all the components on the same piece of semiconductor material. Manufacturers often use hybrids when small size is needed, but there is insufficient volume to justify the expense of a custom IC.

A current application for hybrid circuitry is UHF and microwave amplifiers — they are in wide use by the mobile phone industry. For example, the Motorola MW4IC915N Wideband Integrated Power Amplifier is a complete 15-W transmitting module. Its TO-272 package is only about 1 inch long by $\frac{3}{8}$ -inch wide. This particular device is designed for use between 750 and 1000 MHz and can be adapted for use on the amateur 902 MHz band. Other devices available as hybrid circuits include oscillators, signal processors, preamplifiers and so forth. Surplus hybrids can be hard to adapt to amateur use unless they are clearly identified with manufacturing identification such that a data sheet can be obtained.

MONOLITHIC INTEGRATED CIRCUITS

In order to build entire circuits on a single piece of semiconductor, it must be possible to fabricate resistors and capacitors, as well as transistors and diodes. Only then can the entire circuit be created on one piece of silicon called a *monolithic integrated circuit*.

An integrated circuit (IC) or “chip” is fabricated in layers. An example of a semiconductor circuit schematic and its implementation in an IC is pictured in Fig 3.33. The base layer of the circuit, the *substrate*, is made of P-type semiconductor material. Although less common, the polarity of the substrate can also be N-type material. Since the mobility of electrons is about three times higher than that of holes, bipolar transistors made with N-type collectors and FETs made with N-type channels are capable of higher speeds and power handling. Thus, P-type substrates are far more common. For devices with N-type substrates, all polarities in the ensuing discussion would be reversed.

Other substrates have been used, one of the most successful of which is the *silicon-on-sapphire* (SOS) construction that has been used to increase the bandwidth of integrated circuitry. Its relatively high manufacturing cost has impeded its use, however, except

for the demanding military and aerospace applications.

On top of the P-type substrate is a thin layer of N-type material in which the active and passive components are built. Impurities are diffused into this layer to form the appropriate component at each location. To prevent random diffusion of impurities into the N-layer, its upper surface must be protected. This is done by covering the N-layer with a layer of silicon dioxide (SiO_2). Wherever diffusion of impurities is desired, the SiO_2 is etched away. The precision of placing the components on the semiconductor material depends mainly on the fineness of the etching. The fourth layer of an IC is made of aluminum (copper is used in some high-speed digital ICs) and is used to make the interconnections between the components.

Different components are made in a single piece of semiconductor material by first diffusing a high concentration of acceptor impurities into the layer of N-type material. This process creates P-type semiconductor — often referred to as P⁺-type semiconductor because of its high concentration of acceptor atoms — that isolates regions of N-type material. Each of these regions is then further processed to form single components.

A component is produced by the diffusion of a lesser concentration of acceptor atoms into the middle of each isolation region. This results in an N-type *isolation well* that contains P-type material, is surrounded on its sides by P⁺-type material and has P-type material (substrate) below it. The cross sectional view in Fig 3.33B illustrates the various layers. Connections to the metal layer are often made by diffusing high concentrations of donor atoms into small regions of the N-type well and the P-type material in the well. The material in these small regions is N⁺-type and facilitates electron flow between the metal contact and the semiconductor. In some configurations, it is necessary to connect the metal directly to the P-type material in the well.

Fabricating Resistors and Capacitors

An isolation well can be made into a resistor by making two contacts into the P-type semiconductor in the well. Resistance is inversely proportional to the cross-sectional area of the well. An alternate type of resistor that can be integrated in a semiconductor circuit is a *thin-film resistor*, where a metallic film is deposited on the SiO_2 layer, masked on its upper surface by more SiO_2 and then etched to make the desired geometry, thus adjusting the resistance.

There are two ways to form capacitors in a semiconductor. One is to make use of the PN junction between the N-type well and the P-type material that fills it. Much like a varactor diode, when this junction is reverse biased

Fig 3.33 — Integrated circuit layout. (A) Circuit containing two diodes, a resistor, a capacitor, an NPN transistor and an N-channel MOSFET. Labeled leads are D for diode, R for resistor, DC for diode-capacitor, E for emitter, S for source, CD for collector-drain and G for gate. (B) Integrated circuit that is identical to circuit in (A). Same leads are labeled for comparison. Circuit is built on a P-type semiconductor substrate with N-type wells diffused into it. An insulating layer of SiO₂ is above the semiconductor and is etched away where aluminum metal contacts are made with the semiconductor. Most metal-to-semiconductor contacts are made with heavily doped N-type material (N⁺-type semiconductor).

a capacitance results. Since a bias voltage is required, this type of capacitor is polarized, like an electrolytic capacitor. Nonpolarized capacitors can also be formed in an integrated circuit by using thin film technology. In this case, a very high concentration of donor ions is diffused into the well, creating an N⁺-type region. A thin metallic film is deposited over the SiO₂ layer covering the well and the capacitance is created between the metallic film and the well. The value of the capacitance is adjusted by varying the thickness of the SiO₂ layer and the cross-sectional size of the well. This type of thin film capacitor is also known as a metal oxide semiconductor (MOS) capacitor.

Unlike resistors and capacitors, it is very difficult to create inductors in integrated circuits. Generally, RF circuits that need inductance require external inductors to be connected to the IC. In some cases, particu-

larly at lower frequencies, the behavior of an inductor can be mimicked by an amplifier circuit. In many cases the appropriate design of IC amplifiers can reduce or eliminate the need for external inductors.

Fabricating Diodes and Transistors

The simplest form of diode is generated by connecting to an N⁺-type connection point in the well for the cathode and to the P-type well material for the anode. Diodes are often converted from NPN transistor configurations. Integrated circuit diodes made this way can either short the collector to the base or leave the collector unconnected. The base contact is the anode and the emitter contact is the cathode.

Transistors are created in integrated circuitry in much the same way that they are fabricated in their discrete forms. The NPN transistor is the easiest to make since the wall

of the well, made of N-type semiconductor, forms the collector, the P-type material in the well forms the base and a small region of N⁺-type material formed in the center of the well becomes the emitter. A PNP transistor is made by diffusing donor ions into the P-type semiconductor in the well to make a pattern with P-type material in the center (emitter) surrounded by a ring of N-type material that connects all the way down to the well material (base), and this is surrounded by another ring of P-type material (collector). This configuration results in a large base width separating the emitter and collector, causing these devices to have much lower current gain than the NPN form. This is one reason why integrated circuitry is designed to use many more NPN transistors than PNP transistors.

FETs can also be fabricated in IC form as shown in Fig 3.33C. Due to its many func-

tional advantages, the MOSFET is the most common form used for digital ICs. MOSFETs are made in a semiconductor chip much the same way as MOS capacitors, described earlier. In addition to the signal processing advantages offered by MOSFETs over other transistors, the MOSFET device can be fabricated in 5% of the physical space required for bipolar transistors. CMOS ICs can contain 20 times more circuitry than bipolar ICs with the same chip size, making the devices more powerful and less expensive than those based on bipolar technology. CMOS is the most popular form of integrated circuit.

The final configuration of the switching circuit is CMOS as described in a previous section of this chapter. CMOS gates require two FETs, one of each form (NMOS and PMOS as shown in the figure). NMOS requires fewer processing steps, and the individual FETs have lower on-resistance than PMOS. The fabrication of NMOS FETs is the same as for individual semiconductors; P+ wells form the source and drain in a P-type substrate. A metal gate electrode is formed on top of an insulating SiO₂ layer so that the channel forms in the P-type substrate between the source and drain. For the PMOS FET, the process is similar, but begins with an N-type well in the P-type substrate.

MOSFETs fabricated in this manner also have bias (B) terminals connected to the positive power supply to prevent destructive *latch-up*. This can occur in CMOS gates because the two MOSFETs form a *parasitic SCR*. If the SCR mode is triggered and both transistors conduct at the same time, large currents can flow through the FET and destroy the IC unless power is removed. Just as discrete MOSFETs are at risk of gate destruction, IC chips made with MOSFET devices have a similar risk. They should be treated with the same care to protect them from static electricity as discrete MOSFETs.

While CMOS is the most widely used technology, integrated circuits need not be made exclusively with MOSFETs or bipolar transistors. It is common to find IC chips designed with both technologies, taking advantage of the strengths of each.

INTEGRATED CIRCUIT ADVANTAGES

The primary advantages of using integrated circuits as opposed to discrete components are the greatly decreased physical size of the circuit and improved reliability. In fact, studies show that failure rate of electronic circuitry is most closely related to the number of interconnections between components. Thus, using integrated circuits not only reduces volume, but makes the equipment more reliable.

The amount of circuitry that can be placed onto a single semiconductor chip is a function of two factors: the size of the chip and the size

of the individual features that can be created on the semiconductor wafer. Since the invention of the monolithic IC in the mid-1960s, feature size limits have dropped below 100 nanometers ($\frac{1}{10}$ th of a millionth of a meter) as of 2009. Currently, it is not unusual to find chips with more than one million transistors on them.

In addition to size and reliability of the ICs themselves, the relative properties of the devices on a single chip are very predictable. Since adjacent components on a semiconductor chip are made simultaneously (the entire N-type layer is grown at once; a single diffusion pass isolates all the wells and another pass fills them), the characteristics of identically formed components on a single chip of silicon are nearly identical. Even if the exact characteristics of the components are unknown, very often in analog circuit design the major concern is how components interact. For instance, push-pull amplifiers require perfectly matched transistors, and the gain of many amplifier configurations is governed by the ratio between two resistors and not their absolute values of resistance. With closely matched components on the single substrate, this type of design works very well without requiring external components to adjust or “trim” IC performance.

Integrated circuits often have an advantage over discrete circuits in their temperature behavior. The variation of performance of the components on an integrated circuit due to heat is no better than that of discrete components. While a discrete circuit may be exposed to a wide range of temperature changes, the entire semiconductor chip generally changes temperature by the same amount; there are fewer “hot spots” and “cold spots.” Thus, integrated circuits can be designed to better compensate for temperature changes.

A designer of analog devices implemented with integrated circuitry has more freedom to include additional components that could improve the stability and performance of the implementation. The inclusion of components that could cause a prohibitive increase in the size, cost or complexity of a discrete circuit would have very little effect on any of these factors in an integrated circuit.

Once an integrated circuit is designed and laid out, the cost of making copies of it is very small, often only pennies per chip. Integrated circuitry is responsible for the incredible increase in performance with a corresponding decrease in price of electronics. While this trend is most obvious in digital computers, analog circuitry has also benefited from this technology.

The advent of integrated circuitry has also improved the design of high frequency circuitry, particularly the ubiquitous mobile phone and other wireless devices. One problem in the design and layout of RF equipment is the

radiation and reception of spurious signals. As frequencies increase and wavelengths approach the dimensions of the wires in a circuit board, the interconnections act as efficient antennas. The dimensions of the circuitry within an IC are orders of magnitude smaller than in discrete circuitry, thus greatly decreasing this problem and permitting the processing of much higher frequencies with fewer problems of interstage interference. Another related advantage of the smaller interconnections in an IC is the lower inherent inductance of the wires, and lower stray capacitance between components and traces.

INTEGRATED CIRCUIT DISADVANTAGES

Despite the many advantages of integrated circuitry, disadvantages also exist. ICs have not replaced discrete components, even vacuum tubes, in some applications. There are some tasks that ICs cannot perform, even though the list of these continues to decrease over time as IC technology improves.

Although the high concentration of components on an IC chip is considered to be an advantage of that technology, it also leads to a major limitation. Heat generated in the individual components on the IC chip is often difficult to dissipate. Since there are so many heat generating components so close together, the heat can build up and destroy the circuitry. It is this limitation that currently causes many power amplifiers of more than 50 W output to be designed with discrete components.

Integrated circuits, despite their short interconnection lengths and lower stray inductance, do not have as high a frequency response as similar circuits built with appropriate discrete components. (There are exceptions to this generalization, of course. As described previously, monolithic microwave integrated circuits — MMICs — are available for operation to 10 GHz.) The physical architecture of an integrated circuit is the cause of this limitation. Since the substrate and the walls of the isolation wells are made of opposite types of semiconductor material, the PN junction between them must be reverse biased to prevent current from passing into the substrate. Like any other reverse-biased PN junction, a capacitance is created at the junction and this limits the frequency response of the devices on the IC. This situation has improved over the years as isolation wells have gotten smaller, thus decreasing the capacitance between the well and the substrate, and techniques have been developed to decrease the PN junction capacitance at the substrate. One such technique has been to create an N⁺-type layer between the well and the substrate, which decreases the capacitance of the PN junction as seen by the well. As a result, analog ICs are now available with gain-bandwidth products over 1 GHz.

A major impediment to the introduction

of new integrated circuits, particularly with special applications, is the very high cost of development of new designs for full custom ICs. The masking cost alone for a designed and tested integrated circuit can exceed \$100,000 so these devices must sell in high volume to recoup the development costs. Over the past decade, however, IC design tools and fabrication services have become available that greatly reduce the cost of IC development by using predefined circuit layouts and functional blocks. These *application-specific integrated circuits (ASICs)* and *programmable gate arrays (PGA)* are now routinely created and used for even limited production runs. While still well beyond the reach of the individual amateur's resources, the ASIC or PGA is widely used in nearly all consumer electronics and in many pieces of radio equipment.

The drawback of the ASIC and PGA is that servicing and repairing the equipment at the integrated circuit level is almost impossible for the individual without access to the manufacturer's inventory of parts and proprietary information. Nevertheless, just as earlier amateurs moved beyond replacing individual components to diagnosing ICs, today's amateurs can troubleshoot to the module or circuit-board level, treating them as "components" in their own right.

3.3.6 Comparison of Semiconductor Devices for Analog Applications

Analog signal processing deals with changing a signal to a desired form. The three primary types of devices — bipolar transistors, field-effect transistors and integrated circuits — perform similar functions, each

with specific advantages and disadvantages. The vacuum tube, once the dominant signal processing component, is relegated to high-power amplifier and display applications and is found only in the **RF Power Amplifiers** chapter of this *Handbook*. *Cathode-ray tubes (CRTs)* are covered in a supplement on the *Handbook* CD-ROM.

Bipolar transistors, when treated properly, can have virtually unlimited life spans. They are relatively small and, if they do not handle high currents, do not generate much heat. They make excellent high-frequency amplifiers. Compared to MOSFET devices they are less susceptible to damage from electrostatic discharge. RF amplifiers designed with bipolar transistors in their final amplifiers generally include circuitry to protect the transistors from the high voltages generated by reflections under high SWR conditions. Bipolar transistors and ICs, like all semiconductors, are susceptible to damage from power and lightning transients.

There are many performance advantages to FET devices, particularly MOSFETs. The extremely low gate currents allow the design of analog stages with nearly infinite input resistance. Signal distortion due to loading is minimized in this way. FETs are less expensive to fabricate in ICs and so are gradually replacing bipolar transistors in many IC applications.

The current trend in electronics is portability. Transceivers are decreasing in size and in their power requirements. Integrated circuitry has played a large part in this trend. Extremely large circuits have been designed with microscopic proportions, including combinations of analog and digital circuitry that previously required multiple devices. *Charge-coupled devices (CCD)* imaging technology has replaced vidicon

tubes in video cameras and film cameras of all types. *Liquid crystal displays (LCDs)* in laptop computers and standalone computer displays have largely displaced the bulky and power-hungry cathode-ray tube (CRT), although it is still found in analog oscilloscopes and some types of video display equipment.

An important consideration in the use of analog components is the future availability of parts. At an ever increasing rate, as new components are developed to replace older technology, the older components are discontinued by the manufacturers and become unavailable for future use. ASIC technology, as mentioned earlier, brings the power of custom electronics to the radio, but also makes it nearly impossible to repair at the level of the IC, even if the problem is known. If field repair and service at the component level are to be performed, it is important to use standard ICs wherever possible. Even so, when demand for a particular component drops, a manufacturer will discontinue its production. This happens on an ever-decreasing timeline.

A further consideration is the trend toward digital signal processing and software-defined radio systems. (See the chapter on **DSP and Software Radio Design**.) More and more analog functions are being performed by microprocessors and the analog signals converted to digital at higher and higher frequencies. There will always be a need for analog circuits, but the balance point between analog and digital is shifting towards the latter. In future years, radio and test equipment will consist of a powerful, general-purpose digital signal processor, surrounded by the necessary analog circuitry to convert the signals to digital form and supply the processor with power.

3.4 Analog Systems

Many kinds of electronic equipment are developed by combining basic analog signal processing circuits, often treating them as independent functional blocks. This section describes several topics associated with building analog systems from multiple blocks. Although not all basic electronic functions are discussed here, the concepts associated with combining them can be applied generally.

An analog circuit can contain any number of discrete components (or may be implemented as an IC). Since our main concern is the effect that circuitry has on a signal, we often describe the circuit by its actions rather than by its specific components. A *black box* is a circuit that can be described entirely by the behavior of its interfaces with other blocks and circuitry. When circuits are combined in

such as way as to perform sequential operations on a signal, the individual circuits are called *stages*.

The most general way of referring to a circuit is as a *network*. Two basic properties of analog networks are of principal concern: the effect that the network has on an analog signal and the interaction that the network has with the circuitry surrounding it. Interfaces between the network and the rest of the network are called *ports*.

Many analog circuits are analyzed as *two-port networks* with an input and an output port. The signal is fed into the input port, is modified inside the network and then exits from the output port. (See the chapter on **RF Techniques** for more information on two-port networks.)

3.4.1 Transfer Functions

The specific way in which the analog circuit modifies the signal can be described mathematically as a *transfer function*. The mathematical operation that combines a signal with a transfer function is pictured symbolically in **Fig 3.34**. The transfer function, $h(t)$ or $h(f)$, describes the circuit's modification of the input signal in the time domain where all values are functions of time, such as $a(t)$ or $b(t)$, or in the frequency domain where all values are functions of frequency, such as $a(f)$ or $b(f)$. The mathematical operation by which $h(t)$ operates on $a(t)$ is called *convolution* and is represented as a dot, as in $a(t) \cdot h(t) = b(t)$. In the frequency domain, the transfer function multiplies the input, as in $a(f) \times h(f) = b(f)$.

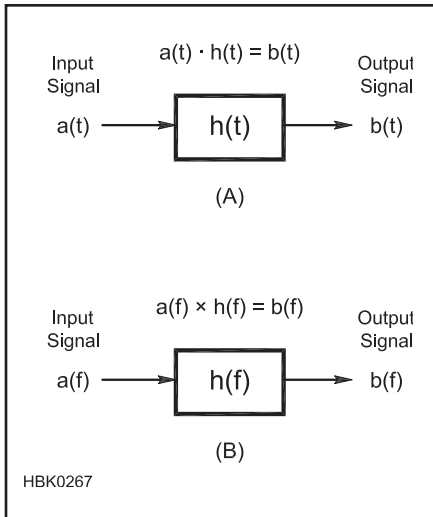

Fig 3.34 — Linear function blocks and transfer functions. The transfer function can be expressed in the time domain (A) or in the frequency domain (B). The transfer function describes how the input signal $a(t)$ or $a(f)$ is transformed into the output signal $b(t)$ or $b(f)$.

While it is not necessary to understand transfer functions mathematically to work with analog circuits, it is useful to realize that they describe how a signal interacts with other signals in an electronic system. In general, the output signal of an analog system depends not only on the input signal at the same time, but also on past values of the input signal. This is a very important concept and is the basis of such essential functions as analog filtering.

3.4.2 Cascading Stages

If an analog circuit can be described with a transfer function, a combination of analog circuits can also be described similarly. This description of the combined circuits depends upon the relationship between the transfer functions of the parts and that of the combined circuits. In many cases this relationship allows us to predict the behavior of large and complex circuits from what we know about the parts of which they are made. This aids in the design and analysis of analog circuits.

When two analog circuits are cascaded (the output signal of one stage becomes the input signal to the next stage) their transfer functions are combined. The mechanism of the combination depends on the interaction between the stages. The ideal case is the functions of the stages are completely independent. In other words, when the action of a stage is unchanged, regardless of the characteristics of any stages connected to its input or output.

Just as the signal entering the first stage is modified by the action of the first transfer

function, the ideal cascading of analog circuits results in changes produced only by the individual transfer functions. For any number of stages that are cascaded, the combination of their transfer functions results in a new transfer function. The signal that enters the circuit is changed by the composite transfer function to produce the signal that exits in the cascaded circuits.

While each stage in a series may use feedback within itself, feedback around more than one stage may create a function — and resultant performance — different from any of the included stages. Examples include oscillation or negative feedback.

3.4.3 Amplifier Frequency Response

At higher frequencies a typical amplifier acts as a low-pass filter, decreasing amplification with increasing frequency. Signals within a range of frequencies are amplified consistently but outside that range the amplification changes. At high gains many amplifiers work properly only over a small range of frequencies. The combination of gain and frequency response is often expressed as a *gain-bandwidth product*. For many amplifiers, gain times bandwidth is approximately constant. As gain increases, bandwidth decreases, and vice versa.

Performance at lower frequencies depends on whether the amplifier is *dc-* or *ac-coupled*. Coupling refers to the transfer of signals between circuits. A dc-coupled amplifier amplifies signals at all frequencies down to dc. An ac-coupled amplifier acts as a high-pass filter, decreasing amplification as the frequency decreases toward dc. Ac-coupled circuits usually use capacitors to allow ac signals to flow between stages while blocking the dc bias voltages of the circuit.

3.4.4 Interstage Loading and Impedance Matching

Every two-port network can be further defined by its input and output impedance. The input impedance is the opposition to current, as a function of frequency, seen when looking into the input port of the network. Likewise, the output impedance is similarly defined when looking back into a network through its output port.

If the transfer function of a stage changes when it is cascaded with another stage, we say that the second stage has *loaded* the first stage. This often occurs when an appreciable amount of current passes from one stage to the next. Interstage loading is related to the relative output impedance of a stage and the input impedance of the stage that is cascaded after it.

In some applications, the goal is to transfer

a maximum amount of power from the output of the stage to a load connected to the output. In this case, the output impedance of the stage is *matched* or transformed to that of the load (or vice versa). This allows the stage to operate at its optimum voltage and current levels. In an RF amplifier, the impedance at the input of the transmission line feeding an antenna is transformed by means of a matching network to produce the resistance the amplifier needs in order to efficiently produce RF power.

In contrast, it is the goal of most analog signal processing circuitry to modify a signal rather than to deliver large amounts of energy. Thus, an impedance-matched condition may not be required. Instead, current between stages can be minimized by using mismatched impedances. Ideally, if the output impedance of a network is very low and the input impedance of the following stage is very high, very little current will pass between the stages, and interstage loading will be negligible.

3.4.5 Noise

Generally we are only interested in specific man-made signals. Nature allows many signals to combine, however, so the desired signal becomes combined with many other unwanted signals, both man-made and naturally occurring. The broadest definition of noise is any signal that is not the one in which we are interested. One of the goals of signal processing is to separate desired signals from noise.

One form of noise that occurs naturally and must be dealt with in low-level processing circuits is called *thermal noise*, or *Johnson noise*. Thermal noise is produced by random motion of free electrons in conductors and semiconductors. This motion increases as temperature increases, hence the name. This kind of noise is present at all frequencies and is proportional to temperature. Naturally occurring noise can be reduced either by decreasing the circuit's bandwidth or by reducing the temperature in the system. Thermal noise voltage and current vary with the circuit impedance and follow Ohm's Law. Low-noise-amplifier-design techniques are based on these relationships.

Analog signal processing stages are characterized in part by the noise they add to a signal. A distinction is made between enhancing existing noise (such as amplifying it) and adding new noise. The noise added by analog signal processing is commonly quantified by the *noise factor*, f . Noise factor is the ratio of the total output noise power (thermal noise plus noise added by the stage) to the amplifier input noise power when the termination is at the standard temperature of 290 K (17 °C). When the noise factor is expressed in dB, we often call it *noise figure*, NF .

NF is calculated as:

$$NF = 10 \log \frac{P_{NO}}{A P_{NTH}} \quad (13)$$

where

P_{NO} = total noise output power,

A = amplification gain

P_{NTH} = input thermal noise power.

Noise factor can also be calculated as the difference between the input and output *signal-to-noise ratios* (SNR), with SNR expressed in dB.

In a system of many cascaded signal processing stages, such as a communications receiver, each stage contributes to the total noise of the system. The noise factor of the first stage dominates the noise factor of the entire system because noise added at the first stage is then multiplied by each following

stage. Noise added by later stages is not multiplied to the same degree and so is a smaller contribution to the overall noise at the output.

Designers try to optimize system noise factor by using a first stage with a minimum possible noise factor and maximum possible gain. (Caution: A circuit that overloads is often as useless as one that generates too much noise.) See the **RF Techniques** chapter for a more complete discussion on noise. Circuit overload is discussed in the **Receivers** chapter.

3.4.6 Buffering

It is often necessary to isolate the stages of an analog circuit. This isolation reduces the loading, coupling and feedback between stages. It is often necessary to connect circuits that operate at different impedance levels be-

tween stages. An intervening stage, a type of amplifier called a *buffer*, is often used for this purpose.

Buffers can have high values of amplification but this is unusual. A buffer used for impedance transformation generally has a low or unity gain. In some circuits, notably power amplifiers, the desired goal is to deliver a maximum amount of power to the output device (such as a speaker or an antenna). Matching the amplifier output impedance to the output-device impedance provides maximum power transfer. A buffer amplifier may be just the circuit for this type of application. Such amplifier circuits must be carefully designed to avoid distortion. Combinations of buffer stages can also be effective at isolating the stages from each other and making impedance transformations, as well.

3.5 Amplifiers

By far, the most common type of analog circuit is the amplifier. The basic component of most electronics — the transistor — is an amplifier in which a small input signal controls a larger signal. Transistor circuits are designed to use the amplifying characteristics of transistors in order to create useful signal processing functions, regardless of whether the input signal is amplified at the output.

3.5.1 Amplifier Configurations

Amplifier configurations are described by the *common* part of the device. The word “common” is used to describe the connection of a lead directly to a reference that is used by both the input and output ports of the circuit. The most common reference is ground, but positive and negative power sources are also valid references.

The type of circuit reference used depends on the type of device (transistor [NPN or PNP] or FET [P-channel or N-channel]), which lead is chosen as common, and the range of signal levels. Once a common lead is chosen, the other two leads are used for signal input and output. Based on the biasing conditions, there is only one way to select these leads. Thus, there are three possible amplifier configurations for each type of three-lead device. (Vacuum tube amplifiers are discussed in the chapter on **RF Power Amplifiers**.)

DC power sources are usually constructed so that ac signals at the output terminals are bypassed to ground through a very low impedance. This allows the power source to be treated as an *ac ground*, even though it may be supplying dc voltages to the circuit. When a circuit is being analyzed for its ac behavior, ac grounds are usually treated as ground, since dc bias is ignored in the ac analysis. Thus, a

transistor’s collector can be considered the “common” part of the circuit, even though in actual operation, a dc voltage is applied to it.

Fig 3.35 shows the three basic types of bipolar transistor amplifiers: the common-base, common-emitter, and common-collector. The common terminal is shown connected to ground, although as mentioned earlier, a dc bias voltage may be present. Each type of amplifier is described in the following sections. Following the description of the amplifier, additional discussion of biasing transistors and their operation at high frequencies and for large signals is presented.

3.5.2 Transistor Amplifiers

Creating a useful transistor amplifier depends on using an appropriate model for the transistor itself, choosing the right configuration of the amplifier, using the design equations for that configuration and insuring that the amplifier operates properly at different temperatures. This section follows that sequence, first introducing simple transistor models and then extending that knowledge to the point of design guidelines for common circuits that use bipolar and FETs.

DEVICE MODELS AND CLASSES

Semiconductor circuit design is based on equivalent circuits that describe the physics of the devices. These circuits, made up of voltage and current sources and passive components such as resistors, capacitors and inductors, are called models. A complete model that describes a transistor exactly over a wide frequency range is a fairly complex circuit. As a result, simpler models are used in specific circumstances. For example, the *small-signal model* works well when the

device is operated close to some nominal set of characteristics such that current and voltage interact fairly linearly. The *large-signal model* is used when the device is operated so that it enters its saturation or cut-off regions, for example.

Different frequency ranges also require different models. The *low-frequency models* used in this chapter can be used to develop circuits for dc, audio and very low RF applications. At higher frequencies, small capacitances and inductances that can be ignored at low frequencies begin to have significant effects on device behavior, such as gain or impedance. In addition, the physical structure of the device also becomes significant as gain begins to drop or phase shifts between input and output signals start to grow. In this region, *high-frequency models* are used.

Amplifiers are also grouped by their *operating class* that describes the way in which the input signal is amplified. There are several classes of analog amplifiers; A, B, AB, AB1, AB2 and C.

The analog class designators specify over how much of the input cycle the active device is conducting current. A class-A amplifier’s active device conducts current for 100 percent of the input signal cycle, such as shown in Fig 3.6. A class-B amplifier conducts during one-half of the input cycle, class-AB, AB1, and AB2 some fraction between 50 and 100 percent of the input cycle, and class-C for less than 50 percent of the input signal cycle.

Digital amplifiers, in which the active device is operated as a switch that is either fully-on or fully-off, similarly to switchmode power supplies, are also grouped by classes beginning with the letter D and beyond. Each different class uses a different method of con-

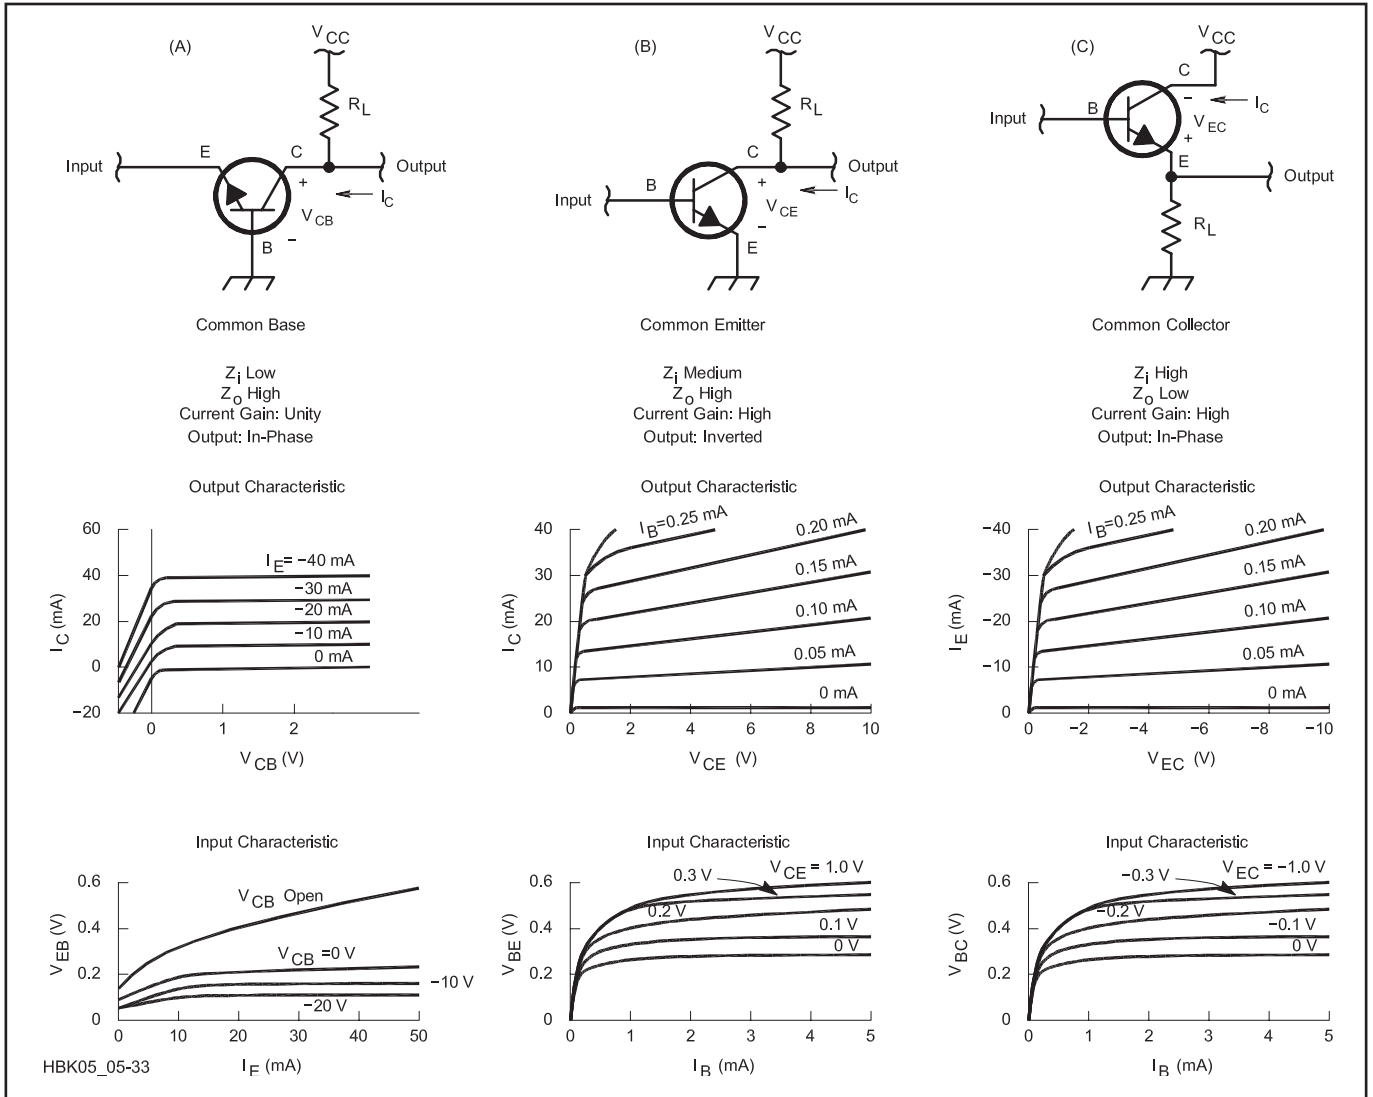

Fig 3.35 — The three configurations of bipolar transistor amplifiers. Each has a table of its relative impedance and current gain. The output characteristic curve is plotted for each, with the output voltage along the x-axis, the output current along the y-axis and various curves plotted for different values of input current. The input characteristic curve is plotted for each configuration with input current along the x-axis, input voltage along the y-axis and various curves plotted for different values of output voltage. (B) Common emitter configuration with input terminal at the base and output terminal at the collector. (C) Common collector with input terminal at the base and output terminal at the emitter.

verting the switch's output waveform to the desired RF waveform.

Amplifier classes, models and their use at high-frequencies are discussed in more detail in the chapter on **RF Techniques**. In addition, the use of models for circuit simulation is discussed at length in the **Computer-Aided Circuit Design** chapter.

3.5.3 Bipolar Transistor Amplifiers

In this discussion, we will focus on simple models for bipolar transistors (BJTs). This discussion is centered on NPN BJTs but applies equally well to PNP BJTs if the bias voltage and current polarities are reversed.

This section assumes the small-signal, low-frequency models for the transistors.

SMALL-SIGNAL BJT MODEL

The transistor is usually considered as a *current-controlled* device in which the base current controls the collector current:

$$I_c = \beta I_b \quad (14)$$

where

- I_c = collector current
- I_b = base current
- β = *common-emitter current gain*, beta.

(The term "common-emitter" refers to the type of transistor circuit described below in which the transistor operates with base cur-

rent as its input and collector circuit as its output.) Current is positive if it flows *into* a device terminal.

The transistor can also be treated as a voltage-controlled device in which the transistor's emitter current, I_e , is controlled by the base-emitter voltage, V_{be} :

$$I_c = I_{es} [e^{(qV_{be}/kT)} - 1] \approx I_{es} e^{(qV_{be}/kT)} \quad (15)$$

where

- q = electronic charge
- k = Boltzmann's constant
- T = temperature in degrees Kelvin (K)
- I_{es} = emitter saturation current, typically 1×10^{-13} A.

The subscripts for voltages indicate the direction of positive voltage, so that V_{be} indicates positive is from the base to the emitter. It is simpler to design circuits using the current-controlled device, but accounting for the transistor's behavior with temperature requires an understanding of the voltage-controlled model.

Transistors are usually driven by both biasing and signal voltages. Equations 14 and 15 apply to both transistor dc biasing and signal design. Both of these equations are approximations of the more complex behavior exhibited by actual transistors. Equation 15 applies to a simplification of the first *Ebers-Moll model* in Reference 1. More sophisticated models for BJTs are described by Getreu in Reference 2. Small-signal models treat only the signal components. We will consider bias later.

The next step is to use these basic equations to design circuits. We will begin with small-signal amplifier design and the limits of where the techniques can be applied. Later, we'll discuss large-signal amplifier design and the distortion that arises from operating the transistor in regions where the relationship between the input and output signals is nonlinear.

Common-Emitter Model

Fig 3.36 shows a BJT amplifier connected in the common-emitter configuration. (The emitter, shown connected to ground, is common to both the input circuit with the voltage source and the output circuit with the transistor's collector.) The performance of this circuit is adequately described by equation 14. Fig 3.37 shows the most common of all transistor small-signal models, a controlled current source with emitter resistance.

There are two variations of the model shown in the figure. Fig 3.37B shows the base as a direct connection to the junction of a current-controlled current source ($I_c = \beta I_b$) and a resistance, r_e , the *dynamic emitter resistance* representing the change in V_{be} with I_e . This resistance also changes with emitter current:

$$r_e = \frac{kT}{qI_c} \approx \frac{26}{I_e} \quad (16)$$

where I_e is the dc bias current in milliamperes.

The simplified approximation only applies at a typical ambient temperature of 300 K because r_e increases with temperature. In Fig 3.37A, the emitter resistance has been moved to the base connection, where it has the value $(\beta+1)r_e$. These models are electrically equivalent.

The transistor's output resistance (the Thevenin or Norton equivalent resistance between the collector and the grounded emitter) is infinite because of the current source.

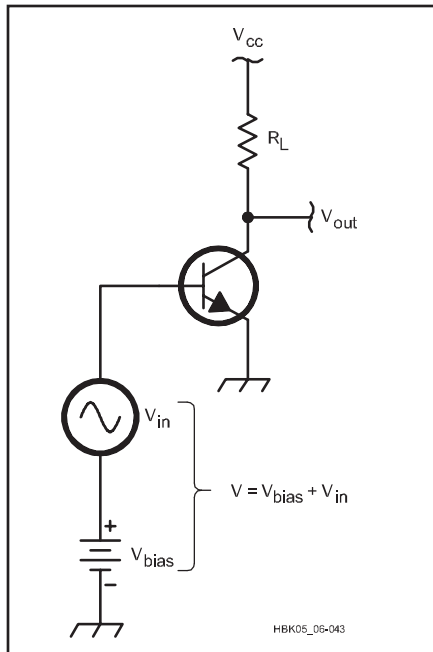

Fig 3.36 — Bipolar transistor with voltage bias and input signal.

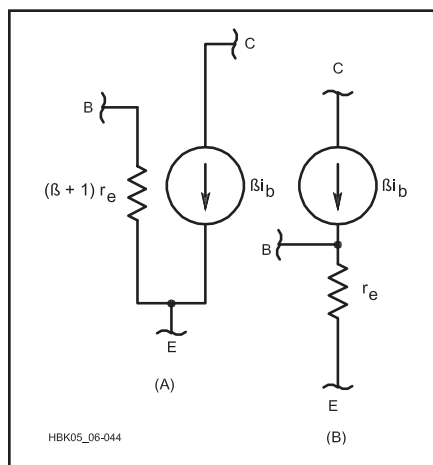

Fig 3.37 — Simplified low-frequency model for the bipolar transistor, a "beta generator with emitter resistance." $r_e = 26 / I_e$ (mA dc).

This is a good approximation for most silicon transistors at low frequencies (well below the transistor's gain-bandwidth product, F_T) and will be used for the design examples that follow.

As frequency increases, the capacitance inherent in BJT construction becomes significant and the *hybrid-pi model* shown in Fig 3.38 is used, adding C_π in parallel with the input resistance. In this model the transfer parameter h_{ie} often represents the input impedance, shown here as a resistance at low frequencies.

Fig 3.38 — The hybrid-pi model for the bipolar transistor.

THREE BASIC BJT AMPLIFIERS

Fig 3.39 shows a small-signal model applied to the three basic bipolar junction transistor (BJT) amplifier circuits: *common-emitter* (CE), *common-base* (CB) and *common-collector* (CC), more commonly known as the *emitter-follower* (EF). As defined earlier, the word "common" indicates that the referenced terminal is part of both the input and output circuits.

In these simple models, transistors in both the CE and CB configurations have infinite output resistance because the collector current source is in series with the output current. (The amplifier circuit's output impedance must include the effects of R_L .) The transistor connected in the EF configuration, on the other hand, has a finite output resistance because the current source is connected in parallel with the base circuit's equivalent resistance. Calculating the EF amplifier's output resistance requires including the input voltage source, V_s , and its impedance.

The three transistor amplifier configurations are shown as simple circuits in Fig 3.35. Each circuit includes the basic characteristics of the amplifier and characteristic curves for a typical transistor in each configuration. Two sets of characteristic curves are presented: one describing the input behavior and the other describing the output behavior in each amplifier configuration. The different transistor amplifier configurations have different gains, input and output impedances and phase relationships between the input and output signals.

Examining the performance needs of the amplifier (engineers refer to these as the circuit's *performance requirements*) determines which of the three circuits is appropriate. Then, once the amplifier configuration is chosen, the equations that describe the circuit's behavior are used to turn the performance requirements into actual circuit component values.

This text presents design information for the CE amplifier in some detail, then summarizes designs for the CC and CB ampli-

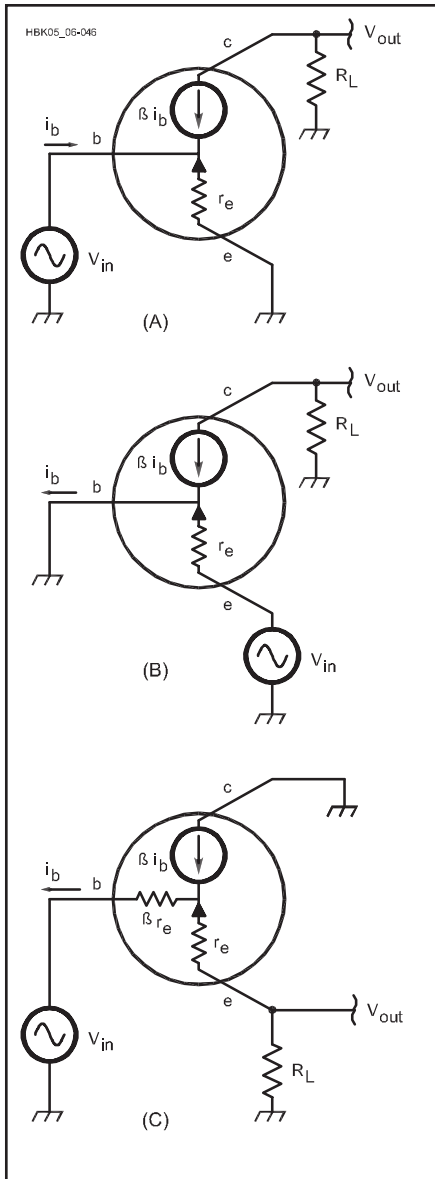

Fig 3.39 — Application of small-signal models for analysis of (A) the CE amplifier, (B) the CB and (C) the EF (CC) bipolar junction transistor amplifiers.

fiers. Detailed design analysis for all three amplifiers is described in the texts listed in the reference section for this chapter. All of the analysis in the following sections assume the small-signal, low-frequency model and ignore the effects of the coupling capacitors. High-frequency considerations are discussed in the **RF Techniques** chapter and some advanced discussion of biasing and large signal behavior of BJT amplifiers is available on the companion CD-ROM.

LOAD LINES AND Q-POINT

The characteristic curves in Fig 3.35 show that the transistor can operate with an infinite number of combinations of current (collector, emitter and base) and voltage (collector-

emitter, collector-base or emitter-collector). The particular combination at which the amplifier is operating is its *operating point*. The operating point is controlled by the selection of component values that make up the amplifier circuit so that it has the proper combination of gain, linearity and so forth. The result is that the operating point is restricted to a set of points that fall along a *load line*. The operating point with no input signal applied is the circuit's *quiescent point* or *Q-point*. As the input signal varies, the operating point moves along the load line, but returns to the Q-point when the input signal is removed.

Fig 3.40 shows the load line and Q-point for an amplifier drawn on a transistor's set of characteristic curves for the CE amplifier circuit. The two end-points of the load line correspond to transistor saturation (I_{Csat} on the I_C current axis) and cutoff (V_{CC} on the V_{CE} voltage axis).

When a transistor is in saturation, further increases in base current do not cause a further increase in collector current. In the CE amplifier, this means that V_{CE} is very close to zero and I_C is at a maximum. In the circuit of Fig 3.35B, imagine a short circuit across the collector-to-emitter so that all of V_{CC} appears across R_L . Increasing base current will not result in any additional collector current. At cutoff, base current is so small that V_{CE} is at a maximum because no collector current is flowing and further reductions in base current cause no additional increase in V_{CE} .

In this simple circuit, $V_{CE} = V_{CC} - I_C R_L$ and the relationship between I_C and V_{CE} is a straight line between saturation and cutoff. This is the circuit's *load line* and it has a slope of $R_L = (V_{CC} - V_{CE}) / I_C$. No matter what value of base current is flowing in the transistor, the resulting combination of I_C and V_{CE} will be somewhere on the load line.

With no input signal to this simple circuit, the transistor is at cutoff where $I_C = 0$ and $V_{CE} = V_{CC}$. As the input signal increases so that base current gets larger, the operating point begins to move along the load line to the left, so that I_C increases and the voltage drop across the load, $I_C R_L$, increases, reducing V_{CE} . Eventually, the input signal will cause enough base current to flow that saturation is reached, where $V_{CE} \approx 0$ (typically 0.1 to 0.3 V for silicon transistors) and $I_C \approx V_{CC} / R_L$. If R_L is made smaller, the load line will become steeper and if R_L increases, the load line's slope is reduced.

This simple circuit cannot reproduce negative input signals because the transistor is already in cutoff with no input signal. In addition, the shape and spacing of the characteristic curves show that the transistor responds nonlinearly when close to saturation and cutoff (the nonlinear regions) than it does in the middle of the curves (the linear or active region). Biasing is required so that the

Fig 3.40 — A load line. A circuit's load line shows all of the possible operating points with the specific component values chosen. If there is no input signal, the operating point is the quiescent or Q-point.

circuit does not operate in nonlinear regions, distorting the signal as shown in Fig 3.6.

If the circuit behaves differently for ac signals than for dc signals, a separate *ac load line* can be drawn as discussed below in the section "AC Performance" for the common-emitter amplifier. For example, in the preceding circuit, if R_L is replaced by a circuit that includes inductive or capacitive reactance, ac collector current will result in a different voltage drop across the circuit than will dc collector current. This causes the slope of the ac load line to be different than that of the dc load line.

The ac load line's slope will also vary with frequency, although it is generally treated as constant over the range of frequencies for which the circuit is designed to operate. The ac and dc load lines intersect at the circuit's Q-point because the circuit's ac and dc operation is the same if the ac input signal is zero.

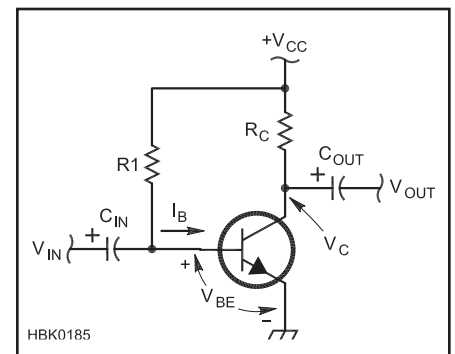

Fig 3.41 — Fixed-bias is the simplest common-emitter (CE) amplifier circuit.

COMMON-EMITTER AMPLIFIER

The *common-emitter amplifier (CE)* is the most common amplifier configuration of all — found in analog and digital circuits, from dc through microwaves, made of discrete components and fabricated in ICs. If you understand the CE amplifier, you've made a good start in electronics.

The CE amplifier is used when modest voltage gain is required along with an *input impedance* (the load presented to the circuit supplying the signal to be amplified) of a few hundred to a few kΩ. The current gain of the CE amplifier is the transistor's current gain, β .

The simplest practical CE amplifier circuit is shown in **Fig 3.41**. This circuit includes both coupling and biasing components. The capacitors at the input (C_{IN}) and output (C_{OUT}) block the flow of dc current to the load or to the circuit driving the amplifier. This is an ac-coupled design. These capacitors also cause the gain at very low frequencies to be reduced — gain at dc is zero, for example, because dc input current is blocked by C_{IN} . Resistor R_1 provides a path for bias current to flow into the base, offsetting the collector current from zero and establishing the Q-point for the circuit.

As the input signal swings positive, more current flows into the transistor's base through C_{IN} , causing more current to flow from the collector to emitter as shown by equation 14. This causes more voltage drop across R_L and so the voltage at the collector also drops. The reverse is true when the input signal swings negative. Thus, the output from the CE amplifier is inverted from its input.

Kirchoff's Voltage Law (KVL, see the **Electrical Fundamentals** chapter) is used to analyze the circuit. We'll start with the collector circuit and treat the power supply as a voltage source.

$$V_{CC} = I_C R_C + V_{ce}$$

We can determine the circuit's voltage gain, A_V , from the variation in output voltage caused by variations in input voltage. The output voltage from the circuit at the transistor collector is

$$V_c = V_{CC} - I_C R_C = V_{CC} - \beta I_B R_C \quad (17)$$

It is also necessary to determine how base current varies with input voltage. Using the transistor's equivalent circuit of Fig 3.37A,

$$I_B = \frac{V_B}{(\beta + 1) r_e}$$

so that

$$V_c = V_{CC} - V_B \frac{\beta}{\beta + 1} \times \frac{R_C}{r_e} \quad (18)$$

We can now determine the circuit's *voltage gain*, the variation in output voltage, ΔV_C , due to variations in input voltage, ΔV_B . Since V_{CC} is constant and β is much greater than 1 in our model:

$$A_V \approx -\frac{R_C}{r_e} \quad (19)$$

Because r_e is quite small (typically a few ohms, see equation 16), A_V for this circuit can be quite high.

The circuit load line's end-points are $V_{CE} = V_{CC}$ and $I_C = V_{CC}/R_C$. The circuit's Q-point is determined by the collector resistor, R_C , and resistor R_1 that causes bias current to flow into the base. To determine the Q-point, again use KVL starting at the power source and assuming that $V_{BE} = 0.7$ V for a silicon transistor's PN junction when forward-biased.

$$V_{CC} - I_B R_1 = V_B = V_{BE} = 0.7 \text{ V}$$

so

$$I_B = \frac{V_{CC} - 0.7 \text{ V}}{R_1} \quad (20)$$

And the Q-point is therefore

$$V_{CEQ} = V_{CC} - \beta I_B R_C \quad (21a)$$

and

$$I_{CQ} = \beta I_B \quad (21b)$$

The actual V_{BE} of silicon transistors will vary from 0.6-0.75 V, depending on the level of base current, but 0.7 V is a good compromise value and widely used in small-signal, low-frequency design. Use 0.6 V for very low-power amplifiers and 0.75 V (or more) for high-current switch circuits.

This simple *fixed-bias* circuit is a good introduction to basic amplifiers, but is not entirely practical because the bias current will change due to the change of V_{BE} with temperature, leading to thermal instability. In addition, the high voltage gain can lead to instability due to positive feedback at high frequencies.

To stabilize the dc bias, **Fig 3.42** adds R_E , a technique called *emitter degeneration* because the extra emitter resistance creates negative feedback: as base current rises, so does V_E , the voltage drop across R_E . This reduces the base-emitter voltage and lowers base current. The benefit of emitter degeneration comes from stabilizing the circuit's dc behavior with temperature, but there is a reduction in gain because of the increased resistance in the emitter circuit. Ignoring the effect of R_L for the moment,

$$A_V \approx -\frac{R_C}{R_E} \quad (22)$$

Fig 3.42 — Emitter degeneration. Adding R_E produces negative feedback to stabilize the bias point against changes due to temperature. As the bias current increases, the voltage drop across R_E also increases and causes a decrease in V_{BE} . This reduces bias current and stabilizes the operating point.

In effect, the load resistor is now split between R_C and R_E , with part of the output voltage appearing across each because the changing current flows through both resistors. While somewhat lower than with the emitter connected directly to ground, voltage gain becomes easy to control because it is the ratio of two resistances.

Biasing the CE Amplifier

Fig 3.43 adds R_1 and R_2 from a voltage divider that controls bias current by fixing the base voltage at:

$$V_B = V_{CC} \frac{R_2}{R_1 + R_2}$$

Since

$$V_B = V_{BE} + (I_B + I_C) R_E = 0.7 \text{ V} + (\beta + 1) I_B R_E$$

Fig 3.43 — Self-bias. R_1 and R_2 form a voltage divider to stabilize V_B and bias current. A good rule of thumb is for current flow through R_1 and R_2 to be 10 times the desired bias current. This stabilizes bias against changes in transistor parameters and component values.

base current is

$$I_B = \frac{V_B - 0.7 V}{(\beta + 1) R_E} \quad (23a)$$

and Q-point collector current becomes for high values of β

$$I_{CQ} = \beta I_B \approx \frac{V_{CC} - 0.7}{R_1 \parallel R_2} \quad (23b)$$

This is referred to as *self-bias* in which the Q-point is much less sensitive to variations in temperature that affect β and V_{BE} .

A good rule-of-thumb for determining the sum of R_1 and R_2 is that the current flowing through the voltage divider, $V_{CC}/(R_1+R_2)$, should be at least 10 times the bias current, I_B . This keeps V_B relatively constant even with small changes in transistor parameters and temperature.

Q-point V_{CEQ} must now also account for the voltage drop across both R_C and R_E ,

$$V_{CEQ} \approx V_{CC} - \beta I_B (R_C + R_E) \quad (24)$$

More sophisticated techniques for designing the bias networks of bipolar transistor circuits are described in reference texts listed at the end of this chapter.

Input and Output Impedance

With R_E in the circuit, the small changes in input current, I_B , when multiplied by the transistor's current gain, β , cause a large voltage change across R_E equal to $\beta I_B R_E$. This is the same voltage drop as if I_B was flowing through a resistance equal to βR_E . Thus, the effect of β on impedance at the base is to multiply the emitter resistance, R_E by β , as well. At the transistor's base,

$$Z_B \approx (\beta + 1) R_E$$

The input source doesn't just drive the base, of course, it also has to drive the combination of R_1 and R_2 , the biasing resistors. From an ac point of view, both R_1 and R_2 can be considered as connected to ac ground and they can be treated as if they were connected in parallel. When $R_1 \parallel R_2$ are considered along with the transistor base impedance, Z_B , the impedance presented to the input signal source is:

$$Z_{IN} = R_1 \parallel R_2 \parallel (\beta + 1) R_E \quad (25)$$

where \parallel designates "in parallel with."

For both versions of the CE amplifier, the collector output impedance is high enough that

$$Z_{OUT} \approx R_C \quad (26)$$

CE Amplifier Design Example

The general process depends on the cir-

Fig 3.44 — Emitter bypass. Adding C_E allows ac currents to flow "around" R_E , returning ac gain to the value for the fixed-bias circuit while allowing R_E to stabilize the dc operating point.

cuit's primary performance requirements, including voltage gain, impedances, power consumption and so on. The most common situation in which a specific voltage gain is required and the circuit's Q-point has been selected based on the transistor to be used, and using the circuit of Fig 3.43, is as follows:

1) Start by determining the circuit's design constraints and assumptions: power supply $V_{CC} = 12 V$, transistor $\beta = 150$ and $V_{BE} = 0.7 V$. State the circuit's design requirements: $|A_v| = 5$, Q-point of $I_{CQ} = 4 mA$ and $V_{CEQ} = 5 V$. (A $V_{CEQ} \approx \frac{1}{2} V_{CC}$ allows a wide swing in output voltage with the least distortion.)

2) Determine the values of R_C and R_E using equation 24: $R_C + R_E = (V_{CC} - V_{CEQ})/I_{CQ} = 1.75 k\Omega$

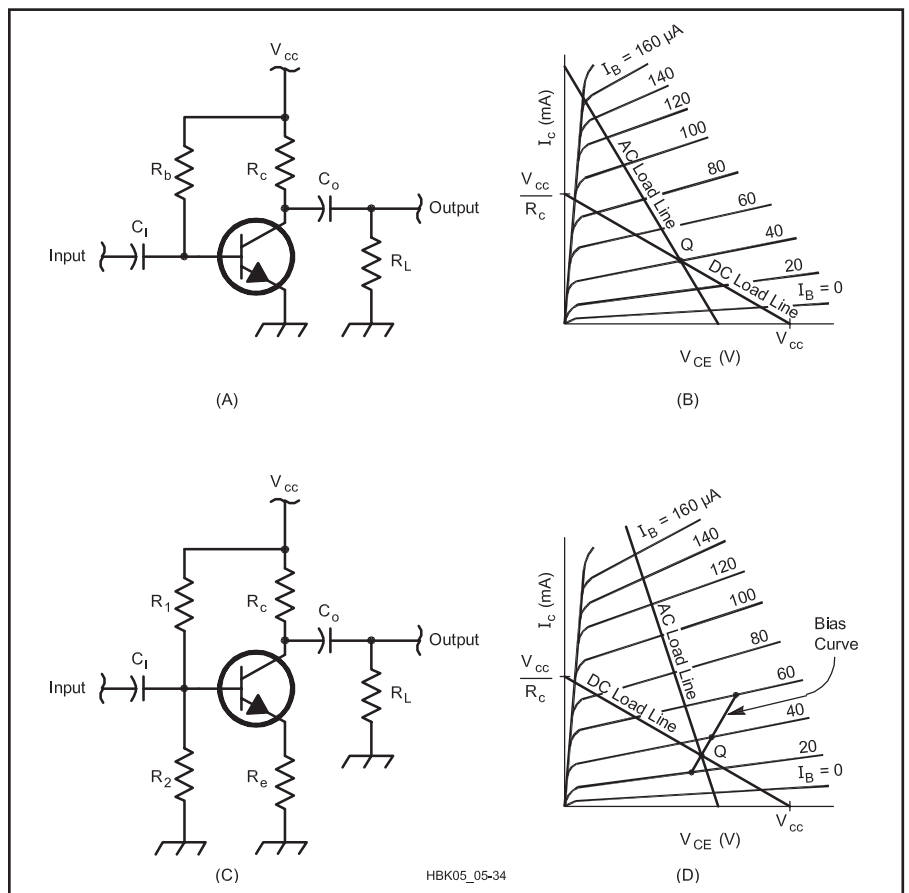

Fig 3.45 — Amplifier biasing and ac and dc load lines. (A) Fixed bias. Input signal is ac coupled through C_i . The output has a voltage that is equal to $V_{CC} - I_C \times R_C$. This signal is ac coupled to the load, R_L , through C_o . For dc signals, the entire output voltage is based on the value of R_C . For ac signals, the output voltage is based on the value of R_C in parallel with R_L . (B) Characteristic curve for the transistor amplifier pictured in (A). The slope of the dc load line is equal to $-1/R_C$. For ac signals, the slope of the ac load line is equal to $-1/(R_C \parallel R_L)$. The quiescent-point, Q, is based on the base bias current with no input signal applied and the point where this characteristic line crosses the dc load line. The ac load line must also pass through point Q. (C) Self-bias. Similar to fixed bias circuit with the base bias resistor split into two: R_1 connected to V_{CC} and R_2 connected to ground. Also an emitter bias resistor, R_E , is included to compensate for changing device characteristics. (D) This is similar to the characteristic curve plotted in (B) but with an additional "bias curve" that shows how the base bias current varies as the device characteristics change with temperature. The operating point, Q, moves along this line and the load lines continue to intersect it as it changes. If C_E was added as in Fig 3.44, the slope of the ac load line would increase further.

3) $A_V = -5$, so from equation 22: $R_C = 5 R_E$, thus $6R_E = 1.75 \text{ k}\Omega$ and $R_E = 270 \Omega$

4) Use equation 14 to determine the base bias current, $I_B = I_{CQ}/\beta = 27 \mu\text{A}$. By the rule of thumb, current through R_1 and $R_2 = 10 I_B = 270 \mu\text{A}$

5) Use equation 23 to find the voltage across $R_2 = V_B = V_{BE} + I_C R_E = 0.7 + 4 \text{ mA} (0.27 \text{ k}\Omega) = 1.8 \text{ V}$. Thus, $R_2 = 1.8 \text{ V} / 270 \mu\text{A} = 6.7 \text{ k}\Omega$

6) The voltage across $R_1 = V_{CC} - V_{R2} = 12 - 1.8 = 10.2 \text{ V}$ and $R_1 = 10.2 \text{ V} / 270 \mu\text{A} = 37.8 \text{ k}\Omega$

Use the nearest standard values ($R_E = 270 \Omega$, $R_1 = 39 \text{ k}\Omega$, $R_2 = 6.8 \text{ k}\Omega$) and circuit behavior will be close to that predicted.

AC Performance

To achieve high gains for ac signals while maintaining dc bias stability, the *emitter-bypass capacitor*, C_E , is added in **Fig 3.44** to provide a low impedance path for ac signals around R_E . In addition, a more accurate formula for ac gain includes the effect of adding R_L through the dc blocking capacitor at the collector. In this circuit, the ac voltage gain is

$$A_V \approx -\frac{R_C // R_L}{r_e} \quad (27)$$

Because of the different signal paths for ac and dc signals, the ac performance of the circuit is different than its dc performance. This is illustrated in **Fig 3.45** by the intersecting load lines labeled "AC Load Line" and "DC Load Line." The load lines intersect at the Q-point because at that point dc performance is the same as ac performance if no ac signal is present.

The equation for ac voltage gain assumes that the reactances of C_{IN} , C_{OUT} , and C_E are small enough to be neglected (less than one-tenth that of the components to which they are connected at the frequency of interest). At low frequencies, where the capacitor reactances become increasingly large, voltage gain is reduced. Neglecting C_{IN} and C_{OUT} , the low-frequency 3 dB point of the amplifier, f_L , occurs where $X_{C_E} = 0.414 r_e$,

$$f_L = \frac{2.42}{2\pi r_e C_E} \quad (28)$$

This increases the emitter circuit impedance such that A_V is lowered to 0.707 of its mid-band value, lowering gain by 3 dB. (This ignores the effects of C_{IN} and C_{OUT} , which will also affect the low-frequency performance of the circuit.)

The ac input impedance of this version of the CE amplifier is lower because the effect of R_E on ac signals is removed by the bypass capacitor. This leaves only the internal emitter resistance, r_e , to be multiplied by the current gain,

$$Z_{IN} \approx R1 // R2 // \beta r_e \quad (29)$$

and

$$Z_{OUT} \approx R_C \quad (30)$$

again neglecting the reactance of the three capacitors.

The power gain, A_P , for the emitter-bypassed CE amplifier is the ratio of output power, V_O^2/Z_{OUT} , to input power, V_I^2/Z_{IN} . Since $V_O = V_I A_V$,

$$A_P = A_V^2 \frac{R1 // R2 // \beta r_e}{R_C} \quad (31)$$

COMMON-COLLECTOR (EMITTER-FOLLOWER) AMPLIFIER

The common-collector (CC) amplifier in **Fig 3.46** is also known as the *emitter-follower* (EF) because the emitter voltage "follows" the input voltage. In fact, the amplifier has no voltage gain (voltage gain ≈ 1), but is used as a buffer amplifier to isolate sensitive circuits such as oscillators or to drive low-impedance loads, such as coaxial cables. As in the CE amplifier, the current gain of the emitter-follower is the transistor's current gain, β . It has relatively high input impedance with low output impedance and good power gain.

The collector of the transistor is connected directly to the power supply without a resistor and the output signal is created by the voltage drop across the emitter resistor. There is no 180° phase shift as seen in the CE amplifier; the output voltage follows the input signal with 0° phase shift because increases in the input signal cause increases in emitter current and the voltage drop across the emitter resistor.

The EF amplifier has high input impedance: following the same reasoning as for the CE amplifier with an unbypassed emitter

Fig 3.46 — Emitter follower (EF) amplifier. The voltage gain of the EF amplifier is unity. The amplifier has high input impedance and low output impedance, making it a good choice for use as a buffer amplifier.

resistor as described by equation 25,

$$Z_{IN} = R1 // R2 // (\beta + 1) R_E \quad (32)$$

The impedance at the EF amplifier's output consists of the emitter resistance, R_E , in parallel with the series combination of the internal emitter resistance, r_e , the parallel combination of biasing resistors $R1$ and $R2$, and the internal impedance of the source providing the input signal. In this case, current gain acts to *reduce* the effect of the input circuit's impedance on output impedance:

$$Z_{OUT} = \left[\frac{R_S // R1 // R2}{(\beta + 1)} \right] // R_E \quad (33)$$

In practice, with transistor β of 100 or more, $Z_{OUT} \approx R_S/\beta$. However, if a very high impedance source is used, such as a crystal microphone element or photodetector, the effects of the biasing and emitter resistors must be considered.

Because the voltage gain of the EF amplifier is unity, the power gain is simply the ratio of input impedance to output impedance,

$$A_P \approx \frac{R1 // R2 // (\beta + 1) R_E}{R_E} \quad (34)$$

EF Amplifier Design Example

The following procedure is similar to the design procedure in the preceding section for the CE amplifier, except $A_V = 1$.

1) Start by determining the circuit's design constraints and assumptions: $V_{CC} = 12 \text{ V}$ (the power supply voltage), a transistor's β of 150 and $V_{BE} = 0.7 \text{ V}$. State the circuit's design requirements: Q-point of $I_{CQ} = 5 \text{ mA}$ and $V_{CEQ} = 6 \text{ V}$.

2) $R_E = (V_{CC} - V_{CEQ})/I_{CQ} = 1.2 \text{ k}\Omega$

3) Base current, $I_B = I_{CQ}/\beta = 33 \mu\text{A}$

4) Current through $R1$ and $R2 = 10 I_B = 330 \mu\text{A}$ ($10 I_B$ rule of thumb as with the CE amplifier)

5) Voltage across $R2 = V_{BE} + I_C R_E = 0.7 + 5 \text{ mA} (1.2 \text{ k}\Omega) = 6.7 \text{ V}$ and $R2 = 6.7 \text{ V} / 330 \mu\text{A} = 20.3 \text{ k}\Omega$ (use the standard value $22 \text{ k}\Omega$)

6) Voltage across $R1 = V_{CC} - 6.7 \text{ V} = 5.3 \text{ V}$
7) $R1 = 5.3 \text{ V} / 330 \mu\text{A} = 16.1 \text{ k}\Omega$ (use $16 \text{ k}\Omega$)

8) $Z_{IN} = R1 // R2 // R_E(\beta + 1) \approx 8.5 \text{ k}\Omega$

COMMON-BASE AMPLIFIER

The common-base (CB) amplifier of **Fig 3.47** is used where low input impedance is needed, such as for a receiver preamp with a coaxial feed line as the input signal source. Complementary to the EF amplifier, the CB amplifier has unity current gain and high output impedance.

Fig 3.47A shows the CB circuit as it is usually drawn, without the bias circuit resistors connected and with the transistor symbol

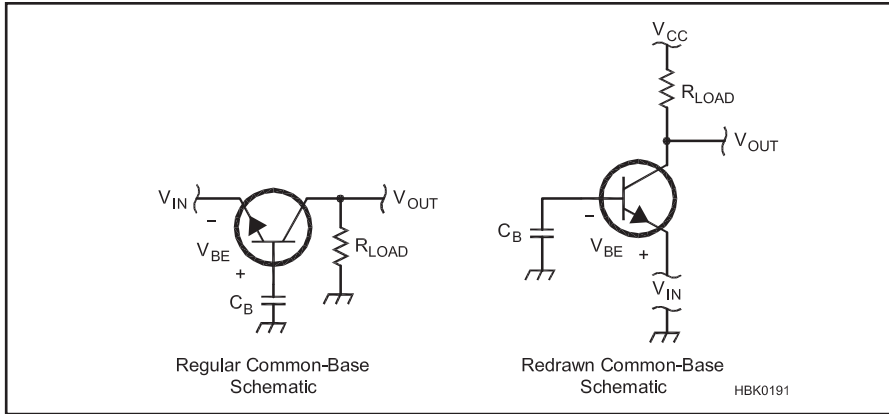

Fig 3.47 — The common-base (CB) amplifier is often drawn in an unfamiliar style (A), but is more easily understood when drawn similarly to the CE and EF amplifiers (B). The input signal to the CB amplifier is applied to the emitter instead of the base.

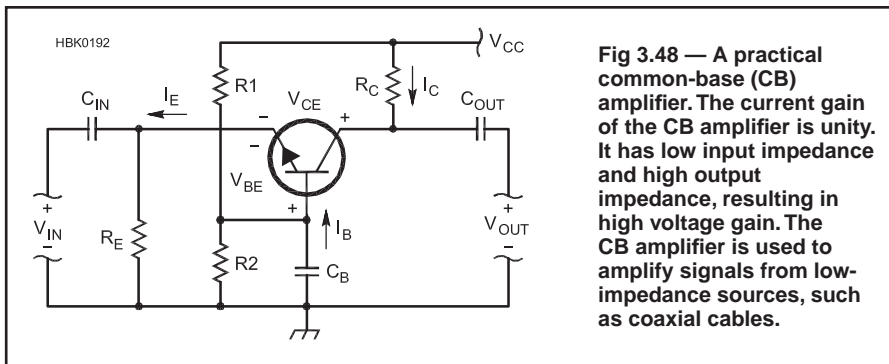

Fig 3.48 — A practical common-base (CB) amplifier. The current gain of the CB amplifier is unity. It has low input impedance and high output impedance, resulting in high voltage gain. The CB amplifier is used to amplify signals from low-impedance sources, such as coaxial cables.

turned on its side from the usual orientation so that the emitter faces the input. In order to better understand the amplifier's function, Fig 3.47B reorients the circuit in a more familiar style. We can now clearly see that the input has just moved from the base circuit to the emitter circuit.

Placing the input in the emitter circuit allows it to cause changes in the base-emitter current as for the CE and EF amplifiers, except that for the CB amplifier a positive change in input amplitude reduces base current by lowering V_{BE} and raising V_C . As a result, the CB amplifier is noninverting, just like the EF, with output and input signals in-phase.

A practical circuit for the CB amplifier is shown in Fig 3.48. From a dc point of view (replace the capacitors with open circuits), all of the same resistors are there as in the CE amplifier. The input capacitor, C_{IN} , allows the dc emitter current to bypass the ac input signal source and C_B places the base at ac ground while allowing a dc voltage for biasing. (All voltages and currents are labeled to aid in understanding the different orientation of the circuit.)

The CB amplifier's current gain,

$$A_I = \frac{i_C}{i_E} = \frac{\beta}{\beta + 1} \quad (35)$$

is relatively independent of input and output impedance, providing excellent isolation between the input and output circuits. Output impedance does not affect input impedance, allowing the CB amplifier to maintain stable input impedance, even with a changing load.

Following reasoning similar to that for the CE and EF amplifiers for the effect of current gain on R_E , we find that input impedance for the CB amp is

$$Z_{IN} = R_E // (\beta + 1) r_e \quad (36)$$

The output impedance for the CB amplifier is approximately

$$Z_{OUT} = R_C // \frac{1}{h_{oe}} \approx R_C \quad (37)$$

where h_{oe} is the transistor's collector output admittance. The reciprocal of h_{oe} is in the range of 100 k Ω at low frequencies.

Voltage gain for the CB amplifier is

$$A_V \approx \frac{R_C // R_L}{r_e} \quad (38)$$

As a result, the usual function of the CB amplifier is to convert input current from a low-impedance source into output voltage at a higher impedance.

Power gain for the CB amplifier is approximately the ratio of output to input impedance,

$$A_P \approx \frac{R_C}{R_E // (\beta + 1) r_e} \quad (39)$$

CB Amplifier Design Example

Because of its usual function as a current-to-voltage converter, the design process for the CB amplifier begins with selecting R_E and A_V , assuming that R_L is known.

1) Start by determining the circuit's design constraints and assumptions: $V_{CC} = 12$ V (the power supply voltage), a transistor's β of 150 and $V_{BE} = 0.7$ V. State the circuit's design requirements: $R_E = 50 \Omega$, $R_L = 1$ k Ω , $I_{CQ} = 5$ mA, $V_{CEQ} = 6$ V.

2) Base current, $I_B = I_{CQ} / \beta = 33 \mu\text{A}$

3) Current through R_1 and $R_2 = 10 I_B = 330 \mu\text{A}$ ($10 I_B$ rule of thumb as with the CE amplifier)

4) Voltage across $R_2 = V_{BE} + I_C R_E = 0.7 + 5 \text{ mA} (1.2 \text{ k}\Omega) = 6.7$ V and $R_2 = 6.7 \text{ V} / 330 \mu\text{A} = 20.3$ k Ω (use the standard value 22 k Ω)

5) Voltage across $R_1 = V_{CC} - 6.7 \text{ V} = 5.3$ V

6) $R_1 = 5.3 \text{ V} / 330 \mu\text{A} = 16.1$ k Ω (use 16 k Ω)

7) $R_C = (V_{CC} - I_{CQ} R_E - V_{CEQ}) / I_{CQ} = (12 - 0.25 - 5) / 5 \text{ mA} = 1.35$ k Ω (use 1.5 k Ω)

8) $A_V = (1.5 \text{ k}\Omega // 1 \text{ k}\Omega) / (26 / I_E) = 115$

3.5.4 FET Amplifiers

The field-effect transistor (FET) is widely used in radio and RF applications. There are many types of FETs, with JFETs (junction FET) and MOSFETs (metal-oxide-semiconductor FET) being the most common types. In this section we will discuss JFETs, with the understanding that the use of MOSFETs is similar. (This discussion is based on N-channel JFETs, but the same discussion applies to P-channel devices if the bias voltages and currents are reversed.)

SMALL-SIGNAL FET MODEL

While bipolar transistors are most commonly viewed as current-controlled devices, the JFET, however, is purely a voltage-controlled device — at least at low frequencies. The input gate is treated as a reverse-biased diode junction with virtually no current flow. As with the bipolar transistor amplifier circuits, the circuits in this section are very basic and more thorough treatments of FET amplifier design can be found in the references at the end of the chapter.

The operation of an N-channel JFET for both biasing and signal amplification can be

Fig 3.49 — Small-signal FET model. The FET can be modeled as a voltage-controlled current source in its saturation region. The gate is treated as an open-circuit due to the reverse-biased gate-channel junction.

characterized by the following equation:

$$I_D = I_{DSS} \left(\frac{V_P - V_{GS}}{V_P} \right)^2 \quad (40)$$

where

- I_{DSS} = drain saturation current
- V_{GS} = the gate-source voltage
- V_P = the pinch-off voltage.

I_{DSS} is the maximum current that will flow between the drain and source for a given value of drain-to-source voltage, V_{DS} . Note that the FET is a *square-law* device in which output current is proportional to the square of an input voltage. (The bipolar transistor's output current is an exponential function of input current.)

Also note that V_{GS} in this equation has the opposite sense of the bipolar transistor's V_{BE} . For this device, as V_{GS} increases (making the source more positive than the gate), drain current decreases until at V_P the channel is completely "pinched-off" and no drain current flows at all. This equation applies only if V_{GS} is between 0 and V_P . JFETs are seldom used with the gate-to-channel diode forward-biased ($V_{GS} < 0$).

None of the terms in Equation 40 depend explicitly on temperature. Thus, the FET is relatively free of the thermal instability exhibited by the bipolar transistor. As temperature increases, the overall effect on the JFET is to reduce drain current and to stabilize the operation.

The small-signal model used for the JFET is shown in **Fig 3.49**. The drain-source channel is treated as a current source whose output is controlled by the gate-to-source voltage so that $I_D = g_m V_{GS}$. The high input impedance allows the input to be modeled as an open circuit (at low frequencies). This simplifies circuit modeling considerably as biasing of the FET gate can be done by a simple voltage divider without having to consider the effects of bias current flowing in the JFET itself.

The FET has characteristic curves as shown in Fig 3.25 that are similar to those of a bipolar

transistor. The output characteristic curves are similar to those of the bipolar transistor, with the horizontal axis showing V_{DS} instead of V_{CE} and the vertical axis showing I_D instead of I_C . Load lines, both ac and dc, can be developed and drawn on the output characteristic curves in the same way as for bipolar transistors.

The set of characteristic curves in Fig 3.25 are called *transconductance response curves* and they show the relationship between input voltage (V_{GS}), output current (I_D) and output voltage (V_{DS}). The output characteristic curves show I_D and V_{DS} for different values of V_{GS} and are similar to the BJT output characteristic curve. The input characteristic curves show I_D versus V_{GS} for different values of V_{DS} .

MOSFETs act in much the same way as JFETs when used in an amplifier. They have a higher input impedance, due to the insulation between the gate and channel. The insulated gate also means that they can be operated with the polarity of V_{GS} such that a JFET's gate-channel junction would be forward biased, beyond V_P . Refer to the discussion of depletion- and enhancement-mode MOSFETs in the previous section on Practical Semiconductors.

THREE BASIC FET AMPLIFIERS

Just as for bipolar transistor amplifiers, there are three basic configurations of amplifiers using FETs; the *common-source* (CS) (corresponding to the common-emitter), *common-drain* (CD) or *source-follower* (corresponding to the emitter-follower) and the *common-gate* (CG) (corresponding to the common base). Simple circuits and design methods are presented here for each, assuming low-frequency operation and a simple, voltage-controlled current-source model for the FET. Discussion of the FET amplifier at high frequencies is available in the **RF Techniques** chapter and an advanced discussion of biasing FET amplifiers and their large-signal behavior is contained on the companion CD-ROM.

COMMON-SOURCE AMPLIFIER

The basic circuit for a common-source FET amplifier is shown in **Fig 3.50**. In the ohmic region (see the previous discussion on FET characteristics), the FET can be treated as a variable resistance as shown in **Fig 3.50A** where V_{GS} effectively varies the resistance between drain and source. However, most FET amplifiers are designed to operate in the saturation region and the model of Fig 3.49 is used in the circuit of **Fig 3.50B** in which,

$$I_D = g_m V_{GS} \quad (41)$$

where g_m is the FET's forward transconductance.

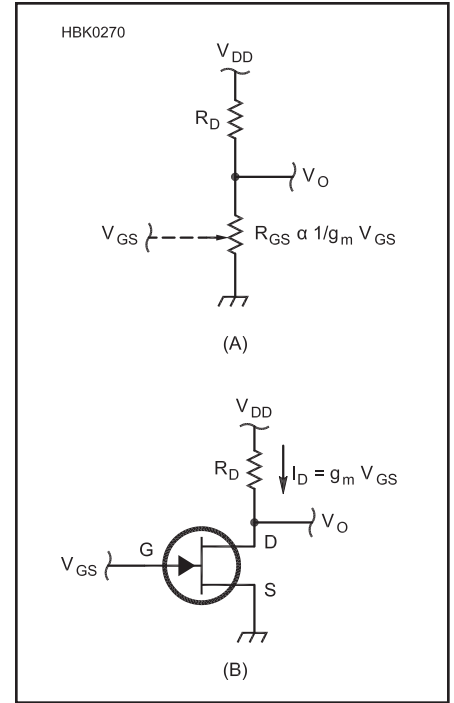

Fig 3.50 — In the ohmic region (A), the FET acts like a variable resistance, R_{DS} , with a value controlled by V_{GS} . The alpha symbol (α) means "is proportional to". In the saturation region (B), the drain-source channel of the FET can be treated like a current source with $I_D = g_m V_{GS}$.

If V_O is measured at the drain terminal (just as the common-emitter output voltage is measured at the collector), then

$$\Delta V_O = -g_m \Delta V_{GS} R_D$$

The minus sign results from the output voltage decreasing as drain current and the voltage drop across R_D increases, just as in the CE amplifier. Like the CE amplifier, the input and output voltages are thus 180° out of phase. Voltage gain of the CS amplifier in terms of transconductance and the drain resistance is:

$$A_V = -g_m R_D \quad (42)$$

As long as $V_{GS} < 0$, this simple CS amplifier's input impedance at low frequencies is that of a reverse-biased diode — nearly infinite with a very small leakage current. Output impedance of the CS amplifier is approximately R_D because the FET drain-to-source channel acts like a current source with very high impedance.

$$Z_{IN} = \infty \text{ and } Z_{OUT} \approx R_D \quad (43)$$

As with the BJT, biasing is required to create a Q-point for the amplifier that allows reproduction of ac signals. The practical circuit

Fig 3.51 — Common-source (CS) amplifier with self-bias.

of Fig 3.50B is used to allow control of V_{GS} bias. A load line is drawn on the JFET output characteristic curves, just as for a bipolar transistor circuit. One end point of the load line is at $V_{DS} = V_{DD}$ and the other at $I_{DS} = V_{DD} / R_D$. The Q-point for the CS amplifier at I_{DQ} and V_{DSQ} is thus determined by the dc value of V_{GS} .

The practical JFET CS amplifier shown in Fig 3.51 uses self-biasing in which the voltage developed across the source resistor, R_S , raises V_S above ground by $I_D R_S$ volts and $V_{GS} = -I_D R_S$ since there is no dc drop across R_G . This is also called *source degeneration*. The presence of R_S changes the equation of voltage gain to

$$A_V = -\frac{g_m R_D}{1 + g_m R_S} \approx -\frac{R_D}{R_S} \quad (44)$$

The value of R_S is obtained by substituting $V_{GS} = I_D R_S$ into Equation 40 and solving for R_S as follows:

$$R_S = \frac{V_P}{I_{DQ}} \left(1 - \sqrt{\frac{I_{DQ}}{I_{DSS}}} \right) \quad (45)$$

Once R_S is known, the equation for voltage gain can be used to find R_D .

The input impedance for the circuit of Fig 3.51 is essentially R_G . Since the gate of the JFET is often ac coupled to the input source through a dc blocking capacitor, C_{IN} , a value of 100 k Ω to 1 M Ω is often used for R_G to provide a path to ground for gate leakage current. If R_G is omitted in an ac-coupled JFET amplifier, a dc voltage can build up on the gate from leakage current or static electricity, affecting the channel conductivity.

$$Z_{IN} = R_G \quad (46)$$

Because of the high impedance of the drain-source channel in the saturation region, the output impedance of the circuit is:

$$Z_{OUT} \approx R_D \quad (47)$$

Designing the Common-Source Amplifier

The design of the CS amplifier begins with selection of a Q-point $I_{DQ} < I_{DSS}$. Because of variations in V_P and I_{DSS} from JFET to JFET, it may be necessary to select devices individually to obtain the desired performance.

1) Start by determining the circuit's design constraints and assumptions: $V_{DD} = 12$ V (the power supply voltage) and the JFET has an I_{DSS} of 35 mA and a V_P of -3.0 V, typical of small-signal JFETs. State the circuit's design requirements: $|A_V| = 10$ and $I_{DQ} = 10$ mA.

2) Use equation 45 to determine $R_S = 139 \Omega$

3) Since $|A_V| = 10$, $R_D = 10 R_S = 1390 \Omega$.

Fig 3.52 — Common-source amplifier with source bypass capacitor, C_S , to increase voltage gain without affecting the circuit's dc performance.

Fig 3.53 — Similar to the EF amplifier, the common-drain (CD) amplifier has a voltage gain of unity, but makes a good buffer with high input and low output impedances.

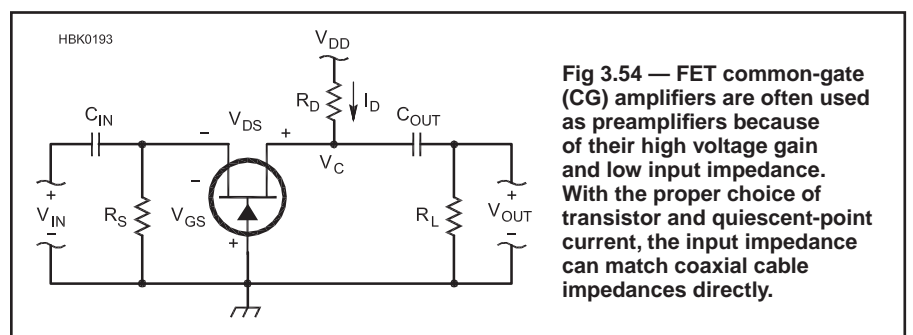

Fig 3.54 — FET common-gate (CG) amplifiers are often used as preamplifiers because of their high voltage gain and low input impedance. With the proper choice of transistor and quiescent-point current, the input impedance can match coaxial cable impedances directly.

Use standard values for $R_S = 150 \Omega$ and $R_D = 1.5$ k Ω .

AC Performance

As with the CE bipolar transistor amplifier, a bypass capacitor can be used to increase ac gain while leaving dc bias conditions unchanged as shown in Fig 3.52. In the case of the CS amplifier, a *source bypass* capacitor is placed across R_S and the load, R_L , connected through a dc blocking capacitor. In this circuit voltage gain becomes:

$$A_V = -g_m (R_D // R_L) \quad (48)$$

Assuming C_{IN} and C_{OUT} are large enough to ignore their effects, the low-frequency cutoff frequency of the amplifier, f_L , is approximately where $X_{CS} = 0.707 (R_D // R_L)$,

$$f_L = \frac{1.414}{2\pi (R_D // R_L) C_S} \quad (49)$$

as this reduces A_V to 0.707 of its mid-band value, resulting in a 3 dB drop in output amplitude.

The low-frequency ac input and output impedances of the CS amplifier remain

$$Z_{IN} = R_G \text{ and } Z_{OUT} \approx R_D \quad (50)$$

COMMON-DRAIN (SOURCE-FOLLOWER) AMPLIFIER

The *common-drain* amplifier in Fig 3.53 is also known as a *source-follower* (SF) because the voltage gain of the amplifier is unity, similar to the emitter follower (EF) bipolar transistor amplifier. The SF amplifier is used primarily as a buffer stage and to drive low-impedance loads.

At low frequencies, the input impedance of the SF amplifier remains nearly infinite. The SF amplifier's output impedance is the source resistance, R_S , in parallel with the impedance of the controlled current source, $1/g_m$.

$$Z_{OUT} = R_S // \frac{1}{g_m} = \frac{R_S}{g_m R_S + 1} \approx \frac{1}{g_m} \text{ for } g_m R_S \gg 1 \quad (51)$$

Design of the SF amplifier follows essentially the same process as the CS amplifier, with $R_D = 0$.

THE COMMON-GATE AMPLIFIER

The *common-gate* amplifier in Fig 3.54 has similar properties to the bipolar transistor common-base (CB) amplifier; unity current gain, high voltage gain, low input impedance and high output impedance. (Refer to the discussion of the CB amplifier regarding placement of the input and how the circuit schematic is drawn.) It is used as a voltage amplifier, particularly for low-impedance sources, such as coaxial cable inputs.

The CG amplifier's voltage gain is

$$A_V = g_m(R_D // R_L) \quad (52)$$

The output impedance of the CG amplifier is very high, we must take into account the output resistance of the controlled current source, r_o . This is analogous to the appearance of h_{oc} in the equation for output impedance of the bipolar transistor CG amplifier.

$$Z_O \approx r_o (g_m R_S + 1) // R_D \quad (53)$$

The CG amplifier input impedance is approximately

$$Z_I = R_S // \frac{1}{g_m} \quad (54)$$

Because the input impedance is quite low, the cascode circuit described later in the section on buffers is often used to present a higher-impedance input to the signal source.

Occasionally, the value of R_S must be fixed in order to provide a specific value of input impedance. Solving equation 40 for I_{DQ} results in the following equation:

$$I_{DQ} = \frac{V_P}{2R_S^2 I_{DSS}} \left(V_P + \sqrt{V_P^2 - 4R_S I_{DSS} V_P} \right) - \frac{V_P}{R_S} \quad (55)$$

Designing the Common-Gate Amplifier

Follow the procedure for designing a CS amplifier, except determine the value of R_D as shown in equation 52 for voltage gain above.

1) Start by determining the circuit's design constraints and assumptions: $V_{DD} = 12$ V (the power supply voltage) and the JFET has a g_m of 15 mA/V, an I_{DSS} of 60 mA and $V_P = -6$ V. State the circuit's design requirements: $A_V = 10$, $R_L = 1$ k Ω and $R_S = 50$ Ω .

2) Solve equation 52 for R_D : $10 = 0.015 \times R_D / R_L$, so $R_D / R_L = 667$ Ω . $R_D = 667 R_L / (R_L - 667) = 2$ k Ω .

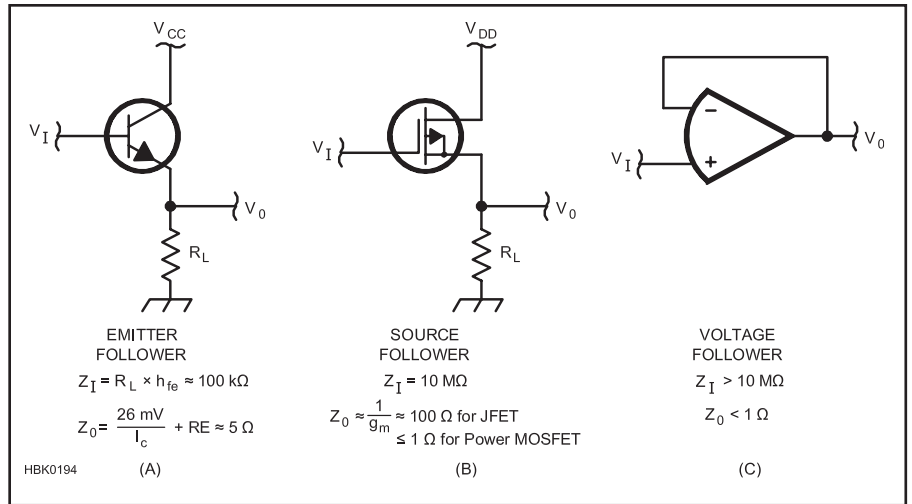

Fig 3.55 — Common buffer stages and some typical input (Z_I) and output (Z_O) impedances. (A) Emitter follower, made with an NPN bipolar transistor; (B) Source follower, made with an FET; and (C) Voltage follower, made with an operational amplifier. All of these buffers are terminated with a load resistance, R_L , and have an output voltage that is approximately equal to the input voltage (gain ≈ 1).

3) I_{DQ} is determined from equation 55: $I_{DQ} = 10$ mA. If I_{DQ} places the Q-point in the ohmic region, reduce A_V and repeat the calculations.

3.5.5 Buffer Amplifiers

Fig 3.55 shows common forms of buffers with low-impedance outputs: the *emitter follower* using a bipolar transistor, the *source follower* using a field-effect transistor and the *voltage follower*, using an operational amplifier. (The operational amplifier is discussed later in this chapter.) These circuits are called “followers” because the output “follows” the input very closely with approximately the same voltage and little phase shift between the input and output signals.

Fig 3.56 — Darlington pair made with two emitter followers. Input impedance, Z_I , is far higher than for a single transistor and output impedance, Z_O , is nearly the same as for a single transistor. DC biasing has been omitted for simplicity.

3.5.6 Cascaded Buffers THE DARLINGTON PAIR

Buffer stages that are made with single active devices can be more effective if cascaded. Two types of such buffers are in common use. The *Darlington pair* is a cascade of two transistors connected as emitter followers as shown in Fig 3.56. The current gain of the Darlington pair is the product of the current gains for the two transistors, $\beta_1 \times \beta_2$.

What makes the Darlington pair so useful is that its input impedance is equal to the load impedance times the current gain, effectively multiplying the load impedance;

$$Z_I = Z_{LOAD} \times \beta_1 \times \beta_2 \quad (56)$$

For example, if a typical bipolar transistor has $\beta = 100$ and $Z_{LOAD} = 15$ k Ω , a pair of these transistors in the Darlington-pair configuration would have:

$$Z_I = 15 \text{ k}\Omega \times 100 \times 100 = 150 \text{ M}\Omega$$

Fig 3.57 — Cascode buffer made with two NPN bipolar transistors has a medium input impedance and high output impedance. DC biasing has been omitted for simplicity.

This impedance places almost no load on the circuit connected to the Darlington pair's input. The shunt capacitance at the input of real transistors can lower the actual impedance as the frequency increases.

Drawbacks of the Darlington pair include lower bandwidth and switching speed. The extremely high dc gain makes biasing very sensitive to temperature and component tolerances. For these reasons, the circuit is usually used as a switch and not as a linear amplifier.

CASCODE AMPLIFIERS

A common-emitter amplifier followed by a common-base amplifier is called a *cascode buffer*, shown in its simplest form in **Fig 3.57**. (Biasing and dc blocking components are omitted for simplicity — replace the transistors with the practical circuits described earlier.) Cascode stages using FETs follow a common-source amplifier with a common-gate configuration. The input impedance and current gain of the cascode amplifier are approximately the same as those of the first stage. The output impedance of the common-base or -gate stage is much higher than that of the common-emitter or common-source amplifier. The power gain of the cascode amplifier is the product of the input stage current gain and the output stage voltage gain.

As an example, a typical cascode buffer made with BJTs has moderate input impedance ($Z_{IN} = 1 \text{ k}\Omega$), high current gain ($h_{fe} = 50$), and high output impedance ($Z_{OUT} = 1 \text{ M}\Omega$). Cascode amplifiers have excellent input/output isolation (very low unwanted internal feedback), resulting in high gain with good stability. Because of its excellent isolation, the cascode amplifier has little effect on external tuning components. Cascode circuits are often used in tuned amplifier designs for these reasons.

3.5.7 Using the Transistor as a Switch

When designing amplifiers, the goal was to make the transistor's output a replica of its input, requiring that the transistor stay within its linear region, conducting some current at all times. A switch circuit has completely different properties — its output current is either zero or some maximum value. **Fig 3.58** shows both a bipolar and metal-oxide semiconductor field-effect transistor (or MOSFET) switch circuit. Unlike the linear amplifier circuits, there are no bias resistors in either circuit. When using the bipolar transistor as a switch, it should operate in saturation or in cutoff. Similarly, an FET switch should be either fully-on or fully-off. The figure shows the waveforms associated with both types of switch circuits.

This discussion is written with power con-

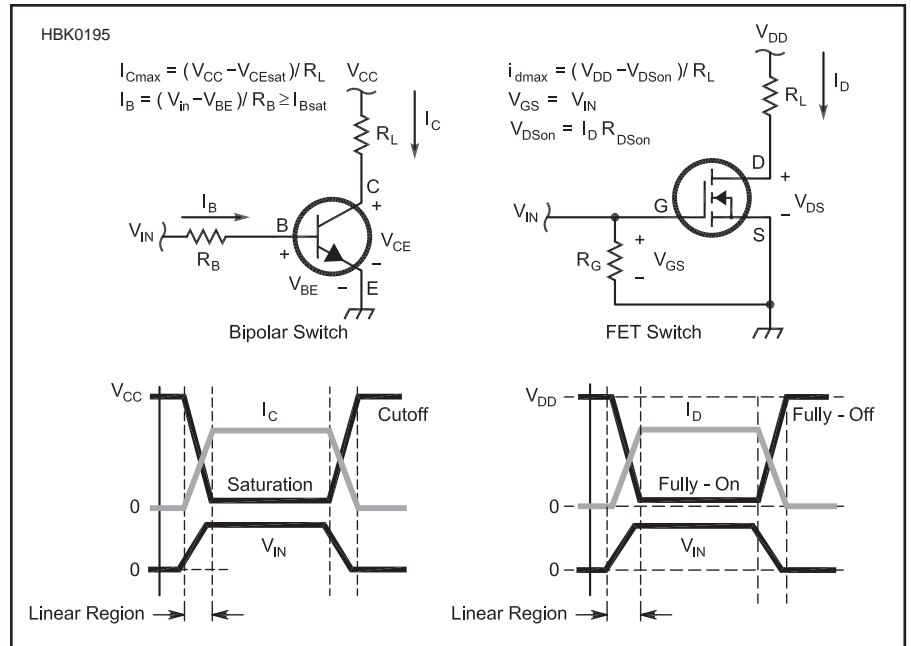

Fig 3.58 — A pair of transistor driver circuits using a bipolar transistor and a MOSFET. The input and output signals show the linear, cutoff and saturation regions.

trol in mind, such as to drive a relay or motor or lamp. The concepts, however, are equally applicable to the much lower-power circuits that control logic-level signals. The switch should behave just the same — switch between on and off quickly and completely — whether large or small.

DESIGNING SWITCHING CIRCUITS

First, select a transistor that can handle the load current and dissipate whatever power is dissipated as heat. Second, be sure that the input signal source can supply an adequate input signal to drive the transistor to the required states, both on and off. Both of these conditions must be met to insure reliable driver operation.

To choose the proper transistor, the load current and supply voltage must both be known. Supply voltage may be steady, but sometimes varies widely. For example, a car's 12 V power bus may vary from 9 to 18 V, depending on battery condition. The transistor must withstand the maximum supply voltage, V_{MAX} , when off. The load resistance, R_L , must also be known. The maximum steady-state current the switch must handle is:

$$I_{MAX} = \frac{V_{MAX}}{R_L} \quad (57)$$

If you are using a bipolar transistor, calculate how much base current is required to drive the transistor at this level of collector current. You'll need to inspect the transistor's data sheet because β decreases as collector current increases, so use a value for β speci-

fied at a collector current at or above I_{MAX} .

$$I_B = \frac{I_{MAX}}{\beta} \quad (58)$$

Now inspect the transistor's data sheet values for V_{CEsat} and make sure that this value of I_B is sufficient to drive the transistor fully into saturation at a collector current of I_{MAX} . Increase I_B if necessary — this is I_{Bsat} . The transistor must be fully saturated to minimize heating when conducting load current.

Using the *minimum* value for the input voltage, calculate the value of R_B :

$$R_B = \frac{V_{IN(min)} - V_{BE}}{I_{Bsat}} \quad (59)$$

The minimum value of input voltage must be used to accommodate the *worst-case* combination of circuit voltages and currents.

Designing with a MOSFET is a little easier because the manufacturer usually specifies the value V_{GS} must have for the transistor to be fully on, $V_{GS(on)}$. The MOSFET's gate, being insulated from the conducting channel, acts like a small capacitor of a few hundred pF and draws very little dc current. R_G in **Fig 3.58** is required if the input voltage source does not actively drive its output to zero volts when off, such as a switch connected to a positive voltage. The MOSFET won't turn off reliably if its gate is allowed to "float." R_G pulls the gate voltage to zero when the input is open-circuited.

Power dissipation is the next design hurdle. Even if the transistors are turned completely on, they will still dissipate some heat. Just as

for a resistor, for a bipolar transistor switch the power dissipation is:

$$P_D = V_{CE} I_C = V_{CE(sat)} I_{MAX}$$

where $V_{CE(sat)}$ is the collector-to-emitter voltage when the transistor is saturated.

Power dissipation in a MOSFET switch is:

$$P_D = V_{DS} I_D = R_{DS(on)} I_{MAX}^2 \quad (60)$$

$R_{DS(on)}$ is the resistance of the channel from drain to source when the MOSFET is on. MOSFETs are available with very low on-resistance, but still dissipate a fair amount of power when driving a heavy load. The transistor's data sheet will contain $R_{DS(on)}$ specification and the V_{GS} required for it to be reached.

Power dissipation is why a switching transistor needs to be kept out of its linear region. When turned completely off or on, either current through the transistor or voltage across it are low, also keeping the product of voltage and current (the power to be dissipated) low. As the waveform diagrams in Fig 3.58 show, while in the linear region, both voltage and current have significant values and so the transistor is generating heat when changing from off to on and vice versa. It's important to make the transition through the linear region quickly to keep the transistor cool.

The worst-case amount of power dissipated during each on-off transition is approximately

$$P_{transition} = \frac{1}{4} V_{MAX} I_{MAX}$$

assuming that the voltage and current increase and decrease linearly. If the circuit turns on and off at a rate of f , the total average power dissipation due to switching states is:

$$P_D = \frac{f}{2} V_{MAX} I_{MAX} \quad (61)$$

since there are two on-off transitions per switching cycle. This power must be added to the power dissipated when the switch is conducting current.

Once you have calculated the power the switch must dissipate, you must check to see whether the transistor can withstand it. The manufacturer of the transistor will specify a *free-air dissipation* that assumes no heat-sink and room temperature air circulating freely around the transistor. This rating should be at least 50% higher than your calculated power dissipation. If not, you must either use a larger transistor or provide some means of getting rid of the heat, such as heat sink. Methods of

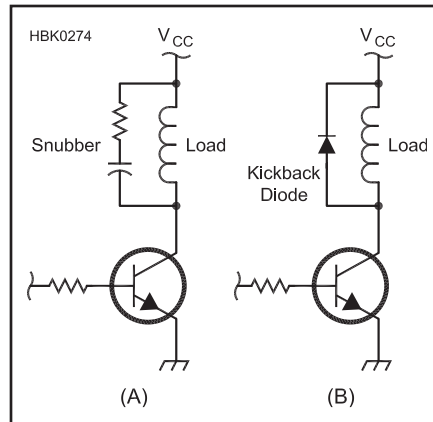

Fig 3.59 — The snubber RC circuit at (A) absorbs energy from transients with fast rise- and fall-times. At (B) a kickback diode protects the switching device when current is interrupted in the inductive load, causing a voltage transient, by conducting the energy back to the power source.

dissipating heat are discussed in the **Electrical Fundamentals** chapter.

INDUCTIVE AND CAPACITIVE LOADS

Voltage transients for inductive loads, such as solenoids or relays can easily reach dozens of times the power supply voltage when load current is suddenly interrupted. To protect the transistor, the voltage transient must be clamped or its energy dissipated. Where switching is frequent, a series-RC *snubber* circuit (see Fig 3.59A) is connected across the load to dissipate the transient's energy as heat. The most common method is to employ a "kickback" diode that is reverse-biased when the load is energized as shown in Fig 3.59B. When the load current is interrupted, the diode routes the energy back to the power supply, clamping the voltage at the power supply voltage plus the diode's forward voltage drop.

Capacitive loads such as heavily filtered power inputs may temporarily act like short circuits when the load is energized or de-energized. The surge current is only limited by the internal resistance of the load capacitance. The transistor will have to handle the temporary overloads without being damaged or overheating. The usual solution is to select a transistor with an I_{MAX} rating greater to the surge current. Sometimes a small current-limiting resistor can be placed in series with the load to reduce the peak surge current at the

expense of dissipating power continuously when the load is drawing current.

HIGH-SIDE AND LOW-SIDE SWITCHING

The switching circuits shown in Fig 3.58 are *low-side switches*. This means the switch is connected between the load and ground. A *high-side switch* is connected between the power source and the load. The same concerns for power dissipation apply, but the methods of driving the switch change because of the voltage of the emitter or source of the switching device will be at or near the power supply voltage when the switch is on.

To drive an NPN bipolar transistor or an N-channel MOSFET in a high-side circuit requires the switch input signal to be at least $V_{BE(sat)}$ or $V_{GS(on)}$ above the voltage supplied to the load. If the load expects to see the full power supply voltage, the switch input signal will have to be *greater* than the power supply voltage. A small step-up or boost dc-to-dc converter is often used to supply the extra voltage needed for the driver circuit.

One alternate method of high-side switching is to use a PNP bipolar transistor as the switching transistor. A small input transistor turns the main PNP transistor on by controlling the larger transistor's base current. Similarly, a P-channel MOSFET could also be employed with a bipolar transistor or FET acting as its driver. P-type material generally does not have the same high conductivity as N-type material and so these devices dissipate somewhat more power than N-type devices under the same load conditions.

3.5.8 Choosing a Transistor

With all the choices for transistors — Web sites and catalogs can list hundreds — selecting a suitable transistor can be intimidating. Start by determining the maximum voltage (V_{CEO} or $V_{DS(MAX)}$), current (I_{MAX}) and power dissipation ($P_{D(MAX)}$) the transistor must handle. Determine what dc current gain, β , or transconductance, g_m , is required. Then determine the highest frequency at which full gain is required and multiply it by either the voltage or current gain to obtain f_T or h_{fe} . This will reduce the number of choices dramatically.

The chapter on **Component Data and References** has tables of parameters for popular transistors that tend to be the lowest-cost and most available parts, as well. You will find that a handful of part types satisfy the majority of your building needs. Only in very special applications will you need to choose a corresponding special part.

3.6 Operational Amplifiers

An *operational amplifier*, or *op amp*, is one of the most useful linear devices. While it is possible to build an op amp with discrete components, and early versions were, the symmetry of the circuit demanded for high performance requires a close match of many components. It is more effective, and much easier, to implement as an integrated circuit. (The term “operational” comes from the op amp’s origin in analog computers where it was used to implement mathematical operations.)

The op amp’s performance approaches that of an ideal analog circuit building block: an infinite input impedance (Z_i), a zero output impedance (Z_o) and an open loop voltage gain (A_v) of infinity. Obviously, practical op amps do not meet these specifications, but they do come closer than most other types of amplifiers. These attributes allow the circuit designer to implement many different functions with an op amp and only a few external components.

3.6.1 Characteristics of Practical Op-Amps

An op amp has three signal terminals (see Fig 3.60). There are two input terminals, the *noninverting input* marked with a + sign and the *inverting input* marked with a – sign. Voltages applied to the noninverting input cause the op amp output voltage to change with the same polarity.

The output of the amplifier is a single terminal with the output voltage referenced to the external circuit’s reference voltage. Usually, that reference is ground, but the op amp’s internal circuitry allows all voltages to *float*, that is, to be referenced to any arbitrary voltage between the op amp’s power supply voltages. The reference can be negative, ground or

positive. For example, an op amp powered from a single power supply voltage amplifies just as well if the circuit reference voltage is halfway between ground and the supply voltage.

GAIN-BANDWIDTH PRODUCT AND COMPENSATION

An ideal op amp would have infinite frequency response, but just as transistors have an f_T that marks their upper frequency limit, the op amp has a *gain-bandwidth product* (GBW or BW). GBW represents the maximum product of gain and frequency available to any signal or circuit: voltage gain \times frequency = GBW. If an op-amp with a GBW of 10 MHz is connected as a $\times 50$ voltage amplifier, the maximum frequency at which that gain could be guaranteed is $GBW / \text{gain} = 10 \text{ MHz} / 50 = 200 \text{ kHz}$. GBW is an important consideration in high-performance filters and signal processing circuits whose design equations require high-gain at the frequencies over which they operate.

Older operational amplifiers, such as the LM301, have an additional two connections for *compensation*. To keep the amplifier from oscillating at very high gains it is often necessary to place a capacitor across the compensation terminals. This also decreases the frequency response of the op amp but increases its stability by making sure that the output signal can not have the right phase to create positive feedback at its inputs. Most modern op amps are internally compensated and do not have separate pins to add compensation capacitance. Additional compensation can be created by connecting a capacitor between the op amp output and the inverting input.

CMRR AND PSRR

One of the major advantages of using an op amp is its very high *common mode rejection ratio* (CMRR). *Common mode* signals are those that appear equally at all terminals. For example, if both conductors of an audio cable pick up a few tenths of a volt of 60 Hz signal from a nearby power transformer, that 60 Hz signal is a common-mode signal to whatever device the cable is connected. Since the op amp only responds to *differences* in voltage at its inputs, it can ignore or reject common mode signals. CMRR is a measure of how well the op amp rejects the common mode signal. High CMRR results from the symmetry between the circuit halves. CMRR is important when designing circuits that process low-level signals, such as microphone audio or the mV-level dc signals from sensors or thermocouples.

The rejection of power-supply imbalance is also an important op amp parameter. Shifts in power supply voltage and noise or ripple

on the power supply voltages are coupled directly to the op amp’s internal circuitry. The op amp’s ability to ignore those disturbances is expressed by the *power supply rejection ratio* (PSRR). A high PSRR means that the op amp circuit will continue to perform well even if the power supply is imbalanced or noisy.

INPUT AND OUTPUT VOLTAGE LIMITS

The op amp is capable of accepting and amplifying signals at levels limited by the power supply voltages, also called *rails*. The difference in voltages between the two rails limits the range of signal voltages that can be processed. The voltages can be symmetrical positive and negative voltages ($\pm 12 \text{ V}$), a positive voltage and ground, ground and a negative voltage or any two different, stable voltages.

In most op amps the signal levels that can be handled are one or two diode forward voltage drops (0.7 V to 1.4 V) away from each rail. Thus, if an op amp has 15 V connected as its upper rail (usually denoted V^+) and ground connected as its lower rail (V^-), input signals can be amplified to be as high as 13.6 V and as low as 1.4 V in most amplifiers. Any values that would be amplified beyond those limits are clamped (output voltages that should be 1.4 V or less appear as 1.4 V and those that should be 13.6 V or more appear as 13.6 V). This clamping action was illustrated in Fig 3.1.

“Rail-to-rail” op amps have been developed to handle signal levels within a few tens of mV of rails (for example, the MAX406, from Maxim Integrated Products processes signals to within 10 mV of the power supply voltages). Rail-to-rail op-amps are often used in battery-powered products to allow the circuits to operate from low battery voltages for as long as possible.

INPUT BIAS AND OFFSET

The inputs of an op amp, while very high impedance, still allow some input current to flow. This is the *input bias current* and it is in the range of nA in modern op amps. Slight asymmetries in the op amp’s internal circuitry result in a slight offset in the op amp’s out-put voltage, even with the input terminals shorted together. The amount of voltage difference between the op amp’s inputs required to cause the output voltage to be exactly zero is the *input offset voltage*, generally a few mV or less. Some op amps, such as the LM741, have special terminals to which a potentiometer can be connected to *null* the offset by correcting the internal imbalance. Introduction of a small dc correction voltage to the noninverting terminal is sometimes used to apply an offset voltage that counteracts the internal mismatch and

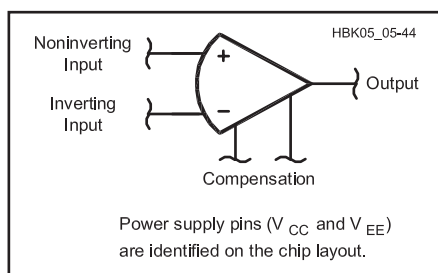

Fig 3.60 — Operational amplifier schematic symbol. The terminal marked with a + sign is the noninverting input. The terminal marked with a – sign is the inverting input. The output is to the right. On some op amps, external compensation is needed and leads are provided, pictured here below the device. Usually, the power supply leads are not shown on the op amp itself but are specified in the data sheet.

centers the signal in the rail-to-rail range.

DC offset is an important consideration in op amps for two reasons. Actual op amps have a slight mismatch between the inverting and noninverting terminals that can become a substantial dc offset in the output, depending on the amplifier gain. The op amp output voltage must not be too close to the clamping limits or distortion will occur.

A TYPICAL OP AMP

As an example of typical values for these parameters, one of today's garden-variety op amps, the TL084, which contains both JFET and bipolar transistors, has a guaranteed minimum CMRR of 80 dB, an input bias current guaranteed to be below 200 pA (1 pA = 1 millionth of a μA) and a gain-bandwidth product of 3 MHz. Its input offset voltage is 3 mV. CMRR and PSRR are 86 dB, meaning that an unwanted signal or power supply imbalance of 1 V will only result in a 2.5 nV change at the op amp's output! All this for 33 cents even purchased in single quantities and there are four op-amps per package — that's a lot of performance.

3.6.2 Basic Op Amp Circuits

If a signal is connected to the input terminals of an op amp without any other circuitry attached, it will be amplified at the device's *open-loop gain* (typically 200,000 for the TL084 at dc and low frequencies, or 106 dB). This will quickly saturate the output at the power supply rails. Such large gains are rarely used. In most applications, negative feedback is used to limit the circuit gain by providing a feedback path from the output terminal to the inverting input terminal. The resulting *closed-loop gain* of the circuit depends solely on the values of the passive components used to form the loop (usually resistors and, for frequency-selective circuits, capacitors). The higher the op-amp's open-loop gain, the closer the circuit's actual gain will approach that predicted from the component values. Note that the gain of the op amp itself has not changed — it is the configuration of the external components that determines the overall gain of the circuit. Some examples of different circuit configurations that manipulate the closed-loop gain follow.

INVERTING AND NONINVERTING AMPLIFIERS

The op amp is often used in either an *inverting* or a *noninverting* amplifier circuit as shown in Fig 3.61. (Inversion means that the output signal is inverted from the input signal about the circuit's voltage reference as described below.) The amount of amplification is determined by the two resistors: the feedback resistor, R_f , and the input resistor, R_i .

In the noninverting configuration shown in

Fig 3.61 — Operational amplifier circuits. (A) Noninverting configuration. (B) Inverting configuration.

Fig 3.61A, the input signal is connected to the op-amp's noninverting input. The feedback resistor is connected between the output and the inverting input terminal. The inverting input terminal is connected to R_i , which is connected to ground (or the circuit reference voltage).

This circuit illustrates how op amp circuits use negative feedback, the high open-loop gain of the op amp itself, and the high input impedance of the op amp inputs to create a stable circuit with a fixed gain. The signal applied to the noninverting input causes the output voltage of the op-amp to change with the same polarity. That is, a positive input signal causes a positive change in the op amp's output voltage. This voltage causes current to flow in the voltage divider formed by R_f and R_i . Because the current into the inverting input is so low, the current through R_f is the same as R_i .

The voltage at the *summing junction*, the connection point for the two resistors and the inverting terminal, V_{INV} , is:

$$V_{INV} = V_O \left(\frac{R_i}{R_i + R_f} \right) \quad (62)$$

The op amp's output voltage will continue to rise until the *loop error signal*, the difference in voltage between the inverting and noninverting inputs, is close to zero. At this point, the voltage at the inverting terminal is approximately equal to the voltage at the noninverting terminal, V_{in} , so that $V_{INV} = V_{in}$. Substituting in equation 62, the gain of this circuit is:

$$\frac{V_O}{V_{in}} = \left(1 + \frac{R_f}{R_i} \right) \quad (63)$$

where

V_O = the output voltage

V_{in} = the input voltage.

The higher the op amp's open-loop gain, the closer will be the voltages at the inverting and noninverting terminals when the circuit is balanced and the more closely the circuit's closed-loop gain will equal that of Equation 63. So the negative feedback creates an electronic balancing act with the op amp increasing its output voltage so that the input error signal is as small as possible.

In the inverting configuration of Fig 3.61B, the input signal (V_{in}) is connected through R_i to the inverting terminal. The feedback resistor is again connected between the inverting terminal and the output. The noninverting terminal is connected to ground (or the circuit reference voltage). In this configuration the feedback action results in the output voltage changing to whatever value is needed such that the current through R_i is balanced by an equal and opposite current through R_f . The gain of this circuit is:

$$\frac{V_O}{V_{in}} = - \frac{R_f}{R_{in}} \quad (64)$$

where V_{in} represents the voltage input to R_{in} .

For the remainder of this section, "ground" or "zero voltage" should be understood to be the circuit reference voltage. That voltage may not be "earth ground potential." For example, if a single positive supply of 12 V is used, 6 V may be used as the circuit reference voltage. The circuit reference voltage is a fixed dc voltage that can be considered to be an ac ground because of the reference source's extremely low ac impedance.

The negative sign in equation 64 indicates that the signal is inverted. For ac signals, inversion represents a 180° phase shift. The gain of the noninverting configuration can vary from a minimum of 1 to the maximum of which the op amp is capable, as indicated by A_v for dc signals, or the gain-bandwidth product for ac signals. The gain of the inverting configuration can vary from a minimum of 0 (gains from 0 to 1 attenuate the signal while gains of 1 and higher amplify the signal) to the maximum of which the device is capable.

The inverting amplifier configuration results in a special condition at the op amp's inverting input called *virtual ground*. Because the op amp's high open-loop gain drives the two inputs to be very close together, if the noninverting input is at ground potential, the inverting input will be very close to ground as well and the op amp's output will change with the input signal to maintain the inverting input at ground. Measured with a voltmeter, the input appears to be grounded, but it is merely maintained at ground potential by the action of the op amp and the feedback loop. This point in the circuit may not be connected

to any other ground connection or circuit point because the resulting additional current flow will upset the balance of the circuit.

The *voltage follower* or *unity-gain buffer* circuit of **Fig 3.62** is commonly used as a buffer stage. The voltage follower has the input connected directly to the noninverting terminal and the output connected directly to the inverting terminal. This configuration has unity gain because the circuit is balanced when the output and input voltages are the same (error voltage equals zero). It also provides the maximum possible input impedance and the minimum possible output impedance of which the device is capable.

Differential and Difference Amplifier

A *differential amplifier* is a special application of an operational amplifier (see **Fig 3.63**). It amplifies the difference between two analog signals and is very useful to cancel noise under certain conditions. For instance, if an analog signal and a reference signal travel over the same cable they may pick up noise, and it is likely that both signals will have the same amount of noise. When the differential amplifier subtracts them, the signal will be unchanged but the noise will be completely removed, within the limits of the CMRR. The equation for differential amplifier operation is

$$V_O = \frac{R_f}{R_i} \left[\frac{1}{\frac{R_n}{R_g} + 1} \left(\frac{R_i}{R_f} + 1 \right) V_n - V_i \right] \quad (65)$$

which, if the ratios R_i/R_f and R_n/R_g are equal, simplifies to:

$$V_O = \frac{R_f}{R_i} (V_n - V_i) \quad (66)$$

Note that the differential amplifier response is identical to the inverting amplifier response (equation 64) if the voltage applied to the noninverting terminal is equal to zero. If the voltage applied to the inverting terminal (V_i) is zero, the analysis is a little more complicated but it is possible to derive the noninverting amplifier response (equation 62)

Fig 3.62 — Voltage follower. This operational amplifier circuit makes a nearly ideal buffer with a voltage gain of about one, and with extremely high input impedance and extremely low output impedance.

Fig 3.63 — Difference amplifier. This operational amplifier circuit amplifies the difference between the two input signals.

from the differential amplifier response by taking into account the influence of R_n and R_g . If all four resistors have the *same* value the *difference amplifier* is created and V_O is just the difference of the two voltages.

$$V_O = V_n - V_i \quad (67)$$

Instrumentation Amplifier

Just as the symmetry of the transistors making up an op amp leads to a device with high values of Z_i , A_v and CMRR and a low value of Z_o , a symmetric combination of op amps is used to further improve these parameters. This circuit, shown in **Fig 3.64** is called an *instrumentation amplifier*. It has three parts; each of the two inputs is connected to a noninverting buffer amplifier with a gain of $1 + R_2/R_1$. The outputs of these buffer amplifiers are then connected to a differential amplifier with a gain of R_4/R_3 . V_2 is the circuit's inverting input and V_1 the noninverting input.

The three amplifier modules are usually all part of the same integrated circuit. This means that they have essentially the same temperature and the internal transistors and resistors are very well matched. This causes the subtle gain and tracking errors caused by temperature differences and mismatched components

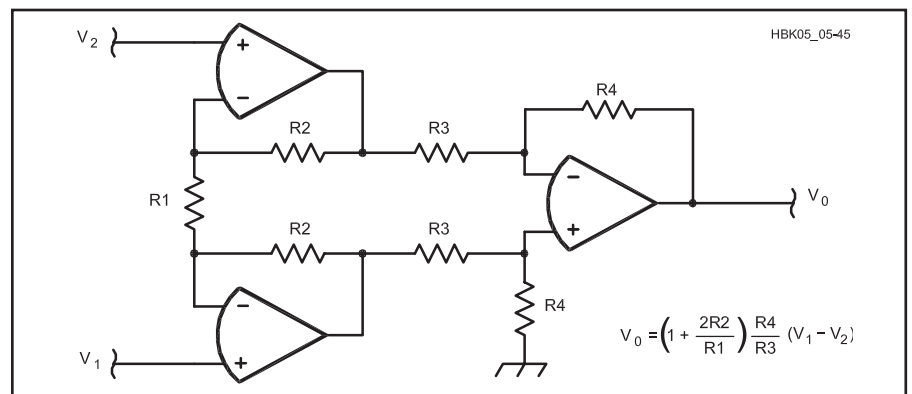

Fig 3.64 — Operational amplifiers arranged as an instrumentation amplifier. The balanced and cascaded series of op amps work together to perform differential amplification with good common-mode rejection and very high input impedance (no load resistor required) on both the inverting (V_1) and noninverting (V_2) inputs.

between individual op amps to be cancelled out or dramatically reduced. In addition, the external resistors using the same designators (R_2 , R_3 , R_4) are carefully matched as well, sometimes being part of a single integrated *resistor pack*. The result is a circuit with better performance than any single-amplifier circuit over a wider temperature range.

Summing Amplifier

The high input impedance of an op amp makes it ideal for use as a *summing amplifier*. In either the inverting or noninverting configuration, the single input signal can be replaced by multiple input signals that are connected together through series resistors, as shown in **Fig 3.65**. For the inverting summing amplifier, the gain of each input signal can be calculated individually using equation 64 and, because of the superposition property of linear circuits, the output is the sum of each input signal multiplied by its gain. In the noninverting configuration, the output is the gain times the weighted sum of the m different input signals:

$$V_O = V_{n1} \frac{R_{p1}}{R_1 + R_{p1}} + V_{n2} \frac{R_{p2}}{R_2 + R_{p2}} + \dots + V_{nm} \frac{R_{pm}}{R_m + R_{pm}} \quad (68)$$

where R_{pm} is the parallel resistance of all m resistors excluding R_m . For example, with three signals being summed, R_{p1} is the parallel combination of R_2 and R_3 .

Comparators

A *voltage comparator* is another special form of op amp circuit, shown in **Fig 3.66**. It has two analog signals as its inputs and its output is either TRUE or FALSE depending on whether the noninverting or inverting signal voltage is higher, respectively. Thus, it “compares” the input voltages. TRUE generally corresponds to a positive output voltage and

FALSE to a negative or zero voltage. The circuit in Fig 3.66 uses external resistors to generate a reference voltage, called the *setpoint*, to which the input signal is compared. A comparator can also compare two variable voltages.

A standard operational amplifier can be made to act as a comparator by connecting the two input voltages to the noninverting and inverting inputs with no input or feedback resistors. If the voltage of the noninverting input is higher than that of the inverting input, the output voltage will be driven to the positive clamping limit. If the inverting input is at a higher potential than the noninverting input, the output voltage will be driven to

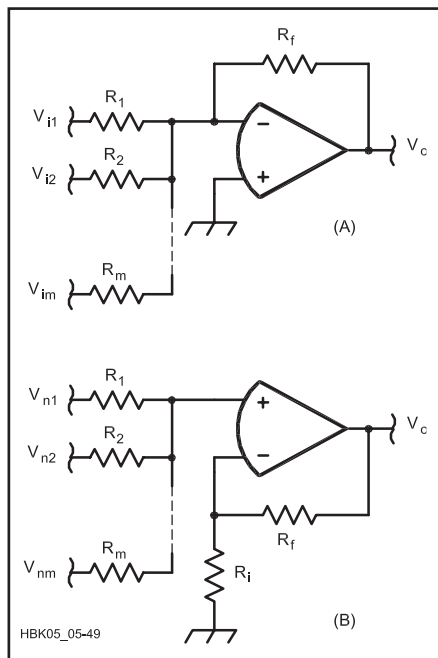

Fig 3.65 — Summing operational amplifier circuits. (A) Inverting configuration. (B) Noninverting configuration.

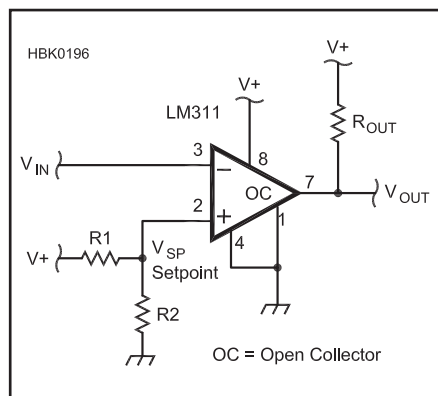

Fig 3.66 — A comparator circuit in which the output voltage is low when voltage at the inverting input is higher than the setpoint voltage at the noninverting input.

the negative clamping limit. If the comparator is comparing an unknown voltage to a known voltage, the known voltage is called the *setpoint* and the comparator output indicates whether the unknown voltage is above or below the setpoint.

An op amp that has been intended for use as a comparator, such as the LM311, is optimized to respond quickly to the input signals. In addition, comparators often have *open-collector outputs* that use an external *pull-up resistor*, R_{OUT} , connected to a positive power supply voltage. When the comparator output is TRUE, the output transistor is turned off and the pull-up resistor "pulls up" the output voltage to the positive power supply voltage. When the comparator output is FALSE, the transistor is driven into the saturation and the output voltage is the transistor's $V_{CE(sat)}$.

Hysteresis

Comparator circuits also use *hysteresis* to

prevent "chatter" — the output of the comparator switching rapidly back and forth when the input voltage is at or close to the setpoint voltage. There may be noise on the input signal, as shown in Fig 3.67A, that causes the input voltage to cross the setpoint threshold repeatedly. The rapid switching of the output can be confusing to the circuits monitoring the comparator output.

Hysteresis is a form of positive feedback that "moves" the setpoint by a few mV in the direction *opposite* to that in which the input signal *crossed* the setpoint threshold. As shown in Fig 3.67B, the slight shift in the setpoint tends to hold the comparator output in the new state and prevents switching back to the old state. Fig 3.68 shows how the output of the comparator is fed back to the positive input through resistor R_3 , adding or subtracting a small amount of current from the divider and shifting the setpoint.

Some applications of a voltage comparator

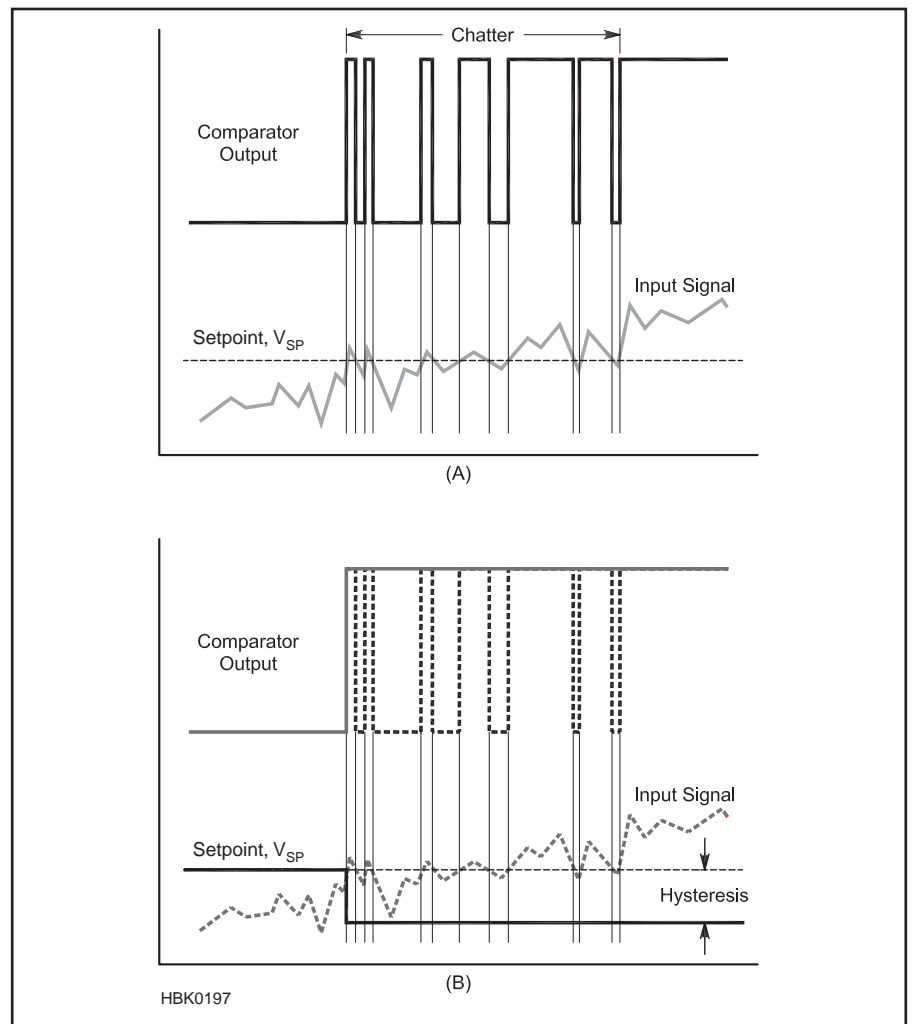

Fig 3.67 — Chatter (A) is caused by noise when the input signal is close to the setpoint. Chatter can also be caused by voltage shifts that occur when a heavy load is turned on and off. Hysteresis (B) shifts the setpoint a small amount by using positive feedback in which the output pulls the setpoint farther away from the input signal after switching.

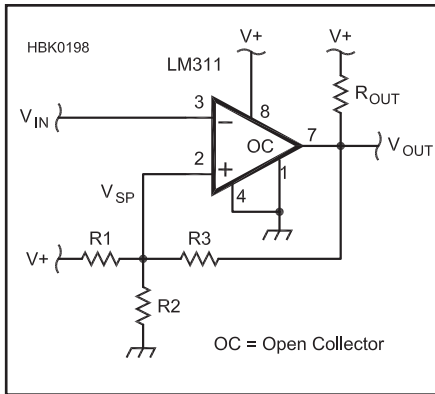

Fig 3.68 — Comparator circuit with hysteresis. R3 causes a shift in the comparator setpoint by allowing more current to flow through R1 when the comparator output is low.

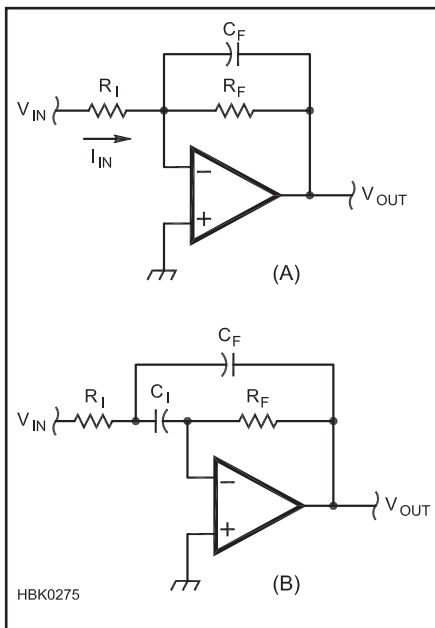

Fig 3.69 — Op amp active filters. The circuit at (A) has a low-pass response identical to an RC filter. The -3 dB frequency occurs when the reactance of C_F equals R_F . The band-pass filter at (B) is a multiple-feedback filter.

are a zero crossing detector, a signal squarer (which turns other cyclical wave forms into square waves) and a peak detector. An amateur station application: Circuits that monitor the CI-V band data output voltage from ICOM HF radios use a series of comparators to sense the level of the voltage and indicate on which band the radio is operating.

FILTERS

One of the most important type of op amp circuits is the *active filter*. Two examples of op amp filter circuits are shown in **Fig 3.69**. The simple noninverting low-pass filter in Fig 3.69A has the same response as a passive single-pole RC low-pass filter, but unlike the passive filter, the op amp filter circuit has a very high input impedance and a very low output impedance so that the filter's frequency and voltage response are relatively unaffected by the circuits connected to the filter input and output. This circuit is a low-pass filter because the reactance of the feedback capacitor decreases with frequency, requiring less output voltage to balance the voltages of the inverting and noninverting inputs.

The *multiple-feedback* circuit in Fig 3.69B results in a band-pass response while using only resistors and capacitors. This circuit is just one of many different types of active fil-

ters. Active filters are discussed in the **RF and AF Filters** chapter.

RECTIFIERS AND PEAK DETECTORS

The high open-loop gain of the op amp can also be used to simulate the I-V characteristics of an ideal diode. A *precision rectifier* circuit is shown in **Fig 3.70** along with the I-V characteristics of a real (dashed lines) and ideal (solid line) diode. The high gain of the op amp compensates for the V_F forward voltage drop of the real diode in its feedback loop with an output voltage equal to the input voltage plus V_F . Remember that the op amp's output increases until its input voltages are balanced. When the input voltage is negative, which would reverse-bias the diode, the op amp's output can't balance the input because the diode blocks any current flow through the feedback loop. The resistor at the output holds the voltage at zero until the input voltage is positive once again. Precision half-wave and full-wave rectifier circuits are shown in **Fig 3.71** and their operation is described in many reference texts.

One application of the precision rectifier circuit useful in radio is the *peak detector*, shown in **Fig 3.72**. A precision rectifier is used to charge the output capacitor which

Fig 3.70 — Ideal and real diode I-V characteristics are shown at (A). The op amp precision rectifier circuit is shown at (B).

Fig 3.71 — Half-wave precision rectifier (A). The extra diode at the output of the op amp prevents the op amp from saturating on negative half-cycles and improves response time. The precision full-wave rectifier circuit at (B) reproduces both halves of the input waveform.

Fig 3.72 — Peak detector. Coupling a precision diode with a capacitor to store charge creates a peak detector. The capacitor will charge to the peak value of the input voltage. R discharges the capacitor with a time constant of $\tau = RC$ and can be omitted if it is desired for the output voltage to remain nearly constant.

Fig 3.73 — Log amplifier. At low voltages, the gain of the circuit is $-R_f/R_i$, but as the diodes begin to conduct for higher-voltage signals, the gain changes to $-\ln(V_{in})$ in because of the diode's exponential current as described in the Fundamental Diode Equation.

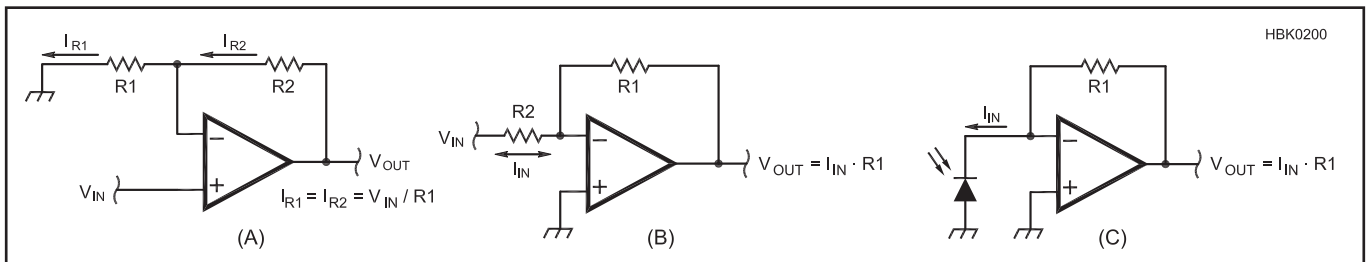

Fig 3.74 — Voltage-current converters. The current through R1 in (A) equals $V_{in}/R1$ because the op amp keeps both input terminals at approximately the same voltage. At (B), input current is balanced by the op amp, resulting in $V_{OUT} = I_{IN} \cdot R1$. Current through a photodiode (C) can be converted into a voltage in this way.

holds the peak voltage. The output resistor sets the time constant at which the capacitor discharges. The resistor can also be replaced by a transistor acting as a switch to reset the detector. This circuit is used in AGC loops, spectrum analyzers, and other instruments that measure the peak value of ac waveforms.

LOG AMPLIFIER

There are a number of applications in radio in which it is useful for the gain of an amplifier to be higher for small input signals than for large input signals. For example, an audio compressor circuit is used to reduce the variations in a speech signal's amplitude so that the average power output of an AM or SSB transmitter is increased. A *log amplifier* circuit whose gain for large signals is proportional to the logarithm of the input signal's amplitude is shown in **Fig 3.73**. The log amp circuit is used in compressors and limiter circuits.

At signal levels that are too small to cause significant current flow through the diodes, the gain is set as in a regular inverting amplifier, $A_v = -R_f/R_i$. As the signal level increases, however, more current flows through the diode according to the Fundamental Diode Equation (equation 4) given earlier in this chapter. That means the op amp output voltage has to increase less (lower gain) to cause enough current to flow through R_i such that the input voltages balance. The larger the input voltage, the more the diode conducts and the lower the gain of the circuit. Since the

diode's current is exponential in response to voltage, the gain of the circuit for large input signals is logarithmic.

Voltage-Current Converters

Another pair of useful op amp circuits convert voltage into current and current into voltage. These are frequently used to convert currents from sensors and detectors into voltages that are easier to measure. **Fig 3.74A** shows a voltage-to-current converter in which the output current is actually the current in the feedback loop. Because the op amp's high open-loop gain insures that its input voltages are equal, the current $I_{R1} = V_{IN}/R1$. Certainly, this could also be achieved with a resistor and Ohm's Law, but the op amp circuit's high input impedance means there is little interaction between the input voltage source and the output current.

Going the other way, **Fig 3.74B** is a current-to-voltage converter. The op amp's output will change so that the current through the feedback resistor, R1, exactly equals the input current, keeping the inverting terminal at ground potential. The output voltage, $V_O = I_{IN} R1$. Again, this could be done with just a resistor, but the op amp provides isolation between the source of input current and the output voltage. **Fig 3.74C** shows an application of a current-to-voltage converter in which the small currents from a photodiode are turned into voltage. This circuit can be used as a detector for amplitude modulated light pulses or waveforms.

3.7 Analog-Digital Conversion

While radio signals are definitely analog entities, much of the electronics associated with radio is digital, operating on binary data representing the radio signals and the information they carry. The interface between the two worlds — analog and digital — is a key element of radio communications systems and the function is performed by analog-digital converters.

This section presents an overview of the different types of analog-digital converters and their key specifications and behaviors. The chapter on **Digital Basics** presents information on interfacing converters to digital circuitry and associated issues. The chapter on **DSP and Software Radio Design** discusses specific applications of analog-digital conversion technology in radio communications systems.

3.7.1 Basic Conversion Properties

Analog-digital conversion consists of taking data in one form, such as digital binary data or an analog ac RF waveform, and creating an equivalent representation of it in the opposite domain. Converters that create a digital representation of analog voltages or currents are called *analog-to-digital converters (ADC)*, *analog/digital converters*, *A/D converters* or *A-to-D converters*. Similarly, converters that create analog voltages or currents from digital quantities are called *digital-to-analog converters (DAC)*, *digital/analog converters*, *D/A converters* or *D-to-A converters*. The word “conversion” in this first section on the properties of converting information between the analog and digital domains will apply equally to analog-to-digital or digital-to-analog conversion.

Converters are typically implemented as integrated circuits that include all of the

necessary interfaces and sub-systems to perform the entire conversion process. Schematic symbols for ADCs and DACs are shown in **Fig 3.75**.

Fig 3.76 shows two different representations of the same physical phenomenon; an analog voltage changing from 0 to 1 V. In the analog world, the voltage is continuous and can be represented by any real number between 0 and 1. In the digital world, the number of possible values that can represent any phenomenon is limited by the number of bits contained in each value.

In **Fig 3.76**, there are only four two-bit digital values 00, 01, 10, and 11, each corresponding to the analog voltage being within a specific range of voltages. If the analog voltage is anywhere in the range 0 to 0.25 V,

Fig 3.76 — The analog voltage varies continuously between 0 and 1 V, but the two-bit digital system only has four values to represent the analog voltage, so representation of the analog voltage is coarse.

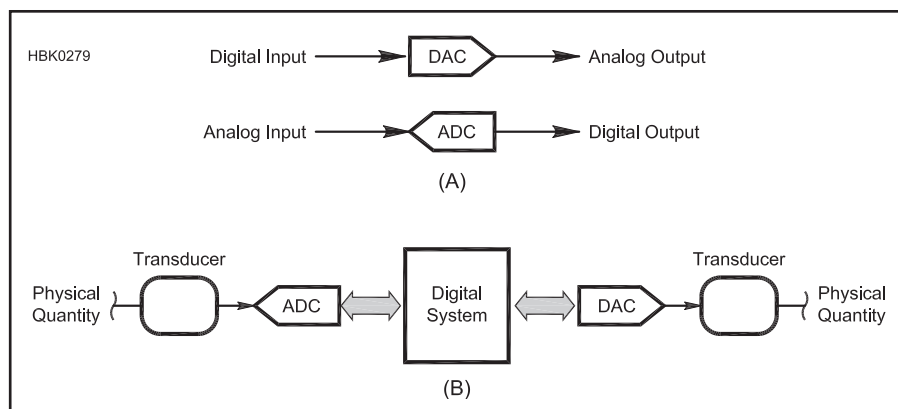

Fig 3.75 — Schematic symbols (A) for digital-to-analog converters (DAC) and analog-to-digital converters (ADC). The general block diagram of a system (B) that digitizes an analog signal, operates on it as digital data, then converts it back to analog form.

the digital value representing the analog voltage will be 00, no matter whether the voltage is 0.0001 or 0.24999 V. The range 0.25 to 0.5 V is represented by the digital value 01, and so forth.

The process of converting a continuous range of possible values to a limited number of discrete values is called *digitization* and each discrete value is called a *code* or a *quantization code*. The number of possible codes that can represent an analog quantity is 2^N , where N is the number of bits in the code. A two-bit number can have four codes as shown in **Fig 3.76**, a four-bit number can have sixteen codes, an eight-bit number 256 codes, and so forth. Assuming that the smallest change in code values is one bit, that value is called the *least significant bit (LSB)* regardless of its position in the format used to represent digital numbers.

RESOLUTION AND RANGE

The *resolution* or *step size* of the conversion is the smallest change in the analog value that the conversion can represent. The *range* of the conversion is the total span of analog values that the conversion can process. The maximum value in the range is called the *full-scale (F.S.)* value. In **Fig 3.76**, the conversion range is 1 V. The resolution of the conversion is

$$\text{resolution} = \frac{\text{range}}{2^N}$$

In **Fig 3.76**, the conversion resolution is $\frac{1}{4} \times 1 \text{ V} = 0.25 \text{ V}$ in the figure. If each code had four bits instead, it would have a resolution of $\frac{1}{2^4} \times 1 \text{ V} = 0.083 \text{ V}$. Conversion range does not necessarily have zero as one end point. For example, a conversion range of 5 V may span 0 to 5 V, -5 to 0 V, 10 to 15 V, -2.5 to 2.5 V, and so on.

Analog-digital conversion can have a range that is *unipolar* or *bipolar*. Unipolar means a conversion range that is entirely positive or negative, usually referring to voltage. Bipolar means the range can take on both positive and negative values.

Confusingly, the format in which the bits are organized is also called a code. The binary code represents digital values as binary numbers with the least significant bit on the right. *Binary-coded-decimal (BCD)* is a code in which groups of four bits represent individual decimal values of 0-9. In the *hexadecimal* code, groups of four bits represent decimal values of 0-15. There are many such codes. Be careful in interpreting the word “code” to be sure the correct meaning is used or understood.

To avoid having to know the conversion range to specify resolution, *percentage resolution* is used instead.

$$\% \text{ resolution} = \frac{\text{resolution}}{\text{fullscale}} \times 100\% \quad (69)$$

In Fig 3.76, the conversion's percentage resolution is

$$\% \text{ resolution} = \frac{0.25 \text{ V}}{1.0 \text{ V}} \times 100\% = 25\%$$

Because each code represents a range of possible analog values, the limited number of available codes creates *quantization error*. This is the maximum variation in analog values that can be represented by the same code. In Fig 3.76, any value from 0.25 through 0.50 V could be represented by the same code: 01. The quantization error in this case is 0.25 V. Quantization error can also be specified as % full-scale by substituting the value of error for resolution in equation 69.

Resolution can also be defined by the number of bits in the conversion. The higher the number of bits, the smaller the resolution as demonstrated above. Since many converters have variable ranges set by external components or voltages, referring to percent resolution or as a number of bits is preferred. The conversions between percent resolution and number of bits are as follows:

$$\% \text{ resolution} = \frac{1}{2^N} \times 100\% \quad (70)$$

and

$$N = \frac{\log\left(\frac{100\%}{\% \text{ resolution}}\right)}{\log 2} \quad (71)$$

Quantization error can also be specified as a number of least significant bits (LSB) where each bit is equivalent to the conversion's resolution.

When applied to receivers, dynamic range is more useful than percent resolution. For each additional bit of resolution, the resolution becomes two times greater, or 6.02 dB.

$$\text{Dynamic range (dB)} = N \times 6.02 \text{ dB} \quad (72)$$

For example, a 16-bit conversion has a dynamic range of $16 \times 6.02 = 96.32$ dB. This is the conversion's theoretical dynamic range with no noise present in the system. If noise is present, some number of the smallest codes will contain only noise, reducing the dynamic range available to represent a signal. The noise inherent in a particular conversion process can be specified as an analog value (mV, μ A and so on) or as a number of bits, meaning the number of codes that only represent noise. For example, if a conversion has five bits of noise, any value represented by the smallest five codes is considered to be noise. The conversion's *effective number of bits* (ENOB) describes the number of bits available to contain information about the signal.

ACCURACY

A companion to resolution, *accuracy* refers to the ability of the converter to either assign the correct code to an analog value or create the true analog value from a specific code. As with resolution, it is most convenient to refer to accuracy as either a percentage of full scale or in bits. *Full-scale error* is the maximum deviation of the code's value or the analog quantity's value as a percentage of the full scale value. If a converter's accuracy is given as 0.02% F.S. and the conversion range is 5 V, the conversion can be in error by as much as $0.02\% \times 5 \text{ V} = 1 \text{ mV}$ from the correct or expected value. *Offset* has the same meaning in conversion as it does in analog electronics — a consistent shift in the value of the conversion from the ideal value.

Linearity error represents the maximum deviation in step size from the ideal step size. This is also called *integral nonlinearity* (INL). In the converter of Fig 3.76, ideal step size is 0.25 V. If the linearity error for the conversion was given as 0.05% F.S., any actual step size could be in error by as much as $0.05\% \times 5 \text{ V} = 2.5 \text{ mV}$. The amount of error is based on the full-scale value, not the step-size value. *Differential nonlinearity* is a measure of how much any two adjacent step sizes deviate from the ideal step size. Errors can be represented as a number of bits, usually assumed to be least significant bits, or LSB, with one bit representing the same range as the conversion resolution.

Accuracy and resolution are particularly important in conversions for radio applications because they represent distortion in the signal being processed. An analog receiver that distorts the received signal creates undesired spurious signals that interfere with the desired signal. While the process is not exactly the same, distortion created by the signal conversion circuitry of a digital receiver also causes degradation in performance.

DISTORTION AND NOISE

Distortion and noise in a conversion are characterized by several parameters all related to linearity and accuracy. THD+N (*Total Harmonic Distortion + Noise*) is a measure of how much distortion and noise is introduced by the conversion. THD+N can be specified in percent or in dB. Smaller values are better. SINAD (*Signal to Noise and Distortion Ratio*) is related to THD+N, generally specified along with a desired signal level to show what signal level is required to achieve a certain level of SINAD or the highest signal level at which a certain level of SINAD can be maintained. *Spurious-free Dynamic Range* (SFDR) is the difference between the amplitude of the desired signal and the highest unwanted signal. SFDR is generally specified in dB and a higher number indicates better performance.

CONVERSION RATE AND BANDWIDTH

Another important parameter of the conversion is the *conversion rate* or its reciprocal, *conversion speed*. A code that represents an analog value at a specific time is called a *sample*, so conversion rate, f_s , is specified in *samples per second* (sps) and conversion speed as some period of time per sample, such as 1 μ sec/s. Because of the mechanics by which conversion is performed, conversion speed can also be specified as a number of cycles of clock signal used by the digital system performing the conversion. Conversion rate then depends on the frequency of the clock. Conversion speed may be smaller than the reciprocal of conversion rate if the system controlling the conversion introduces a delay between conversions. For example, if a conversion can take place in 1 μ s, but the system only performs a conversion once per ms, the conversion rate is 1 ksp/s, not the reciprocal of 1 μ s/s = 1 Msps.

The time accuracy of the digital clock that controls the conversion process can also affect the accuracy of the conversion. An error in long-term frequency will cause all conversions to have the same frequency error. Short-term variations in clock period are called *jitter* and they add noise to the conversion.

According to the *Nyquist Sampling Theorem*, a conversion must occur at a rate twice the highest frequency present in the analog signal. This minimum rate is the *Nyquist rate* and the maximum frequency allowed in the analog signal is the *Nyquist frequency*. In this way, the converter *bandwidth* is limited to one-half the conversion rate.

Referring to the process of converting analog signals to digital samples, if a lower rate is used, called *undersampling*, false signals called *aliases* will be created in the digital representation of the input signal at frequencies related to the difference between the Nyquist sampling rate and f_s . This is called *aliasing*. Sampling faster than the Nyquist rate is called *oversampling*.

Because conversions occur at some maximum rate, there is always the possibility of signals greater than the Nyquist frequency being present in an analog signal undergoing conversion or that is being created from digital values. These signals would result in aliases and must be removed by *band-limiting filters* that remove them prior to conversion. The mechanics of the sampling process are discussed further in the chapter **DSP and Software Radio Design**.

3.7.2 Analog-to-Digital Converters (ADC)

There are a number of methods by which the conversion from an analog quantity to a set of digital samples can be performed. Each has its strong points — simplicity, speed,

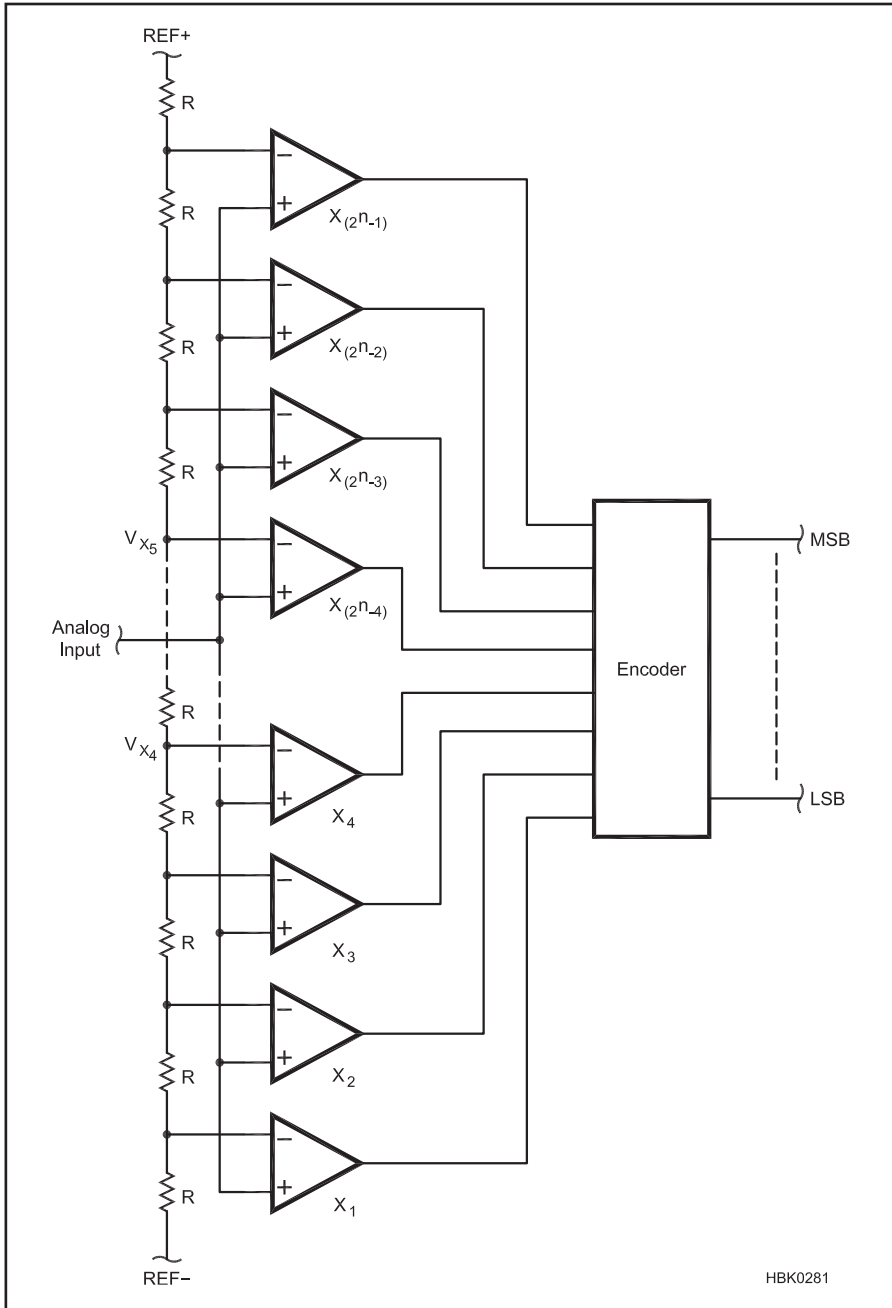

Fig 3.77 — The comparators of the flash converter are always switching state depending on the input signal's voltage. The decoder section converts the array of converter output to a single digital word.

resolution, accuracy — all affect the decision of which method to use for a particular application. In order to pick the right type of ADC, it is important to decide which of these criteria most strongly affect the performance of your application.

FLASH CONVERTER

The simplest type of ADC is the *flash converter*, shown in **Fig 3.77**, also called a *direct-conversion ADC*. It continually generates a digital representation of the analog

signal at its input. The flash converter uses an array of comparators that compare the amplitude of the input signal to a set of reference voltages. There is one reference voltage for each step.

The outputs of the comparator array represent a digital value in which each bit indicates whether the input signal is greater (1) or less than (0) the reference voltage for that comparator. A digital logic *priority encoder* then converts the array of bits into a digital output code. Each successive conversion is

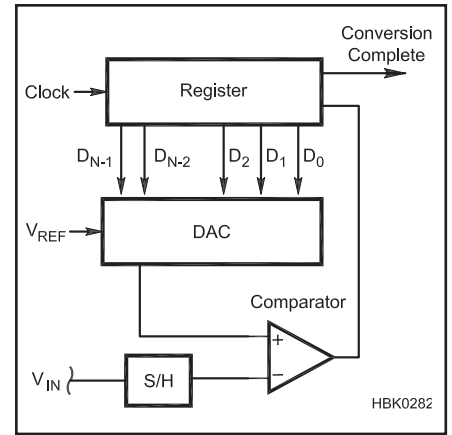

Fig 3.78 — The successive-approximation converter creates a digital word as it varies the DAC signal in order to keep the comparator's noninverting terminal close to the input voltage. A sample-and-hold circuit (S/H) holds the input signal steady while the measurement is being made.

available as quickly as the comparators can respond and the priority encoder can create the output code.

Flash converters are the fastest of all ADCs (conversion speeds can be in the ns range) but do not have high resolution because of the number of comparators and reference voltages required.

SUCCESSIVE-APPROXIMATION CONVERTER

The *successive-approximation converter* (SAC) is one of the most widely-used types of converters. As shown in **Fig 3.78**, it uses a single comparator and DAC (digital-to-analog converter) to arrive at the value of the input voltage by comparing it to successive analog values generated by the DAC. This type of converter offers a good compromise of conversion speed and resolution.

The DAC control logic begins a conversion by setting the output of the DAC to $\frac{1}{2}$ of the conversion range. If the DAC output is greater than the analog input value, the output of the comparator is 0 and the most significant bit of the digital value is set to 0. The DAC output then either increases or decreases by $\frac{1}{4}$ of the range, depending on whether the value of the first comparison was 1 or 0. One test is made for each bit in digital output code and the result accumulated in a storage register. The process is then repeated, forming a series of approximations (thus the name of the converter), until a test has been made for all bits in the code.

While the digital circuitry to implement the SAC is somewhat complex, it is less expensive to build and calibrate than the array of comparators and precision resistors of the flash converter. Each conversion also takes

a known and fixed number of clock cycles. The higher the number of bits in the output code, the longer the conversion takes, all other things being equal.

DUAL-SLOPE INTEGRATING CONVERTERS

The *dual-slope integrating ADC* is shown in Fig 3.79. It makes a conversion by measuring the time it takes for a capacitor to charge and discharge to a voltage level proportional to the analog quantity.

A constant-current source charges a capacitor (external to the converter IC) until the comparator output indicates that the capacitor voltage is equal to the analog input signal. The capacitor is then discharged by the constant-current source until the capacitor is discharged. This process is repeated continuously. The frequency of the charge-discharge cycle is determined by the values of R and C in Fig 3.79. The frequency is then measured by frequency counter circuitry and converted to the digital output code.

Dual-slope ADCs are low-cost and relatively immune to noise and temperature variations. Due to the slow speed of the conversion (measured in tens of ms) these converters are generally only used in test instruments, such as multimeters.

DELTA-ENCODED CONVERTERS

Instead of charging and discharging a capacitor from 0 V to the level of the input signal, and then back to 0 V, the *delta-encoded ADC* in Fig 3.80 continually compares the output of a DAC to the input signal using a comparator. Whenever the signal changes, the DAC is adjusted until its output is equal to the input signal. Digital counter circuits keep track of the DAC value and generate the digital output code. Delta-encoded counters are available with wide conversion ranges and high resolution.

SIGMA-DELTA CONVERTERS

The *sigma-delta converter* also uses a DAC and a comparator in a feedback loop to generate a digital signal as shown in Fig 3.81. An integrator stores the sum of the input signal and the DAC output. (This is “sigma” or sum in the converter’s name.) The comparator output indicates whether the integrator output is above or below the reference voltage and that signal is used to adjust the DAC’s output so that the integrator output stays close to the reference voltage. (This is the “delta” in the name.) The stream of 0s and 1s from the comparator forms a high-speed digital bit stream that is digitally-filtered to form the output code.

Sigma-delta converters are used where high resolution (16 to 24 bits) is required at low sampling rates of a few kHz. The digital filtering in the converter also reduces the

need for external band-limiting filters on the input signal.

ADC SUBSYSTEMS

Sample-and-Hold

ADCs that use a sequence of operations to create the digital output code must have

a means of holding the input signal steady while the measurements are being made. This function is performed by the circuit of Fig 3.82. A high input-impedance buffer drives the external storage capacitor, C_{HOLD} , so that its voltage is the same as the input signal. Another high input-impedance buffer

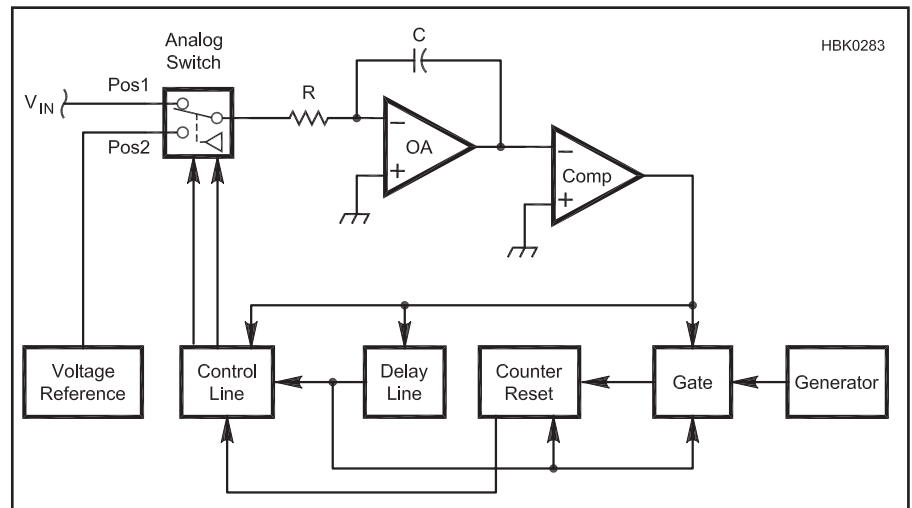

Fig 3.79 — Dual-slope integrating converter. By using a constant-current source to continually charge a capacitor to a known reference voltage then discharge it, the resulting frequency is directly proportional to the resistor value.

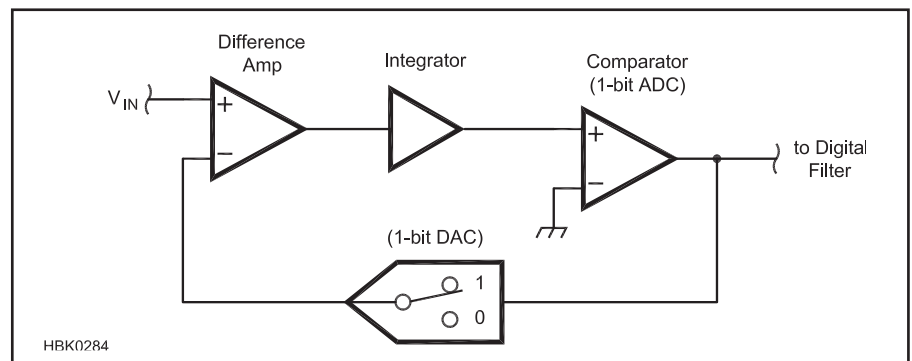

Fig 3.80 — Delta-encoded converter. The 1-bit DAC is operated in such a way that the bit stream out of the comparator represents the value of the input voltage.

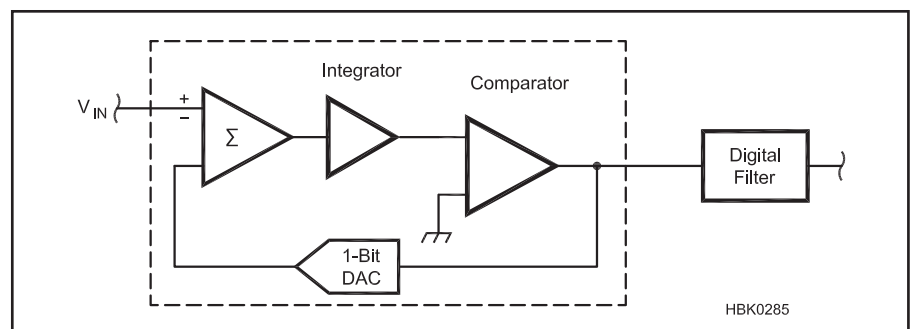

Fig 3.81 — Sigma-delta converter. Similar to the delta-encoded converter (Fig 3.80), the converter runs much faster than the output samples and uses a digital filter to derive the actual output value.

is used to provide a replica of the voltage on C_{HOLD} to the conversion circuitry.

When a conversion is started, a digital control signal opens the input switch, closes the output switch, and the capacitor's voltage is measured by the converter. It is important that the capacitor used for C_{HOLD} have low *leakage* so that while the measurement is being made, the voltage stays constant for the few ms required. This is of particular important in high-precision conversion.

Single-Ended and Differential Inputs

The input of most ADCs is *single-ended*, in which the input signal is measured between the input pin and a common ground. Shown in **Fig 3.83A**, this is acceptable for most applications, but if the voltage to be measured is small or is the difference between two non-zero voltages, an ADC with *differential inputs* should be used as in Fig 3.83B. Differential inputs are also useful when measuring current as the voltage across a small resistor in series with the current. In that case, neither side of the resistor is likely to be at ground, so a differential input is very useful. Differential inputs also help avoid the issue of noise contamination as discussed below.

Input Buffering and Filtering

The input impedance of most ADCs is high enough that the source of the input signal is unaffected. However, to protect the ADC input and reduce loading on the input source, an external buffer stage can be used. **Fig 3.84** shows a typical buffer arrangement with clamping diodes to protect against electrostatic discharge (ESD) and an RC-filter to prevent RF signals from affecting the input signal. In addition, to attenuate higher-frequency signals that might cause aliases, the input filters can also act as band-limiting filters.

Analog and Digital "Ground"

By definition, ADCs straddle the analog and digital domain. In principle, the signals remain separate and isolated from each other. In practice, however, voltages and currents from the analog and digital circuitry can be mixed together. This can result in the contamination of an analog signal with components of digital signals, and rarely, vice versa. Mostly, this is a problem when trying to measure small voltages in the presence of large power or RF signals.

The usual problem is that currents from high-speed digital circuitry find their way into analog signal paths and create transients and other artifacts that affect the measurement of the analog signal. Thus, it is important to have separate current paths for the two types of signals. The manufacturer of the converter will provide guidance for the proper use of the converter either in the device's data sheet or as application notes. Look for separate pins on

Fig 3.82 — Sample-and-hold (S/H). An input buffer isolates the sampled voltage from the input signal by charging the capacitor C_{HOLD} to that voltage with the input switch closed and the output switch open. When a measurement is being taken, the input switch is open to prevent the input signal from changing the capacitor voltage, and the output switch is closed so that the output buffer can generate a steady voltage at its output.

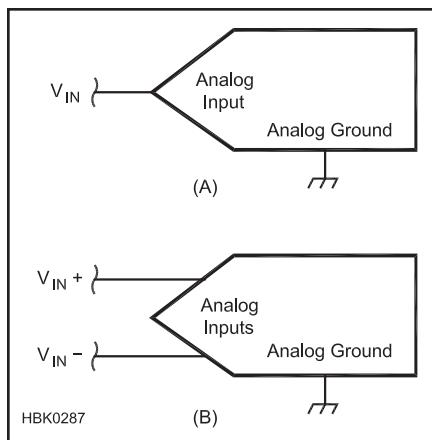

Fig 3.83 — Single-ended ADC inputs have a single active line and a ground or return line (A). Single-ended ADC input are often susceptible to noise and common mode signals or any kind of disturbance on their ground rails. In (B), the differential inputs used help the circuit "ignore" offsets and shifts in the input signal.

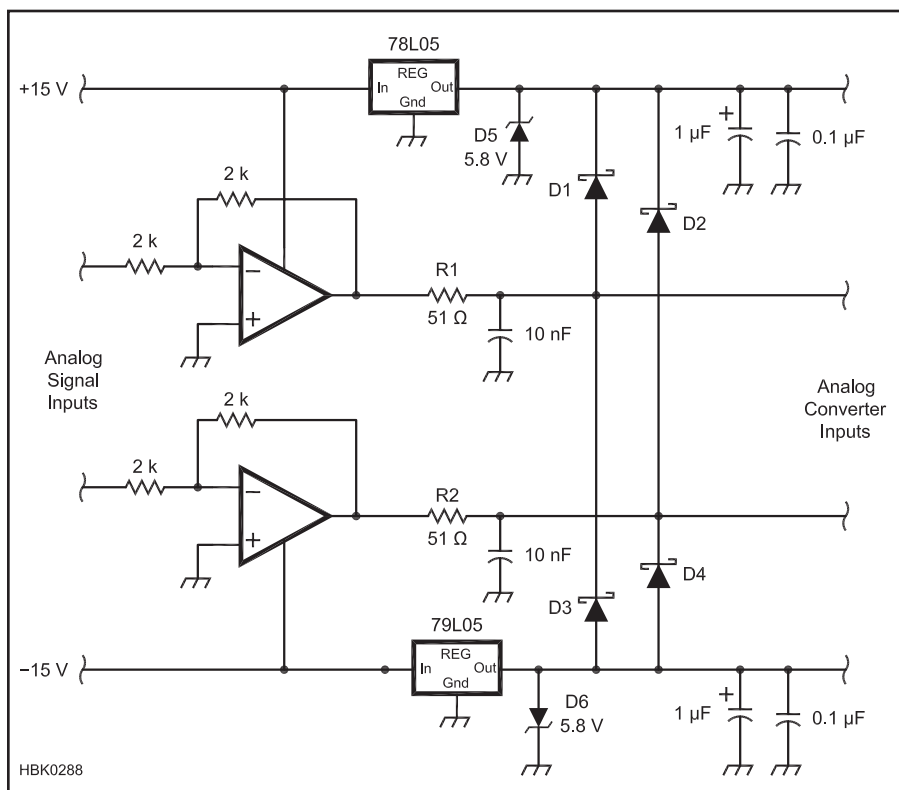

Fig 3.84 — Typical ADC input buffer-filter circuit. Unity-gain voltage followers help isolate the ADC from the input source. RC filters following the buffers act as band-limiting filters to prevent aliasing. Zener diodes are used to clamp the transient voltage and route the energy of transient into the power supply system.

the converter, such as “AGND” or “DGND” that indicate how the two types of signal return paths should be connected.

3.7.3 Digital-to-Analog Converters (DAC)

Converting a digital value to an analog quantity is considerably simpler than the reverse, but there are several issues primarily associated with DACs that affect the selection of a particular converter.

As each new digital value is converted to analog, the output of the DAC makes an abrupt *step change*. Even if very small, the response of the DAC output does not respond perfectly or instantaneously. *Settling time* is the amount of time required for the DAC’s output to stabilize within a certain amount of the final value. It is specified by the manufacturer and can be degraded if the load connected to the DAC is too heavy or if it is highly reactive. In these cases, using a buffer amplifier is recommended.

Monotonicity is another aspect of characterizing the DAC’s accuracy. A DAC is monotonic if in increasing the digital input value linearly across the conversion range, the output of the DAC increases with every step. Because of errors in the internal conversion circuitry, it is possible for there to be some steps that are too small or too large, leading to output values that seem “out of order.” These are usually quite small, but if used in a precision application, monotonicity is important.

SUMMING DAC

A *summing DAC*, shown in Fig 3.85, is a summing amplifier with all of the inputs connected to a single reference voltage through switches. The digital value to be converted controls which switches are closed. The larger the digital value, the more switches are closed. Higher current causes the summing amplifier’s output voltage to be higher, as well. Most summing DACs have a digital signal interface to hold the digital value between successive conversions, but not all, so be sure before you select a particular DAC.

The input resistors are *binary weighted* so that the summing network resistors representing the more significant bit values inject more current into the op amp’s summing junction. Each resistor differs from its neighboring resistors in the amount of current it injects into the summing node by a factor of two, recreating the effect of each digital bit in the output voltage. At high resolutions, this becomes a problem because of the wide spread in resistor values — a 12-bit DAC would require a spread of 2048 between the largest and smallest resistor values. Summing DACs are generally only available with low resolution for that reason.

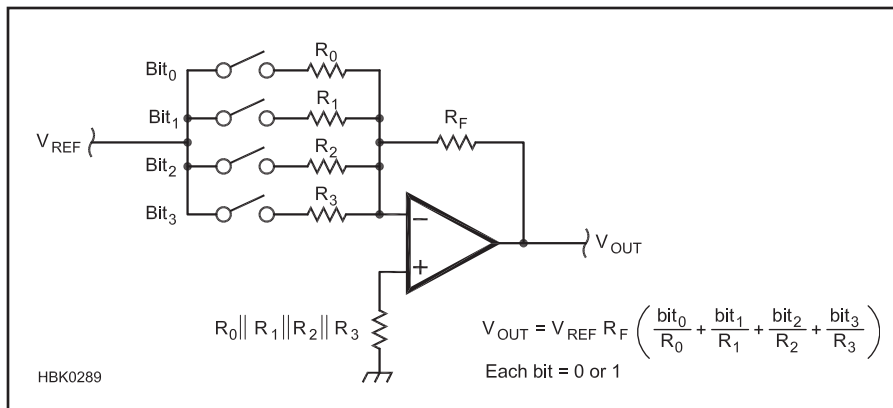

Fig 3.85 — Summing DAC. The output voltage is the inverted, weighted sum of the inputs to each summing resistor at the input. Digital data at the input controls the current into the summing resistors and thus, the output voltage.

Fig 3.86 — R-2R Ladder DAC. This is the most common form of DAC because all of the resistor values are similar, making it easier to manufacture. The similarity in resistor values also means that there will be less variation of the comparator with temperature and other effects that affect all resistors similarly.

The *current output DAC* functions identically to the summing DAC, but does not have an op amp to convert current in the digitally-controlled resistor network to voltage. It consists only of the resistor network, so an external current-to-voltage circuit (discussed in the previous section on op amps) is required to change the current to a voltage. In some applications, the conversion to voltage is not required or it is already provided by some other circuit.

R-2R LADDER DAC

The summing and current output DACs both used binary weighted resistors to convert the binary digital value into the analog output. The practical limitation of this design is the large difference in value between the smallest and largest resistor. For example, in a 12-bit DAC, the smallest and largest resistors differ by a factor of 2048 (which is 2^{12-1}). This can be difficult to fabricate in an IC without

expensive *trimming* processes that adjust each resistor to the correct value and that maintain the powers-of-two relationship over wide temperature variations. For DACs with high-resolutions of 8 bits or more, the R-2R ladder DAC of Fig 3.86 is a better design.

If the resistances are fairly close in value, the problems of manufacturing are greatly reduced. By using the *R-2R ladder* shown in the figure, the same method of varying current injected into an op amp circuit’s summing junction can be used with resistors of only two values, R and 2R. In fact, since the op amp feedback resistor is also one of the IC resistors, the absolute value of the resistance R is unimportant, as long as the ratio of R:2R is maintained. This simplifies manufacturing greatly and is an example of IC design being based on ratios instead of absolute values. For this reason, most DACs use the R-2R ladder design and the performance differences lie mostly in their speed and accuracy.

3.7.4 Choosing a Converter

From the point of view of performance, choosing a converter, either an ADC or a DAC, comes down to resolution, accuracy and speed. Begin by determining the percent resolution or the dynamic range of the converter. Use the equations in the preceding section to determine the number of bits the converter must have. Select from converters with the next highest number of bits. For example, if you determine that you need 7 bits of resolution, use an 8-bit converter.

Next, consider accuracy. If the converter is needed for test instrumentation, you'll need to perform an *error budget* on the instrument's conversion processes, include errors in the analog circuitry. Once you have calculated percent errors, you can determine the requirements for FS error, offset error,

and nonlinearities. If an ADC is going to be used for receiving applications, the spur-free dynamic range may be more important than high precision. (The chapter on **DSP and Software Radio Design** goes into more detail about the performance requirements for ADCs used in these applications.)

The remaining performance criterion is the speed and rate at which the converter can operate. Conversions should be able to be made at a minimum of twice the highest frequency of signal you wish to reproduce. (The signal is assumed to be a sinusoid. If a complex waveform is to be converted, you must account for the higher frequency signals that create the nonsinusoidal shapes.) If the converter will be running near its maximum rate, be sure that the associated digital interface, supporting circuitry,

and software can support the required data rates, too!

Having established the conversion performance requirements, the next step is to consider cost, amount of associated circuitry, power requirements, and so forth. For example, a self-contained ADC is easier to use and takes up less PC board space, but is not as flexible as one that allows the designer to use an external voltage reference to set the conversion range. Many DACs with "current output" in their description are actually R-2R DACs with additional analog circuitry to provide the current output. DACs are available with both current and voltage outputs, as well. Other considerations, such as the nature of the required digital interface, as discussed in the next section, can also affect the selection of the converter.

3.8 Miscellaneous Analog ICs

The three main advantages of designing a circuit into an IC are to take advantage of the matched characteristics of its components, to make highly complex circuitry more economical, and to miniaturize the circuit and reduce power consumption. As circuits standardize and become widely used, they are often converted from discrete components to integrated circuits. Along with the op amp described earlier, there are many such classes of linear ICs.

3.8.1 Transistor and Driver Arrays

The most basic form of linear integrated circuit and one of the first to be implemented is the component array. The most common of these are the resistor, diode and transistor arrays. Though capacitor arrays are also possible, they are used less often. Component arrays usually provide space saving but this is not the major advantage of these devices. They are the least densely packed of the integrated circuits because each device requires a separate off-chip connection. While it may be possible to place over a million transistors on a single semiconductor chip, individual access to these would require a total of three million pins and this is beyond the limits of practicability. More commonly, resistor and diode arrays contain from five to 16 individual devices and transistor arrays contain from three to six individual transistors. The advantage of these arrays is the very close matching of component values within the array. In a circuit that needs matched components, the component array is often a good method of

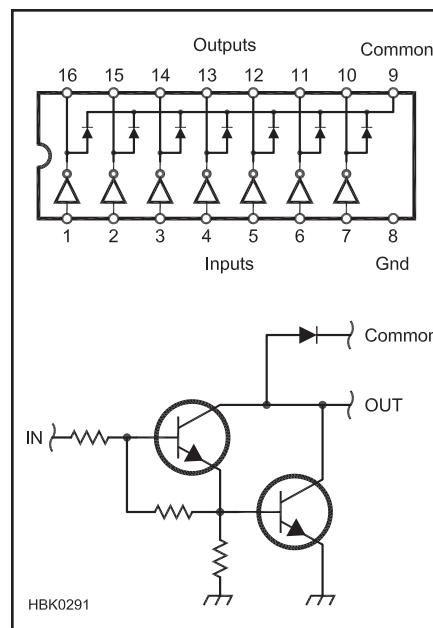

Fig 3.87 — Typical ULN2000-series driver array configuration and internal circuit. The use of driver array ICs is very popular as an interface between microprocessor or other low-power digital circuits and loads such as relays, solenoids or lamps.

obtaining this feature. The components within an array can be internally combined for special functions, such as termination resistors, diode bridges and Darlington pair transistors. A nearly infinite number of possibilities exists for these combinations of components and many of these are available in arrays.

Driver arrays, such as the ULN2000-series devices shown in **Fig 3.87** are very useful in creating an interface between low-power circuits such as microprocessors and higher-power loads and indicators. Each driver consists of a Darlington pair switching circuit as described earlier in this chapter. There are different versions with different types and arrangements of resistors and diodes.

Many manufacturers offer driver arrays. They are available with built-in kickback diodes to allow them to drive inductive loads, such as relays, and are heavy enough to source or sink current levels up to 1 A. (All of the drivers in the array can not operate at full load at the same time, however. Read the data sheet carefully to determine what limitations on current and power dissipation may exist.)

3.8.2 Voltage Regulators and References

One of the most popular linear ICs is the voltage regulator. There are two basic types, the three-terminal regulator and the regulator controller. Examples of both are described in the **Power Sources** chapter.

The three-terminal regulator (input, ground, output) is a single package designed to perform all of the voltage regulation functions. The output voltage can be fixed, as in the 7800-series of regulators, or variable, as in the LM317 regulator. It contains a voltage reference, comparator circuits, current and temperature sensing protective circuits, and the main pass element. These ICs are usually contained in the same packages as power transistors and the same techniques of thermal

management are used to remove excess heat.

Regulator controllers, such as the popular 723 device, contain all of the control and voltage reference circuitry, but require external components for the main pass element, current sensing, and to configure some of their control functions.

Voltage references such as the Linear Technology LT1635 are special semiconductor diodes that have a precisely controlled I-V characteristic. A buffer amplifier isolates the sensitive diode and provides a low output impedance for the voltage signal. Voltage references are used as part of power regulators and by analog-digital converter circuits.

3.8.3 Timers (Multivibrators)

A *multivibrator* is a circuit that oscillates between two states, usually with a square wave or pulse train output. The frequency of oscillation is accurately controlled with the addition of appropriate values of external resistance and capacitance. The most common multivibrator in use today is the 555 timer IC (NE555 by Signetics [now Philips] or LM555 by National Semiconductor). This very simple eight-pin device has a frequency range from less than one hertz to several hundred kilohertz. Such a device can also be used in *monostable* operation, where an input pulse generates an output pulse of a different duration, or in a *stable* or *free-running* operation, where the device oscillates continuously. Other applications of a multivibrator include a frequency divider, a delay line, a pulse width modulator and a pulse position modulator. (These can be found in the IC's data sheet or in the reference listed at the end of this chapter.)

Fig 3.88 shows the basic components of a 555. Connected between power input (V_{CC}) and ground, the three resistors labeled "R" at the top left of the figure form a *voltage divider* that divides V_{CC} into two equal steps—one at $\frac{2}{3} V_{CC}$ and one at $\frac{1}{3} V_{CC}$. These serve as reference voltages for the rest of the circuit.

Connected to the reference voltages are blocks labeled *trigger comparator* and *threshold comparator*. (Comparators were discussed in a preceding section.) The trigger comparator in the 555 is wired so that its output is high whenever the trigger input is *less* than $\frac{1}{3} V_{CC}$ and vice versa. Similarly, the threshold comparator output is high whenever the threshold input is *greater* than $\frac{2}{3} V_{CC}$. These two outputs control a digital *flip-flop* circuit. (Flip-flops are discussed in the **Digital Basics** chapter.)

The flip-flop output, Q , changes to high or low when the state of its *set* and *reset* input changes. The Q output stays high or low (it *latches* or *toggles*) until the opposite input changes. When the set input changes from low to high, Q goes low. When reset changes from low to high, Q goes high. The flip-flop

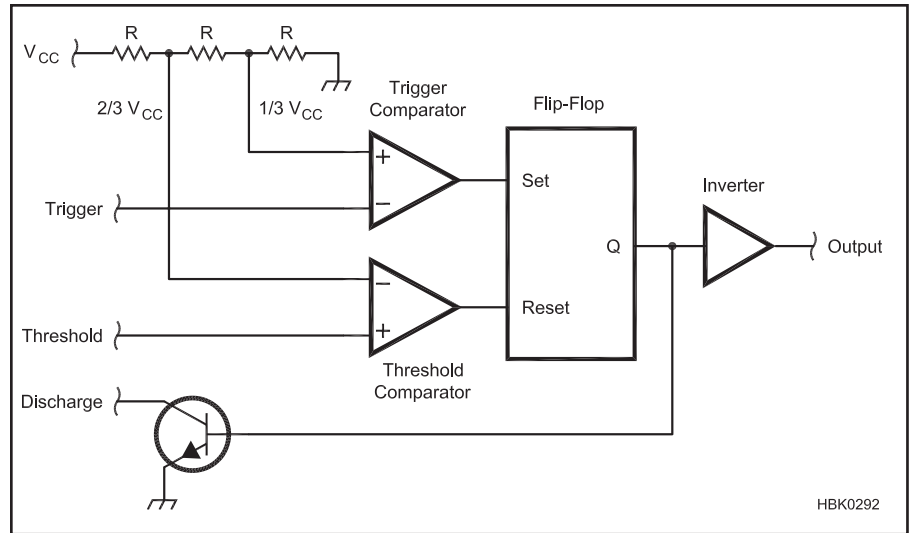

Fig 3.88 — Internal NE555 timer components. This simple array of components combine to make one of the most popular analog ICs. The 555 timer IC uses ratios of internal resistors to generate a precise voltage reference for generating time intervals based on charging and discharging a capacitor.

ignores any other changes. An inverter makes the 555 output high when Q is low and vice versa — this makes the timer circuit easier to interface with external circuits.

The transistor connected to Q acts as a switch. When Q is high, the transistor is on and acts as a closed switch connected to ground. When Q is low, the transistor is off and the switch is open. These simple building blocks — voltage divider, comparator, flip-flop and switch — build a surprising number of useful circuits.

THE MONOSTABLE OR "ONE-SHOT" TIMER

The simplest 555 circuit is the monostable circuit. This configuration will output one fixed-length pulse when triggered by an input pulse. **Fig 3.89** shows the connections for this circuit.

Starting with capacitor C discharged, the flip-flop output, Q , is high, which keeps the discharge transistor turned on and the voltage on C below $\frac{2}{3} V_{CC}$. The circuit is in its stable state, waiting for a trigger pulse.

When the voltage at the trigger input drops below $\frac{1}{3} V_{CC}$, the trigger comparator output changes from low to high, which causes Q to toggle to the low state. This turns off the transistor (opens the switch) and allows C to begin charging toward V_{CC} .

When C reaches $\frac{2}{3} V_{CC}$, this causes the threshold comparator to switch its output from low to high and that resets the flip-flop. Q returns high, turning on the transistor and discharging C . The circuit has returned to its stable state. The output pulse length for the monostable configuration is:

$$T = 1.1 RC_1 \quad (73)$$

Notice that the timing is independent of the absolute value of V_{CC} — the output pulse width is the same with a 5 V supply as it is with a 15 V supply. This is because the 555 design is based on ratios and not absolute voltage levels.

THE ASTABLE MULTIVIBRATOR

The complement to the monostable circuit is the astable circuit in **Fig 3.90**. Pins 2, 6 and 7 are configured differently and timing resistor is now split into two resistors, R_1 and R_2 .

Start from the same state as the monostable circuit, with C completely discharged. The monostable circuit requires a trigger pulse to initiate the timing cycle. In the astable circuit, the trigger input is connected directly to the capacitor, so if the capacitor is discharged, then the trigger comparator output must be high. Q is low, turning off the discharge transistor, which allows C to immediately begin charging.

C charges toward V_{CC} , but now through the combination of R_1 and R_2 . As the capacitor voltage passes $\frac{2}{3} V_{CC}$, the threshold comparator output changes from low to high, resetting Q to high. This turns on the discharge transistor and the capacitor starts to discharge through R_2 . When the capacitor is discharged below $\frac{1}{3} V_{CC}$, the trigger comparator changes from high to low and the cycle begins again, automatically. This happens over and over, causing a train of pulses at the output while C charges and discharges between $\frac{1}{3}$ and $\frac{2}{3} V_{CC}$ as seen in the figure.

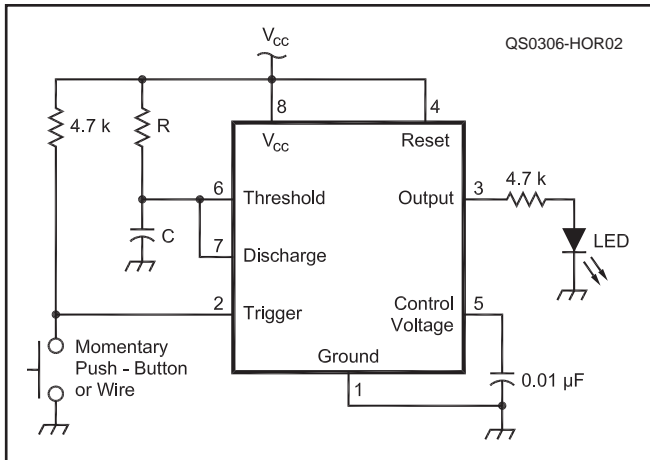

Fig 3.89 — Monostable timer. The timing capacitor is discharged until a trigger pulse initiates the charging process and turns the output on. When the capacitor has charged to $2/3 V_{CC}$, the output is turned off, the capacitor is discharged and the timer awaits the next trigger pulse.

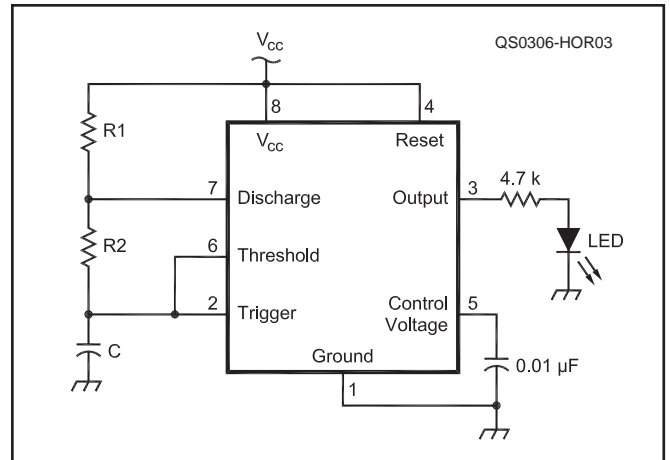

Fig 3.90 — Astable timer. If the capacitor discharge process initiates the next charge cycle, the timer will output a pulse train continuously.

The total time it takes for one complete cycle is the charge time, T_c , plus the discharge time, T_d :

$$T = T_c + T_d = 0.693 (R_1 + R_2) C + 0.693 R_2 C = 0.693 (R_1 + 2R_2) C \quad (74)$$

and the output frequency is:

$$f = \frac{1}{T} = \frac{1.443}{(R_1 + 2R_2) C} \quad (75)$$

When using the 555 in an application in or around radios, it is important to block any RF signals from the IC power supply or timing control inputs. Any unwanted signal present on these inputs, especially the Control Voltage input, will upset the timer's operation and cause it to operate improperly. The usual practice is to use a $0.01 \mu\text{F}$ bypass capacitor (shown on pin 5 in both Fig 3.89 and 3.90) to bypass ac signals such as noise or RF to ground. Abrupt changes in V_{CC} will also cause changes in timing and these may be prevented by connecting filter capacitors at the V_{CC} input to ground.

3.8.4 Analog Switches and Multiplexers

Arrays of analog switches, such as the Maxim MAX312-series, allow routing of audio through lower frequency RF signals without mechanical switches. There are several types of switch arrays. Independent switches have isolated inputs and outputs and are turned on and off independently. Both SPST and SPDT configurations are available. Multiple switches can be wired with common control signals to implement multiple-pole configurations.

Use of analog switches at RF through microwave frequencies requires devices specifically designed for those frequencies. The Analog Devices ADG901 is a switch usable to 2.5 GHz. It absorbs the signal when off, acting as a terminating load. The ADG902 instead reflects the signal as an open circuit when off. Arrays of three switches called "tee-switches" are used when very high isolation between the input and output is required.

Multiplexers or "muxes" are arrays of SPST switches configured to act as a multiposition switch that connects one of four to sixteen input signals to a single output. Demultiplexers ("demuxes") have a single input and multiple outputs. Multiplexer ICs are available as single N-to-1 switches (the MAX4617 is an 8-to-1 mux) or as groups of N-to-1 switches (the MAX4618 is a dual 4-to-1 mux).

Crosspoint switch arrays are arranged so that any of four to sixteen signal inputs can be connected to any of four to sixteen output signal lines. The Analog Devices AD8108 is an 8-by-8 crosspoint switch with eight inputs and eight outputs. These arrays are used when it is necessary to switch multiple signal sources among multiple signal receivers. They are most commonly used in telecommunications.

All analog switches use FET technology as the switching element. To switch ac signals, most analog switches require both positive and negative voltage power supplies. An alternative is to use a single power supply voltage and ground, but bias all inputs and output at one-half the power supply voltage. This requires dc blocking capacitors in all signal paths, both input and output, and loading resistors may be required at the device outputs. The blocking capacitors can also introduce low-frequency roll-off.

The impedance of the switching ele-

ment varies from a few ohms to more than 100 ohms. Check the switch data sheet to determine the limits for how much power and current the switches can handle. Switch arrays, because of the physical size of the array, can have significant coupling or *crosstalk* between signal paths. Use caution when using analog switches for high-frequency signals as coupling generally increases with frequency and may compromise the isolation required for high selectivity in receivers and other RF signal processing equipment.

3.8.5 Audio Output Amplifiers

While it is possible to use op amps as low power audio output drivers for headphones, they generally have output impedances that are too high for most audio transducers such as speakers and headphones. The LM380 series of audio driver ICs has been used in radio circuits for many years and a simple schematic for a speaker driver is shown in Fig 3.91.

The popularity of personal music players has resulted in the creation of many new and inexpensive audio driver ICs, such as the National Semiconductor LM4800- and LM4900-series. Drivers that operate from voltages as low as 1.5 V for battery-powered devices and up to 18 V for use in vehicles are now available.

When choosing an audio driver IC for communications audio, the most important parameters to evaluate are its power requirements and power output capabilities. An overloaded or underpowered driver will result in distortion. Driver ICs intended for music players have frequency responses well in excess of the 3000 Hz required for communications. This can lead to annoying and fatiguing hiss unless steps are taken to reduce

the circuit's frequency response.

Audio power amplifiers should also be carefully decoupled from the power supply and the manufacturer may recommend specific circuit layouts to prevent oscillation or feedback. Check the device's data sheet for this information.

3.8.6 Temperature Sensors

Active temperature sensors use the temperature-dependent properties of semiconductor devices to create voltages that correspond to absolute temperature in degrees Fahrenheit (LM34) or degrees Celsius (LM35). These sensors (of which many others are available than the two examples given here) are available in small plastic packages, both leaded and surface-mount, that respond quickly to temperature changes. They are available with 1% and better accuracy, requiring only a source of voltage at very low current and ground. Complete application information is available in the manufacturer data sheets. Thermistors, a type of passive temperature sensor, are discussed in the **Electrical Fundamentals** chapter. Temperature sensors are used in radio mostly in cooling and thermal management systems.

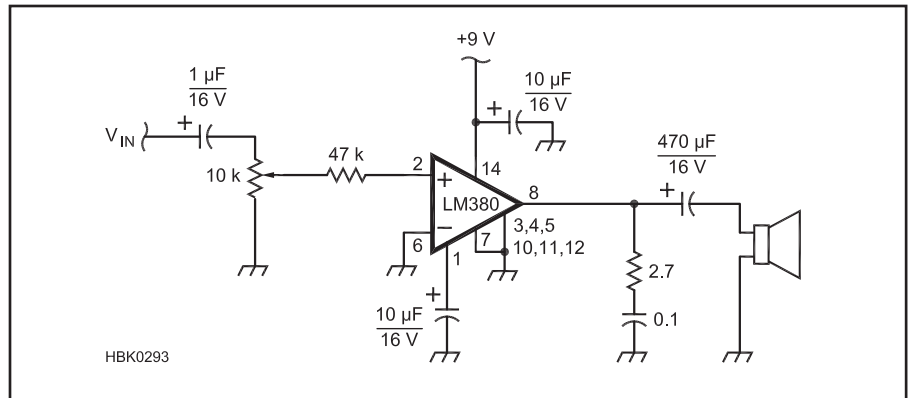

Fig 3.91 — Speaker driver. The LM380-series of audio output drivers are well-suited for low-power audio outputs, such as for headphones and small speakers. When using IC audio output drivers, be sure to refer to the manufacturer's data sheet for layout and power supply guidelines.

3.8.7 Electronic Subsystems

As a particular technology becomes popular, a wave of integrated circuitry is developed to service that technology and reduce its cost of production and service. A good example is the wireless telephony industry. IC manufacturers have developed a large number of devices targeting this industry; receivers, transmitters,

couplers, mixers, attenuators, oscillators and so forth. In addition, other wireless technologies such as data transmission provide opportunities for manufacturers to create integrated circuits that implement radio-related functions at low cost. Analog ICs used in the construction of various radio systems and supporting equipment are discussed in the appropriate chapters of this book.

3.9 Analog Glossary

AC ground — A circuit connection point that presents a very low impedance to ac signals.

Accuracy — The ability of an analog-to-digital conversion to assign the correct code to an analog value or create the true analog value from a specific code.

Active — A device that requires power to operate.

Active region — The region in the characteristic curve of an analog device in which it is capable of processing the signal linearly.

Amplification — The process by which amplitude of a signal is increased. Gain is the amount by which the signal is amplified.

Analog signal — A signal that can have any amplitude (voltage or current) value and exists at any point in time.

Analog-to-digital converter (ADC) — Circuit (usually an IC) that generates a digital representation of an analog signal.

Anode — The element of an analog device that accepts electrons or toward which electrons flow.

Attenuation — The process of reducing the amplitude of a signal.

Avalanche breakdown — Current flow

through a semiconductor device in response to an applied voltage beyond the device's ability to control or block current flow.

Base — The terminal of a bipolar transistor in which control current flows.

Beta (β) — The dc current gain of a bipolar transistor, also designated h_{FE} .

Biasing — The addition of a dc voltage or current to a signal at the input of an analog device, changing or controlling the position of the device's operating point on the characteristic curve.

Bipolar transistor — An analog device made by sandwiching a layer of doped semiconductor between two layers of the opposite type: PNP or NPN.

Black box — Circuit or equipment that is analyzed only with regards to its external behavior.

Bode plot — Graphs showing amplitude response in dB and phase response in degrees versus frequency on a logarithmic scale.

Buffer — An analog stage that prevents loading of one analog stage by another.

Carrier — (1) Free electrons and holes in semiconductor material. (2) An unmodulated component of a modulated signal.

Cascade — Placing one analog stage after another to combine their effects on the signal.

Cathode — The element of an analog device that emits electrons or from which electrons are emitted or repelled.

Characteristic curve — A plot of the relative responses of two or three analog-device parameters, usually of an output with respect to an input. (Also called *I-V* or *V-I curve*.)

Class — For analog amplifiers (Class A, B, AB, C), a categorization of the fraction of the input signal cycle during which the amplifying device is active. For digital or switching amplifiers (Class D and above), a categorization of the method by which the signal is amplified.

Clipping — A nonlinearity in amplification in which the signal's amplitude can no longer be increased, usually resulting in distortion of the waveform. (Also called *clamping* or *limiting*.)

Closed-loop gain — Amplifier gain with an external feedback circuit connected.

Collector — The terminal of a bipolar transistor from which electrons are removed.

- Code** — One possible digital value representing an analog quantity. (Also called *quantization code*.)
- Common** — A terminal shared by more than one port of a circuit or network.
- Common mode** — Signals that appear equally on all terminals of a signal port.
- Comparator** — A circuit, usually an amplifier, whose output indicates the relative amplitude of two input signals.
- Compensation** — The process of counteracting the effects of signals that are inadvertently fed back from the output to the input of an analog system. Compensation increases stability and prevents oscillation.
- Compression** — Reducing the dynamic range of a signal in order to increase the average power of the signal or prevent excessive signal levels.
- Conversion efficiency** — The amount of light energy converted to electrical energy by a photoelectric device, expressed in percent.
- Conversion rate** — The amount of time in which an analog-digital conversion can take place. *Conversion speed* is the reciprocal of conversion rate.
- Coupling (ac or dc)** — The type of connection between two circuits. DC coupling allows dc current to flow through the connection. AC coupling blocks dc current while allowing ac current to flow.
- Cutoff frequency** — Frequency at which a circuit's amplitude response is reduced to one-half its mid-band value (also called *half-power* or *corner* frequency).
- Cutoff (region)** — The region in the characteristic curve of an analog device in which there is no current through the device. Also called the OFF region.
- Degeneration (emitter or source)** — Negative feedback from the voltage drop across an emitter or source resistor in order to stabilize a circuit's bias and operating point.
- Depletion mode** — An FET with a channel that conducts current with zero gate-to-source voltage and whose conductivity is progressively reduced as reverse bias is applied.
- Depletion region** — The narrow region at a PN junction in which majority carriers have been removed. (Also called *space-charge* or *transition* region.)
- Digital-to-analog converter (DAC)** — Circuit (usually an IC) that creates an analog signal from a digital representation.
- Diode** — A two-element semiconductor with a cathode and an anode that conducts current in only one direction.
- Drain** — The connection at one end of a field-effect-transistor channel from which electrons are removed.
- Dynamic range** — The range of signal levels over which a circuit operates properly. Usually refers to the range over which signals are processed linearly.
- Emitter** — The terminal of a bipolar transistor into which electrons are injected.
- Enhancement mode** — An FET with a channel that does not conduct with zero gate-to-source voltage and whose conductivity is progressively increased as forward bias is applied.
- Feedback** — Routing a portion of an output signal back to the input of a circuit. Positive feedback causes the input signal to be reinforced. Negative feedback results in partial cancellation of the input signal.
- Field-effect transistor (FET)** — An analog device with a semiconductor channel whose width can be modified by an electric field. (Also called *unipolar transistor*.)
- Forward bias** — Voltage applied across a PN junction in the direction to cause current flow.
- Forward voltage** — The voltage required to cause forward current to flow through a PN junction.
- Free electron** — An electron in a semiconductor crystal lattice that is not bound to any atom.
- Frequency response** — A description of a circuit's gain (or other behavior) with frequency.
- Gain** — see *Amplification*.
- Gain-bandwidth product** — The relationship between amplification and frequency that defines the limits of the ability of a device to act as a linear amplifier. In many amplifiers, gain times bandwidth is approximately constant.
- Gate** — The control electrode of a field-effect transistor.
- High-side** — A switch or controlling device connecting between a power source and load.
- Hole** — A positively charged carrier that results when an electron is removed from an atom in a semiconductor crystal structure.
- Hysteresis** — In a comparator circuit, the practice of using positive feedback to shift the input setpoint in such a way as to minimize output changes when the input signal(s) are near the setpoint.
- Integrated circuit (IC)** — A semiconductor device in which many components, such as diodes, bipolar transistors, field-effect transistors, resistors and capacitors are fabricated to make an entire circuit.
- Isolation** — Eliminating or reducing electrical contact between one portion of a circuit and another or between pieces of equipment.
- Junction FET (JFET)** — A field-effect transistor whose gate electrode forms a PN junction with the channel.
- Linearity** — Processing and combining of analog signals independently of amplitude.
- Load line** — A line drawn through a family of characteristic curves that shows the operating points of an analog device for a given load or circuit component values.
- Loading** — The condition that occurs when the output behavior of a circuit is affected by the connection of another circuit to that output.
- Low-side** — A switch or controlling device connected between a load and ground.
- Metal-oxide semiconductor (MOSFET)** — A field-effect transistor whose gate is insulated from the channel by an oxide layer. (Also called *insulated gate FET* or *IGFET*)
- Multivibrator** — A circuit that oscillates between two states.
- NMOS** — N-channel MOSFET.
- N-type impurity** — A doping atom with an excess of valence electrons that is added to semiconductor material to act as a source of free electrons.
- Network** — General name for any type of circuit.
- Noise** — Any unwanted signal, usually random in nature.
- Noise figure (NF)** — A measure of the noise added to a signal by an analog processing stage, given in dB. (Also called *noise factor*.)
- Open-loop gain** — Gain of an amplifier with no feedback connection.
- Operating point** — Values of a set of circuit parameters that specify a device's operation at a particular time.
- Operational amplifier (op amp)** — An integrated circuit amplifier with high open-loop gain, high input impedance, and low output impedance.
- Optoisolator** — A device in which current in a light-emitting diode controls the operation of a phototransistor without a direct electrical connection between them.
- Oscillator** — A circuit whose output varies continuously and repeatedly, usually at a single frequency.
- P-type impurity** — A doping atom with a shortage of valence electrons that is added to semiconductor material to create an excess of holes.
- Passive** — A device that does not require power to operate.
- Peak inverse voltage (PIV)** — The highest voltage that can be tolerated by a reverse biased PN junction before current is conducted. (See also *avalanche breakdown*.)
- Photoconductivity** — Phenomenon in

which light affects the conductivity of semiconductor material.

Photoelectricity — Phenomenon in which light causes current to flow in semiconductor material.

PMOS — P-channel MOSFET.

PN junction — The structure that forms when P-type semiconductor material is placed in contact with N-type semiconductor material.

Pole — Frequency at which a circuit's transfer function becomes infinite.

Port — A pair of terminals through which a signal is applied to or output from a circuit.

Quiescent (Q-) point — Circuit or device's operating point with no input signal applied. (Also called *bias point*.)

Pinch-off — The condition in an FET in which the channel conductivity has been reduced to zero.

Products — Signals produced as the result of a signal processing function.

Rail — Power supply voltage(s) for a circuit.

Range — The total span of analog values that can be processed by an analog-to-digital conversion.

Recombination — The process by which free electrons and holes are combined to produce current flow across a PN junction.

Recovery time — The amount of time required for carriers to be removed from a PN junction device's depletion region, halting current flow.

Rectify — Convert ac to pulsating dc.

Resolution — Smallest change in an analog value that can be represented in a conversion between analog and digital quantities. (Also called *step size*.)

Reverse bias — Voltage applied across a PN junction in the direction that does not cause current flow.

Reverse breakdown — The condition in which reverse bias across a PN junction exceeds the ability of the depletion region to block current flow. (See also *avalanche breakdown*.)

Roll-off — Change in a circuit's amplitude response per octave or decade of frequency.

Safe operating area (SOA) — The region of a device's characteristic curve in which it can operate without damage.

Sample — A code that represents the value of an analog quantity at a specific time.

Saturation (Region) — The region in the characteristic curve of an analog device in which the output signal can no longer be increased by the input signal. See *Clamping*.

Schottky barrier — A metal-to-semiconductor junction at which a depletion region is formed, similarly to a PN junction.

Semiconductor — (1) An element such as silicon with bulk conductivity between that of an insulator and a metal. (2) An electronic device whose function is created by a structure of chemically-modified semiconductor materials.

Signal-to-noise ratio (SNR) — The ratio of the strength of the desired signal to that of the unwanted signal (noise), usually expressed in dB.

Slew rate — The maximum rate at which a device can change the amplitude of its output.

Small-signal — Conditions under which the variations in circuit parameters due to the input signal are small compared to the quiescent operating point and the

device is operating in its active region.

Source — The connection at one end of the channel of a field-effect transistor into which electrons are injected.

Stage — One of a series of sequential signal processing circuits or devices.

Substrate — Base layer of material on which the structure of a semiconductor device is constructed.

Superposition — Process in which two or more signals are added together linearly.

Total harmonic distortion (THD) — A measure of how much noise and distortion are introduced by a signal processing function.

Thermal runaway — The condition in which increasing device temperature increases device current in a positive feedback cycle.

Transconductance — Ratio of output current to input voltage, with units of Siemens (S).

Transfer characteristics — A set of parameters that describe how a circuit or network behaves at and between its signal interfaces.

Transfer function — A mathematical expression of how a circuit modifies an input signal.

Unipolar transistor — see *Field-effect transistor (FET)*.

Virtual ground — Point in a circuit maintained at ground potential by the circuit without it actually being connected to ground.

Zener diode — A heavily-doped PN-junction diode with a controlled reverse breakdown voltage, used as a voltage reference or regulator.

Zero — Frequency at which a circuit's transfer function becomes zero.

Digital Basics

Radio amateurs have been involved with digital technology since the first spark transmitters, a form of pulse-coded transmission, were connected to an “aerial.” Modern digital technology use by radio amateurs probably arrived first in CW keyers, where hams learned about flip-flops and gates to replace their semi-automatic mechanical “bug” keys.

Amateur use of digital technology echoed public use of these new abilities, starting with using the first home computers for calculations and later digital communications terminals. Today’s Amateur Radio digital applications range from simple shack accessories like keyers and timers, to computer based digital modes such as PSK31 and Hellschreiber, to computer networking using TCP/IP over AX.25, computer controlled rigs, digital signal processing and software defined radios.

This chapter was written by Dale Botkin, NØXAS, building on material in previous editions by Christine Montgomery, KGØGN and Paul Danzer, N1II. It presents digital theory fundamentals and some applications of that theory in Amateur Radio. The fundamentals introduce digital mathematics, including number systems, logic devices and simple digital circuits. Next, the implementation of these simple circuits is explored in integrated circuits, their families and interfacing. Finally, some Amateur Radio applications are discussed involving digital logic, embedded microcontrollers and interfacing to personal computers.

4.1 Digital vs Analog

An analog signal can represent an infinitely variable indication of voltage, current, frequency, the position of a dial, or some other condition or value. As an example, using a potentiometer as a volume control will give you infinitely variable control over the volume of a signal. In theory, there is no limit to the difference in volume that can be produced. Though the control may be marked from 1 to 10, the actual value would have to be represented by a real number somewhere between 0 and 10. There are an infinite number of settings in between.

In its simplest form, a digital signal simply indicates the *on* or *off* state of some value or input signal. For example, the straight key you may use to key your CW transmitter (or the PTT switch of your voice transmitter) produces an on or off binary signal. In one state the transmitter produces an output signal of some sort; in the other state it does not. Another example is a simple light switch. The light is either on, or it’s off. We represent these two states using 0 for off and 1 for on.

Digital electronics gets more interesting when we combine several or many simple on/off digital states to perform more complex tasks. For example, a relatively simple digital circuit can connect the antenna to either the transmitter or the receiver depending on a PTT or other keying signal. It can turn a preamp on or off depending on the state of the transmitter, mute the speaker while transmitting, and even select an antenna based on the selected frequency band. No special digital integrated circuits (chips) are needed to do any of these tasks; we can simply use bipolar transistors or MOSFETs, driven to saturation, as on/off switches. Simple circuits like this can often even be implemented with relays or diodes. The important fact is that the system is digital. There is no “almost transmitting” or “PTT switch partially pressed” state — it’s either on, or it’s off.

A very useful aspect of digital electronics is our ability to construct simple circuits that can maintain their on/off state indefinitely, until some event causes them to change. These *flip-flop* circuits can be used in various combinations to form *registers* that store information for later use or *counters* that count events and can be read or reset when needed. All of these circuits can be combined in ever larger groups until we finally arrive at the modern microprocessor. A microprocessor can accept input signals from many sources, follow a stored program to perform complex data storage and mathematical calculations, and produce output that we can use to do things that would be far more difficult with analog circuits.

So let’s revisit our volume control example from the earlier paragraph. Let’s assume we have a volume control, but it is used as an input to a digital system that will produce output at the desired level. This is quite

Fig 4.1 — An analog signal and its analog approximation. Note that the analog waveform has continuously varying voltage while the approximated waveform is composed of discrete steps.

common in modern equipment, whether it is amateur or consumer gear. Since the control is now digital, we know we can't have an infinite number of values. However, a simple on/off volume control would not be very useful. Using digital electronics, we can break the range between "off" and "fully on" into as many discrete steps as we need. With enough steps, we can give the user of the equipment an approximation of the original analog con-

trol while keeping the actual control digital.

By using coding, as discussed in the following pages, the two binary values (off and on, or 0 and 1) can represent any number of real values. **Fig 4.1** illustrates the contrast of an analog signal (in this case a sine wave) and its digital approximation. Four positive and four negative values are shown as an approximation to the sine wave, but any number of coded value steps can be used as an approximation.

The more values are used to approximate the wave, the closer you can come to the actual wave form.

While the focus in this chapter will be on digital theory, many circuits and systems involve *both* digital and analog components. Often, a designer may choose between using digital technology, analog technology or a combination.

4.2 Number Systems

If you have been around computer hobbyists, some of whom are also hams, you may have seen a T-shirt or bumper sticker that reads, "There are 10 kinds of people in the world: those who understand binary, and those who don't." If this has puzzled you in the past, after reading this chapter you will be able to laugh with the rest of us.

In order to understand digital electronics, you must first understand the binary numbering system. Any number system has two distinct characteristics: a set of *symbols* (digits or numerals) and a *base* or radix. A *number* is a collection of these digits, where the left-most digit is the *most significant digit (MSD)* and the right-most digit is the *least significant digit (LSD)*. The value of this number is a weighted sum of its digits. The *weights* are determined by the system's base and the digit's position relative to the decimal point.

While these definitions may seem strange with all the technical terms, they will be more

familiar when seen in a decimal system example. See **Table 4.1**. This is the "traditional" number system with which we are all familiar. In the *base-10* or decimal numbering system we use every day, the digits used are 0 through 9. The weights are powers of ten: 10^0 or 1 for the right-most column, 10^1 or 10 for the next column, 10^2 or 100 for the next and so on. Thus the number 548 represents five hundreds, four tens and eight ones. In this case, 5 is the MSD, and 8 is the LSD. Once you understand this concept, it can be applied to numbering systems using bases other than 10 such as base-2, base-8, or even base-16.

4.2.1 Binary

Binary is a *base-2* number system and therefore limited to two symbols: {0, 1}. The weight factors are now powers of 2, like 2^0 , 2^1 and 2^2 . For example, the decimal number, 163

and its equivalent binary number, 10100011, are shown in **Table 4.2**.

The digits of a binary number are now *bits* (short for binary digit). The MSD is the *most significant bit (MSB)* and the LSD is the *least significant bit (LSB)*. Four bits make a *nibble* (which you will occasionally see spelled *nybble*) and two nibbles, or eight bits, make a *byte*. The length of a *word* is dependent upon the hardware; it generally can consist of two or four or more bytes, but occasionally will be some other number of bits. These groupings are useful when converting to hexadecimal notation, which is explained later. It is important to remember that while everyone agrees on the meaning of a bit, a nibble (regardless of spelling) and a byte, the meaning of *word* can vary.

Counting in binary follows the same pattern we would use for decimal or any other number system. Consider the three digit binary number XXX. First fill up the right-hand column.

Table 4.1
Decimal Numbers

Example: 548

Digit = 5; Weight = 10; Position = 2

548	= 5(10 ²)	+ 4(10 ¹)	+ 8(10 ⁰)	
	= 5(100)	+ 4(10)	+ 8(1)	
	= 500	+ 40	+ 8	
	= 5	4	8	
	MSD		LSD	

Binary Number	Decimal Equivalent
0000	0
0001	1

The column has been filled, and much quicker than with decimal, since there are only two values instead of 10. But just as we would with a decimal number, we now reset the right-hand column to 0, increase the next column by 1, and continue.

Table 4.2
Decimal and Binary Number Equivalents

163	= 128	+ 0	+ 32	+ 0	+ 0	+ 0	+ 2+	1	decimal
	= 1(128)	+ 0(64)	+ 1(32)	+ 0(16)	+ 0(8)	+ 0(4)	+ 1(2)	+ 1(1)	
	= 1(2 ⁷)	+ 0(2 ⁶)	+ 1(2 ⁵)	+ 0(2 ⁴)	+ 0(2 ³)	+ 0(2 ²)	+ 1(2 ¹)	+ 1(2 ⁰)	
10100011	= 1	0	1	0	0	0	1	1	binary
	MSB							LSB	
	Nibble			Nibble					
	Byte = 8 digits								

0010	2
0011	3
Now the first two columns are full, so reset both back to 0 and increase the next column by 1 and continue:	
0100	4
0101	5
0110	6
0111	7
1000	8
...	
1111	15

And so on.

4.2.2 Hexadecimal

The *hexadecimal*, or *hex*, *base-16* number system is widely used in computer systems for its ease in conversion to and from binary numbers and the fact that it is somewhat more human-friendly than long strings of 1s and 0s. A base-16 number requires 16 symbols. Since our normal mathematical number, as set up in the decimal system, has only 10 digits (0 through 9), a set of additional new symbols is required. Hex uses both numbers and characters in its set of sixteen symbols: {0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E, F}. Here, the letters A to F have the decimal equivalents of 10 to 15 respectively: A=10, B=11, C=12, D=13, E=14 and F=15. Again, the weights are powers of the base, such as 16^0 , 16^1 and 16^2 .

The four-bit binary listing in the previous paragraph shows that the individual 16 hex digits can be represented by a four-bit binary number. Since a byte is equal to eight binary digits, two hex digits provide a byte — the equivalent of 8 binary digits. Conversion from binary to hex is therefore simplified. Take a binary number, divide it into groups of four binary digits starting from the right, and convert each of the four binary digits to an individual value.

Conversion from hex to binary is equally convenient; simply replace each hex digit with its four-bit binary equivalent. As an example, the decimal number 163 is shown in Table 4.2 as binary 10100011. Divide the binary number in groups of four, so 1010 is equivalent to decimal 10 or “A” hex, and 0011 is equivalent to decimal 3, thus decimal number 163 is equivalent to hex A3.

4.2.3 Binary Coded Decimal (BCD)

The binary number system representation is the most appropriate form for fast internal computations since there is a direct mathematical relationship for every bit in the number. To interface with a human user — who usually wants to see inputs and outputs in terms of decimal numbers — other codes are more useful. The *Binary Coded Decimal*

(*BCD*) system is a simple method for converting binary values to and from decimal for inputs and outputs for user-oriented digital systems. Back in the days when the most common method of presenting output to a user was via seven-segment LED displays, BCD was widely used. Since we now mostly use powerful microprocessors that can easily present information in decimal form, BCD is not nearly as common as it once was. You may, however, run into BCD when using or repairing older digital gear. It is also used in some chips intended for use in digital voltmeters.

In the BCD system, each decimal digit is expressed as a corresponding 4-bit binary number. In other words, the decimal digits 0 to 9 are encoded as the bit strings 0000 to 1001. To make the number easier to read, a space is left between each 4-bit group. For example, the decimal number 163 is equivalent to the BCD number 0001 0110 0011, as shown in Table 4.3.

The important difference between BCD and the previous number systems is that, starting with decimal 10, BCD loses the standard mathematical relationship of a weighted sum. BCD is simply a cut-off hexadecimal. Instead of using the 4-bit code strings 1010 to 1111 for decimal 10 to 15, BCD uses 0001 0000 to 0001 0101. This is one of the reasons that we have moved away from BCD.

4.2.4 Conversion Techniques

An easy way to convert a number from decimal to another number system is to do repeated division, recording the remainders

in a tower just to the right. The converted number, then, is the remainders, reading up the tower. This technique is illustrated in Table 4.4 for hexadecimal and binary conversions of the decimal number 163.

For example, to convert decimal 163 to hex, repeated divisions by 16 are performed. The first division gives $163/16 = 10$ remainder 3. The remainder 3 is written in a column to the right. The second division gives $10/16 = 0$ remainder 10. Since 10 decimal = A hex, A is written in the remainder column to the right. This division gave a divisor of 0 so the process is complete. Reading up the remainders column, the result is A3. The most common mistake in this technique is to forget that the Most Significant Digit ends up at the bottom.

Another technique that should be briefly mentioned can be even easier: use a calculator with a binary and/or hex mode option. Many inexpensive and readily available calculators intended for scientific and programming use will convert between number systems quite easily. In addition, calculator programs are available for all types of personal computers regardless of the operating system used.

One warning for this technique: this chapter doesn't discuss negative binary numbers. If your calculator does not give you the answer you expected, it may have interpreted the number as negative. This would happen when the number's binary form has a 1 in its MSB, such as the highest (leftmost) bit for the binary mode's default size. To avoid learning about negative binary numbers the hard way, always use a leading 0 when you enter a number in binary or hex into your calculator.

Table 4.3
Binary Coded Decimal Number Conversion

	0 0 0 1	0 1 1 0	0 0 1 1	BCD
	<u> </u>	<u> </u>	<u> </u>	
=	$1(2^0)$	$1(2^2) + 1(2^1)$	$1(2^1) + 1(2^0)$	
=	(1)	(4 + 2)	(2 + 1)	
163 =	1	6	3	decimal

Table 4.4
Number System Conversions

Hex	Remainder	Binary	Remainder
16	<u>163</u>	2	<u>163</u>

4.3 Physical Representation of Binary States

4.3.1 State Levels

Most digital systems use the binary number system because many simple physical systems are most easily described by two state levels (0 and 1). For example, the two states may represent “on” and “off” or a “mark” and “space” in a communications transmission. In electronic systems, state levels are physically represented by voltages. A typical choice is state 0 = 0 V

state 1 = 5 V

Since it is unrealistic to obtain these exact voltage values, a more practical choice is a range of values, such as

state 0 = 0.0 to 0.4 V

state 1 = 2.4 to 5.0 V

Fig 4.2 illustrates this representation of states by voltage levels. The undefined region between the two binary states is also known as the *transition region* or *noise margin*.

4.3.2 Transition Time

The gap in Fig 4.2, between binary 0 and binary 1, shows that a change in state does not occur instantly. There is a *transition time* between states. This transition time is a result of the time it takes to charge or discharge the stray capacitance in wires and other components because voltage cannot change instantaneously across a capacitor. (Stray inductance in the wires also has an effect because the current through an inductor can't change instantaneously.) The transition from a 0 to a 1 state is called the *rise time*, and is usually specified as the time for the pulse to rise from 10% of its final value to 90% of its final value. Similarly, the transition from a 1 to a 0 state is called the *fall time*, with a similar 10% to 90% definition. Note that these times need not be the same. **Fig 4.3A** shows an ideal signal, or *pulse*, with zero-time switching. **Fig 4.3B** shows a typical pulse, as it changes between states in a smooth curve.

Rise and fall times vary with the logic family used and the location in a circuit. Typical values of transition time are in the microsecond to nanosecond range. In a circuit, distributed inductances and capacitances in wires or

Fig 4.2 — Representation of binary states 1 and 0 by a selected range of voltage levels.

PC-board traces may cause rise and fall times to increase as the pulse moves away from the source. One reason rise and fall times may be of interest to the radio designer is because of the possibility of generating RF noise in a digital circuit.

4.3.3 Propagation Delay

Rise and fall times only describe a relationship within a pulse. For a circuit, a pulse input into the circuit must propagate through the circuit; in other words it must pass through each component in the circuit until eventually it arrives at the circuit output. The time delay between providing an input to a circuit and seeing a response at the output is the *propagation delay* and is illustrated by **Fig 4.4**.

For modern switching logic, typical propagation delay values are in the 1 to 15 nanosecond range. (It is useful to remember that the propagation delay along a wire or printed-circuit-board trace is about 1.0 to 1.5 ns per inch.) Propagation delay is the result of cumulative transition times as well as transistor switching delays, reactive element charging times and the time for signals to travel through wires. In complex circuits, different propagation delays through different paths can cause problems when pulses must arrive somewhere at exactly the same time.

The effect of these delays on digital devices can be seen by looking at the speed of the digital pulses. Most digital devices use *clock*

Fig 4.3 — (A) An ideal digital pulse and (B) a typical actual pulse, showing the gradual transition between states.

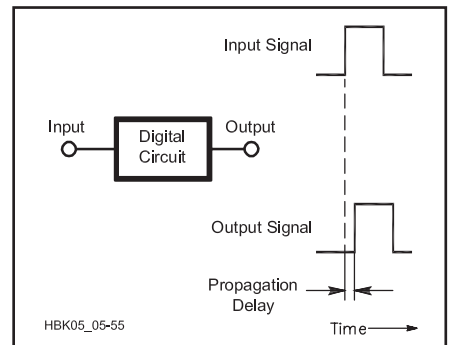

Fig 4.4 — Propagation delay in a digital circuit.

pulses. If two pulses are supposed to arrive at a logic circuit at the same time, or very close to the same time, the path length for the two signals cannot be any different than two to three inches. This can be a very significant design problem for high-speed logic designs.

4.4 Combinational Logic

Having defined a way to use voltage levels to physically represent digital numbers, we can apply digital signal theory to design useful circuits. Digital circuits combine binary inputs to produce a desired binary output or combination of outputs. This simple combination of 0s and 1s can become very powerful, implementing everything from simple switches to powerful computers.

A digital circuit falls into one of two types: combinational logic or sequential logic. In a *combinational logic* circuit, the output depends only on the *present inputs* (if we ignore propagation delay). In contrast, in a *sequential logic* circuit, the output depends on the present inputs, the *previous sequence of inputs* and often a clock signal. Later sections of this chapter will examine some circuits

built using the basics established here.

4.4.1 Boolean Algebra and the Basic Logical Operators

Combinational circuits are composed of logic gates, which perform binary operations. Logic gates manipulate binary numbers, so you need an understanding of the algebra of

binary numbers to understand how logic gates operate. *Boolean algebra* is the mathematical system used to describe and design binary digital circuits. It is named after George Boole, the mathematician who developed the system. Standard algebra has a set of basic operations: addition, subtraction, multiplication and division. Similarly, Boolean algebra has a set of basic operations, called *logical operations*: NOT, AND and OR.

The function of these operators can be described by either a Boolean equation or a truth table. A Boolean *equation* describes an operator's function by representing the inputs and the operations performed on them. An equation is of the form "B = A," while an *expression* is of the form "A." In an assignment equation, the inputs and operations appear on the right and the result, or output, is assigned to the variable on the left.

A *truth table* describes an operator's function by listing all possible inputs and the corresponding outputs. Truth tables are sometimes written with Ts and Fs (for true and false) or with their respective equivalents, 1s and 0s. In company databooks (catalogs of logic devices a company manufactures), truth tables are usually written with Hs and Ls (for high and low). In the figures, 1 will mean high and 0 will mean low. This representation is called positive logic. The meaning of different logic types and why they are useful is discussed in a later section.

Each Boolean operator also has two circuit symbols associated with it. The traditional symbol — used by ARRL and other US publications — appears on top in each of the figures; for example, the triangle and bubble for the NOT function in Fig 4.7. In the traditional symbols, a small circle, or *bubble*, always represents "NOT." (This *bubble* is called a state indicator.)

Appearing just below the traditional symbol is the newer ANSI/IEEE Standard symbol. This symbol is always a square box with notations inside it. In these newer symbols, a small triangular flag represents "NOT." The new notation is an attempt to replace the detailed logic drawing of a complex function with a simpler block symbol. Adoption of the newer symbols has been spotty, and you are therefore still more likely to see the traditional symbols for basic logic functions than the ANSI/IEEE symbols.

4.4.2 Common Gates

Figs 4.5, 4.6 and 4.7 show the truth tables, Boolean algebra equations and circuit symbols for the three basic Boolean operations: AND, OR and NOT, respectively. All combinational logic functions, no matter how complex, can be described in terms of these three operators. Each truth table can be converted into words. The truth table for the two-input AND gate can be expressed as "the output C

Fig 4.5 — Two-input AND gate.

Fig 4.6 — Two-input OR gate.

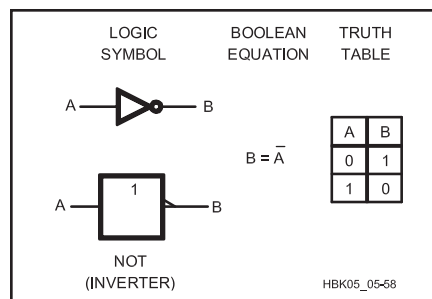

Fig 4.7 — Inverter.

is a 1 only when the inputs are both 1s." This can be seen by examining the output column C — it remains at a 0 and becomes a 1 only when the input column A and the input column B are both 1s — the last line of the table.

The NOT operation is also called *inversion*, *negation* or *complement*. The circuit that implements this function is called an *inverter* or *inverting buffer*. The most common notation for NOT is a bar over a variable or expression. For example, NOT A is denoted \bar{A} . This is read as either "Not A" or as "A bar." A less common notation is to denote Not A by A' , which is read as "A prime." You will also see various other notations in schematic diagrams and component data sheets, such as a leading exclamation point or has symbol — !A or #A indicating "Not A."

While the inverting buffer and the noninverting buffer covered later have only one input and output, many combinational logic elements can have multiple inputs. When a combinational logic element has two or more inputs and one output, it is called a *gate*. (The term "gate" has a number of different but

specific technical uses. For a clarification of the many definitions of gate, see the section on **Synchronicity and Control Signals**, later in this chapter.) For simplicity, the figures and truth tables for multiple-input elements will show the operations for only two inputs, the minimum number. Remember, though, that it is quite common to have gates with more than two inputs. A three-, four-, or eight-input gate works in the exact same manner as a two-input gate.

The output of an AND function is 1 only if *all* of the inputs are 1. Therefore, if *any* of the inputs are 0, then the output is 0. The notation for an AND is either a dot (\cdot) between the inputs, as in $C = A \cdot B$, or nothing between the inputs, as in $C = AB$. Read these equations as "C equals A AND B."

The OR gate detects if one or more inputs are 1. In other words, if *any* of the inputs are 1, then the output of the OR gate is 1. Since this includes the case where more than one input may be 1, the OR operation is also known as an **INCLUSIVE OR**. The OR operation detects if *at least one* input is 1. Only if all the inputs are 0, then the output is 0. The notation for an OR is a plus sign (+) between the inputs, as in $C = A + B$. Read this equation as "C equals A OR B."

4.4.3 Additional Gates

More complex logical functions are derived from combinations of the basic logical operators. These operations — NAND, NOR, XOR and the noninverter or buffer — are illustrated in Figs 4.8 through 4.11, respectively. As before, each is described by a truth table, Boolean algebra equation and circuit symbols. Also as before, except for the noninverter, each could have more inputs than the two illustrated.

The NAND gate (short for NOT AND) is equivalent to an AND gate followed by a NOT gate. Thus, its output is the complement of the AND output: The output is a 0 only if all the inputs are 1. If any of the inputs is 0, then the output is a 1.

The NOR gate (short for NOT OR) is equivalent to an OR gate followed by a NOT gate. Thus, its output is the complement of the OR output: If any of the inputs are 1, then the output is a 0. Only if all the inputs are 0, then the output is a 1.

The operations so far enable a designer to determine two general cases: (1) if *all* inputs have a desired state or (2) if *at least one* input has a desired state. The XOR and XNOR gates enable a designer to determine if *one and only one* input of a desired state is present.

The XOR gate (read as EXCLUSIVE OR) is a combination of an OR and a NAND gate. It has an output of 1 if one and only one of the inputs is a 1 state. The output is 0 otherwise. The symbol for XOR is \oplus . This is easy to remember if you think of the "+" OR symbol

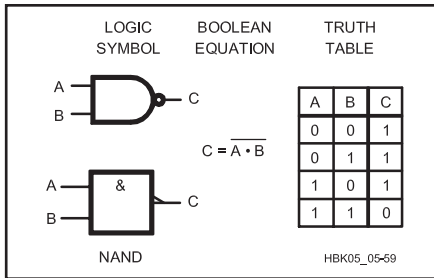

Fig 4.8 — Two-input NAND gate.

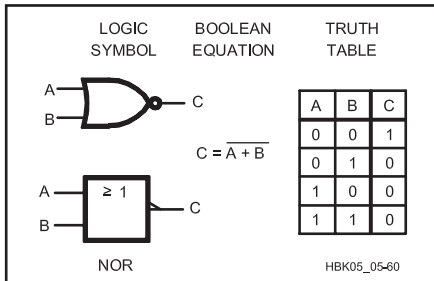

Fig 4.9 — Two-input NOR gate.

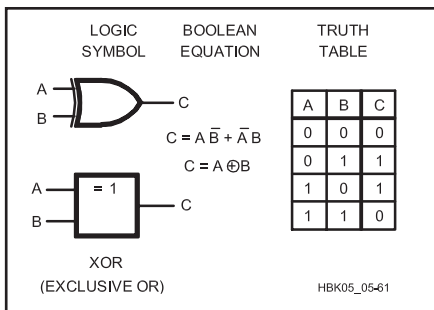

Fig 4.10 — Two-input XOR gate.

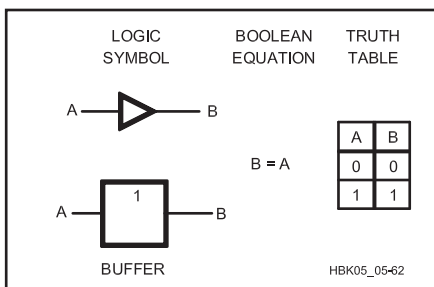

Fig 4.11 — Noninverting buffer.

enclosed in an “O” for *only one*.

The XOR gate is also known as a “half adder,” because in binary arithmetic it does everything but the “carry” operation. The following examples show the possible binary additions for a two-input XOR.

A	0	0	1	1
B	0	1	0	1
Sum	0	1	1	0

The XNOR gate (read as EXCLUSIVE

NOR) is the complement of the XOR gate. The output is 0 if one and only one of the inputs is a 1. The output is 1 either if all inputs are 0 or more than one input is 1.

NONINVERTERS (BUFFERS)

A *noninverter*, also known as a *buffer*, *amplifier* or *driver*, at first glance does not seem to do anything. It simply receives an input and produces the same output. In reality, it is changing other properties of the signal in a useful fashion, such as amplifying the current level. While not useful for logical operations, applications of a noninverter include providing sufficient current to drive a number of gates or some other circuit such as a relay; interfacing between two logic families; obtaining a desired pulse rise time; and providing a slight delay to make pulses arrive at the proper time.

TRI-STATE GATES

Under normal circumstances, a logic element can drive or feed several other logic elements. A typical AND gate might be able to drive or feed 10 other gates. This is known as *fan-out*. However, with certain exceptions only one gate output can be connected to a single wire. If you have two possible driving sources to feed one particular wire, some logic network that probably includes a number of OR gates must be used.

In many applications, including computers, data is routed internally on a set of wires called *buses*. The data on the bus can come from many circuits or drivers, and many other devices may be *listening* on the bus. To eliminate the need for the network of OR gates to drive each bus wire, a set of gates known as *tri-state* gates are used.

The symbol and truth table for a tri-state gate are shown in Fig 4.12. A tri-state gate can be any of the common gates previously described, but with one additional control lead. When this lead is enabled (it can be designed to allow either a 0 or a 1 to enable it) the gate operates normally, according to the truth table for that type of gate. However, when the gate is not enabled, the output goes to a high impedance (Hi-Z), and so far as the output wire is concerned, the gate does not exist.

Each device that has to send data down a bus wire is connected to the bus wire through a tri-state gate. However, as long as only one device, through its tri-state gate, is enabled, it is as though all the other connected tri-state gates do not exist.

4.4.4 Boolean Theorems

The analysis of a circuit starts with a logic diagram and then derives a circuit description. In digital circuits, this description is in the form of a truth table or logical equation. The

Fig 4.12 — Tri-State gate.

synthesis, or design, of a circuit goes in the reverse: starting with an informal description, determining an equation or truth table and then expanding the truth table to components that will implement the desired response. In both of these processes, we need to either simplify or expand a complex logical equation.

To manipulate an equation, we use mathematical *theorems*. Theorems are statements that have been proven to be true. The theorems of Boolean algebra are very similar to those of standard algebra, such as commutivity and associativity. Proofs of the Boolean algebra theorems can be found in an introductory digital design textbook.

BASIC THEOREMS

Table 4.5 lists the theorems for a single variable and Table 4.6 lists the theorems for two or more variables. These tables illustrate the *principle of duality* exhibited by the Boolean theorems: Each theorem has a dual in which, after swapping all ANDs with ORs and all 1s with 0s, the statement is still true.

The tables also illustrate the *precedence* of the Boolean operations: the order in which operations are performed when not specified by parenthesis. From highest to lowest, the precedence is NOT, AND then OR. For example, the distributive law includes the expression “A + B•C.” This is equivalent to

Fig 4.13 — Equivalent gates from DeMorgan’s Theorem: Each gate in column A is equivalent to the opposite gate in column B. The Boolean equations in column C formally state the equivalences.

“ $A + (B \cdot C)$.” The parenthesis around $(B \cdot C)$ can be left out since an AND operation has higher priority than an OR operation. Precedence for Boolean algebra is similar to the convention of standard algebra: raising to a power, then multiplication, then addition.

DeMORGAN'S THEOREM

One of the most useful theorems in Boolean algebra is DeMorgan's Theorem:

$$\overline{A \cdot B} = \overline{A} + \overline{B}$$

and its dual

$$\overline{A + B} = \overline{A} \cdot \overline{B}$$

Table 4.5
Boolean Algebra Single Variable Theorems

Identities:	$A \cdot 1 = A$	$A + 0 = A$
Null elements:	$A \cdot 0 = 0$	$A + 1 = 1$
Idempotence:	$A \cdot A = A$	$A + A = A$
Complements:	$A \cdot \overline{A} = 0$	$A + \overline{A} = 1$
Involution:	$\overline{(\overline{A})} = A$	

The truth table in **Table 4.7** proves these statements. DeMorgan's Theorem provides a way to simplify the complement of a large expression. It also enables a designer to interchange a number of equivalent gates, as shown by **Fig 4.13**.

The equivalent gates show that the duality principle works with symbols the same as it does for Boolean equations: just swap ANDs with ORs and switch the bubbles. For example, the NAND gate — an AND gate followed by an inverter bubble — becomes an OR gate preceded by two inverter bubbles. DeMorgan's Theorem is important because it means any logical function can be implemented using either inverters and AND gates or inverters and OR gates. Also, the ability to change placement of the bubbles using DeMorgan's Theorem is useful in dealing with mixed logic, to be discussed next.

POSITIVE AND NEGATIVE LOGIC

The truth tables shown in the figures in this chapter are drawn for positive logic. In *positive logic*, or *high true*, a higher voltage means true (logic 1) while a lower voltage means false (logic 0). This is also referred to as *active high*:

a signal performs a named action or denotes a condition when it is “high” or 1. In *negative logic*, or *low true*, a lower voltage means true (1) and a higher voltage means false (0). An *active low* signal performs an action or denotes a condition when it is “low” or 0.

In both logic types, true = 1 and false = 0; but whether true means high or low differs. Company databooks are drawn for general truth tables: an H for high and an L for low. (Some tables also have an X for a “don't care” state. “Don't care” means that the output does not depend on the state of that variable.) The function of the table can differ depending on whether it is interpreted for positive logic or negative logic.

Device data sheets often show positive logic convention, or positive logic is assumed. However, a signal into an IC is represented with a bar above it, indicating that the “enable” on that wire is active low — it does not mean negative logic (0 V = a logical 1) is used! Similarly a bubble on the input of a logic element also usually means active low. These can be sources of confusion.

Fig 4.14 shows how a general truth table differs when interpreted for different logic types. The same truth table gives two equivalent gates: positive logic gives the function of

Table 4.6
Boolean Algebra Multivariable Theorems

Commutativity:	$A \cdot B = B \cdot A$ $A + B = B + A$
Associativity:	$(A \cdot B) \cdot C = A \cdot (B \cdot C)$ $(A + B) + C = A + (B + C)$
Distributivity:	$(A + B) \cdot (A + C) = A + B \cdot C$ $A \cdot B + A \cdot C = A \cdot (B + C)$
Covering:	$A \cdot (A + B) = A$ $A + A \cdot B = A$
Combining:	$(A + B) \cdot (A + \overline{B}) = A$ $A \cdot B + A \cdot \overline{B} = A$
Consensus:	$A \cdot B + \overline{A} \cdot C + B \cdot C = A \cdot B + \overline{A} \cdot C$ $(A + B) \cdot (\overline{A} + C) \cdot (B + C) = (A + B) \cdot (\overline{A} + C)$ $A + \overline{A}B = A + B$

(A) and (B) are statements of DeMorgan's Theorem. The truth table at (C) is proof of these statements: (A) is proven by the equivalence of columns 6 and 10 and (B) by columns 8 and 9.

a NAND gate while negative logic gives the function of a NOR gate.

Note that these gates correspond to the equivalent gates from DeMorgan's Theorem. A bubble on an input or output terminal indicates an active low device. The absence of bubbles indicates an active high device.

Like the bubbles, signal names can be used to indicate logic states. These names can aid the understanding of a circuit by indicating control of an action (GO, /ENABLE) or detection of a condition (READY, /ERROR). The action or condition occurs when the signal is

in its active state. When a signal is in its active state, it is called *asserted*; a signal not in its active state is called *negated* or *deasserted*.

A prefix can easily indicate a signal's active state. Active low signals are preceded by a symbol such as /, |, ! or # (for example /READY or !READY). Active low signals are also denoted by an overscore, such as \overline{CL} . Active high signals have no prefix or overscore. As an example, see the truth table for a flip-flop later in this chapter. Standard practice is that the signal name and input pin match (have the same active level). For

example, an input with a bubble (active low) may be called /READY, while an input with no bubble (active high) is called READY. Output signal names should always match the device output pin.

In this chapter, positive logic is used unless indicated otherwise. Although using mixed logic can be confusing, it does have some advantages. Mixed logic combined with DeMorgan's Theorem can promote more effective use of available gates. Also, well-chosen signal names and placement of bubbles can promote more understandable logic diagrams.

4.5 Sequential Logic

The previous section discussed combinational logic, whose outputs depend only on the present inputs. In contrast, in *sequential logic* circuits, the new output depends not only on the present inputs but also on the present outputs. The present outputs depended on the previous inputs and outputs and those earlier outputs depended on even earlier inputs and outputs and so on. Thus, the present outputs depend on the previous *sequence of inputs* and the system has *memory*. Having the outputs become part of the new inputs is known as *feedback*.

4.5.1 Synchronicity and Control Signals

When a combinational circuit is given a set of inputs, the outputs take on the expected values after a propagation delay during which the inputs travel through the circuit to the output. In a sequential circuit, however, the travel through the circuit is more complicated. After application of the first inputs and one propagation delay, the outputs take on the resulting state; but then the outputs start trickling back through a circuit. A gate can also be a logic circuit with two or more inputs and one output, as used earlier in this chapter. Of course, "gate" can also be one of the electrodes of an FET as described in another chapter. To *toggle* means a signal changes state, from 1 to 0 or

vice versa. A *clock* signal is one that toggles at a regular rate.

There are two types of sequential circuits: synchronous circuits and asynchronous circuits, which are analyzed differently for valid outputs. In *asynchronous* operation, the outputs respond to the inputs immediately after the propagation delay. To work properly, this type of circuit must eventually reach a *stable* state: the inputs and the fed back outputs result in the new outputs staying the same. When the nonfeedback inputs are changed, the feedback cycle needs to eventually reach a new stable state. Generally, the output of this type of logic is not valid until the last input has changed,

and enough time has elapsed for all propagation delays to have occurred.

In *synchronous* operation, the outputs change state only at specific times. These times are determined by the presence of a particular input signal: a clock, toggle, latch or enable. Synchronicity is important because it ensures proper timing: all the inputs are present where needed when the control signal causes a change of state.

CONTROL SIGNALS

Some authors vary the meanings slightly for the different control signals. The following is a brief illustration of common uses, as well as showing uses for noun, verb and adjective. *Enabling* a circuit generally means the control signal goes to its asserted level, allowing the circuit to change state. *Latch* implies memory: a latch circuit can store a bit of information. A latch signal can cause a circuit to keep its present state indefinitely. *Gate* can have several meanings, some unrelated to synchronous control. For example, a gate can be a signal used to trigger the passage of other signals. A gate can also be a logic circuit with two or more inputs and one output, as used earlier in this chapter. Of course, "gate" can also be one of the electrodes of an FET as described in another chapter. To *toggle* means a signal changes state, from 1 to 0 or

vice versa. A *clock* signal is one that toggles at a regular rate.

Clock control is the most common method of synchronizing logic circuits, so it has some additional terms as illustrated by Fig 4.15. The *clock period* is the time between successive transitions in the same direction; the *clock frequency* is the reciprocal of the period. A *pulse* or *clock tick* is the first edge in a clock period, or sometimes the period itself or the first half of the period. The *duty cycle* is the percentage of time that the clock signal is at its asserted level. A common application of the use of clock pulses is to limit the input to a logic circuit such that the circuit is only enabled on one clock phase; that is the inputs occur before the clock changes to a logic 1.

Fig 4.15 — Clock signal terms. The duty cycle would be t_H / t_{PERIOD} for an active high signal and t_L / t_{PERIOD} for an active low signal.

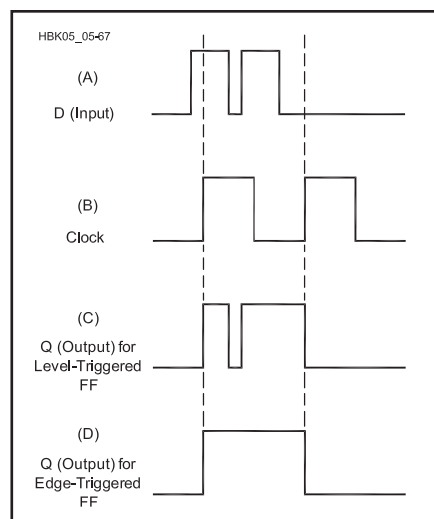

Fig 4.16 — Level-triggered vs edge-triggered for a D flip-flop: (A) D input, (B) clock input, (C) output Q for level-triggered: circuit responds whenever clock is 1. (D) output Q for edge-triggered: circuit responds only at rising edge of clock. Notice that the short negative pulse on the D input is not reproduced by the edge-triggered flip-flop.

The outputs are sampled only after this point; perhaps when the clock next changes back to a logic 0.

The reaction of a synchronous circuit to its control signal is *static* or *dynamic*. *Static*, *gated* or *level-triggered* control allows the circuit to change state whenever the control signal is at its active or asserted level. *Dynamic*, or *edge-triggered*, control allows the circuit to change state only when the control signal *changes* from unasserted to asserted. By convention, a control signal is active high if state changes occur when the signal is high or at the rising edge and active low in the opposite case. Thus, for positive logic, the convention is enable = 1 or enable goes from 0 to 1. This transition from 0 to 1 is called *positive edge-triggered* and is indicated by a small triangle inside the circuit box. A circuit responding to the opposite transition, from 1 to 0, is called *negative edge-triggered*, indicated by a bubble with the triangle.

Whether a circuit is level-triggered or edge-triggered can affect its output, as shown by **Fig 4.16**. The D input includes a very brief pulse, called a *glitch*, which may be caused by noise. The differing results at the output illustrate how noise can cause errors. We have both edge and level triggered circuits available so that we can meet the requirements of our particular design.

4.5.2 Flip-Flops

Flip-flops are the basic building blocks of sequential circuits. A *flip-flop* is a device with two stable states: the *set* state (1) and the *reset* or *cleared* state (0). The flip-flop can be placed in one or the other of the two states by applying the appropriate input. Since a common use of flip-flops is to store one bit of information, some use the term *latch* interchangeably with flip-flop. A set of latches, or flip-flops holding an n-bit number is called a *register*. While gates have special symbols, the schematic symbol for most sequential logic components is a rectangular box with the circuit name or abbreviation, the signal names and assertion bubbles. For flip-flops, the circuit name is usually omitted since the signal names are enough to indicate a flip-flop and its type. The four basic types of flip-flops are the S-R, D, T and J-K. The most common flip-flops available to Amateurs today are the J-K and D- flip-flops; the others can be synthesized if needed by utilizing these two varieties.

TRIGGERING A FLIP-FLOP

Although the S-R (Set-reset) flip flop is no longer generally available or used, it does provide insight in basic flip-flop operations and triggering. It is also not uncommon to build S-R flip-flops out of gates for jobs such as switch contact debouncing. In **Fig 4.17** the

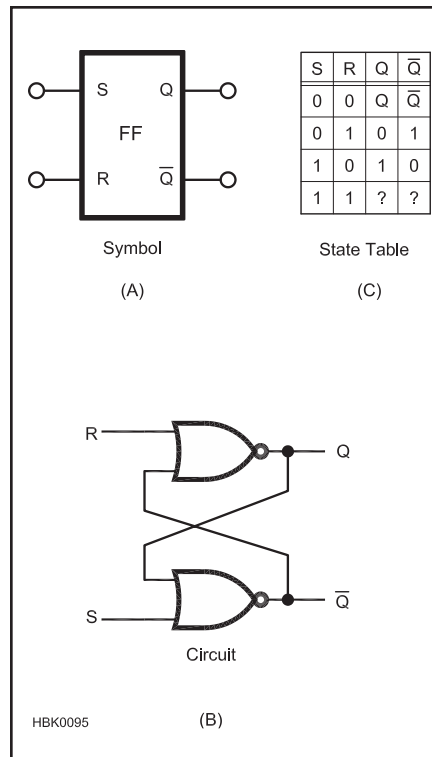

Fig 4.17 — Unlocked S-R Flip-Flop. (A) schematic symbol. (B) circuit diagram. (C) state table or truth table.

symbol for an S-R flip flop and its truth table are accompanied by a logic implementation, using NAND gates. As the truth table shows, this basic implementation requires a positive or logic 1 input on the set input to put the flip-flop in the Q or set state. Remove the input, and the flip flop stays in the Q state, which is what is expected of a flip-flop. Not until the S input receives a logic 1 input does the flip-flop change state and go to the reset or Q=0 state.

Note that the input can be a short pulse or a level; as long as it is there for some minimum duration (established by the propagation delay of the gates used), the flip-flop will respond. By contrast the clocked S-R flip-flop in **Fig 4.18** requires both a positive level to be present at either the S or R inputs and a positive clock pulse. The clock pulse is ANDed with the S or R input to trigger the flip-flop. In this case the flip-flop shown is implemented with a set of NOR gates.

A final triggering method is edge triggering. Here, instead of using the clock pulse as shown in the timing diagram of Fig 4.18, just the edge of the clock pulse is used. The edge-triggered flip-flop helps solve a problem with noise. Edge-triggering minimizes the time during which a circuit responds to its inputs: the chance of a glitch occurring during

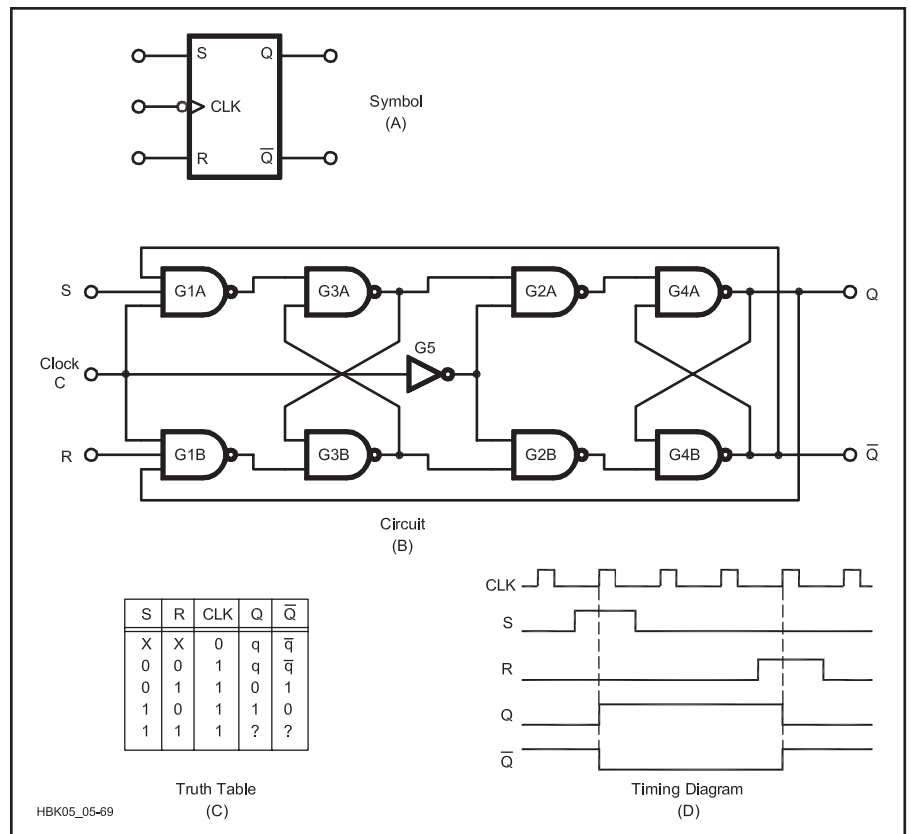

Fig 4.18 — Master-Slave Flip-Flop. (A) logic symbol. (B) NAND gate implementation. (C) truth table. (D) timing diagram.

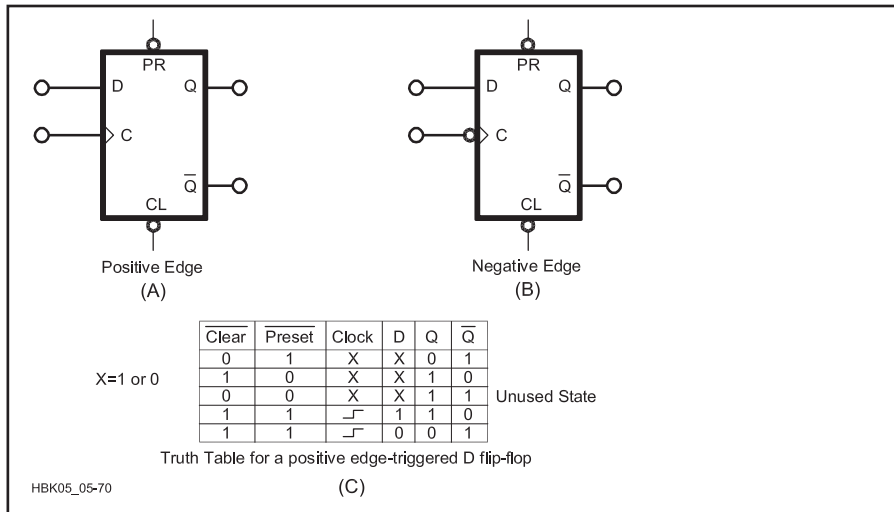

Fig 4.19 — (A & B) The D flip-flop. (C) A truth table for the positive edge-triggered D flip-flop.

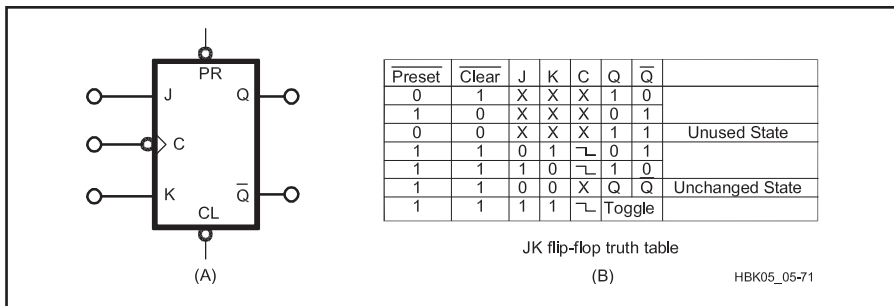

Fig 4.20 — (A) JK flip-flop. (B) JK flip-flop truth table.

the nanosecond transition of a clock pulse is remote. A side benefit of edge-triggering is that only one new output is produced per clock period. Edge-triggering is denoted by a small rising-edge or falling-edge symbol in the clock column of the flip-flop's truth table. It can also appear, instead of the clock triangle, inside the schematic symbol.

MASTER/SLAVE FLIP-FLOP

One major problem with the simple flip-flop shown up to now is the question of when is there a valid output. Suppose a flip-flop receives input that causes it to change state; at the same time the output of this flip-flop is being sampled to control some other logic element. There is a real risk here that the output will be sampled just as it is changing and thus the validity of the output is questionable.

A solution to this problem is a circuit that samples and stores its inputs before changing its outputs. Such a circuit is built by placing two flip-flops in series; both flip-flops are triggered by a common clock but an inverter on the second flip-flop's clock input causes it to be asserted only when the first flip-flop is not asserted. The action for a given clock pulse is as follows: The first, or master, flip-flop can

change only when the clock is high, sampling and storing the inputs. The second, or slave, flip-flop gets its input from the master and changes when the clock is low. Hence, when the clock is 1, the input is sampled; then when the clock becomes 0, the output is generated. Note that a bubble may appear on the schematic symbol's clock input, reminding us that the output appears when the clock is asserted low. This is conventional for TTL-style J-K flip-flops, but it can be different for CMOS devices.

The master/slave method isolates output changes from input changes, eliminating the problem of series-fed circuits. It also ensures only one new output per clock period, since the slave flip-flop responds to only the single sampled input. A problem can still occur, however, because the master flip-flop can change more than once while it is asserted; thus, there is the potential for the master to sample at the wrong time. There is also the potential that either flip-flop can be affected by noise.

A master-slave, S-R clocked input flip-flop synthesized from NAND gates, Fig 4.18B, is accompanied by its logic symbol, Fig 4.18A. From the logic symbols you can tell that the

output changes on a negative-going clock edge.

G3A and G3B form the master set-reset flip-flop, and G4A and G4B the slave flip flop. The input signals S and R are controlled by the positive going edge of the clock through gates G1A and G1B. G2A and G2B control the inputs into the slave flip-flop; these inputs are the outputs of the master flip-flop. Note G5 inverts the clock; thus while the positive-going edge places new data into the master flip-flop, the other edge of the clock transfers the output of the master into the slave on the following negative clock edge.

D FLIP-FLOP

In a D (data) flip-flop, the *data* input is transferred to the outputs when the flip-flop is enabled. The logic level at the D input is transferred to Q when the clock is positive; the Q output retains this logic level until the next positive clock pulse (see Fig 4.19). The truth table summarizes this operation. If D = 1 the next clock pulse makes Q = 1. If D = 0, the next clock pulse makes Q = 0. A D flip-flop is useful to store one bit of information. A collection of D flip-flops forms a register.

J-K FLIP-FLOP

The J-K flip-flop, shown schematically in Fig 4.20A, has five inputs. The unit shown uses both positive active inputs (the J and K inputs) and negative active inputs (note the bubbles on the C or clock, PR or preset and CL or clear inputs). With these inputs almost any other type of flip-flop may be synthesized.

The truth table of Fig 4.20B provides an explanation. Lines (rows) 1 and 2 show the preset and clear inputs and their use. These are active low, meaning that when one (and only one) of them goes to a logic 0, the flip-flop responds, just as if it was a S-R or set-reset flip-flop. Make PR a logic 0, and leave CL a logic 1, and the flip-flop goes into the Q = 1 state (line 1). Do the reverse (line 2) – PR = 1, CL = 0 and the flip-flop goes into a Q' = 1 state. When these two inputs are used, J, K and C are marked as X or don't care, because the PR and CL inputs override them. Line 3 corresponds to the unused state of the R-S flip-flop.

Line 5 shows that if J = 1 and K = 0, the next clock transition from high to low sets Q = 1 and Q' = 0. Alternately, line 4 shows J = 0 and K = 1 sets Q = 0 and Q' = 1. Therefore if a signal is applied to J, and the inverted signal sent to K, the J-K flip-flop will mimic a D flip-flop, echoing its input.

The most unique feature of the J-K flip-flop is line 7. If both J and K are connected to a 1, then each clock 1 to 0 transition will flip or toggle the flop-flop. Thus the J-K flip-flop can be used as a T flip-flop, as in a ripple counter (see the following **Counters** section.)

Table 4.8 summarizes D and J-K flip-flops.

HBK0668

t: If J = K, the clock toggles the flip-flop

The advantage of the synchronous counter is that at any instant, except during clock pulse transition, all counter stage outputs are correct and delay due to propagation through the flip flops is not a problem.

In the synchronous counter, Fig 4.21B, each stage is controlled by a common clock signal.

There are numerous variations on this first example of a counter. Most counters have the ability to clear the count to 0. Some counters can also preset to a desired count. The clear and preset control inputs are often asynchronous — they change the output state without being clocked. Counters may either count up (increment) or down (decrement). Up/down counters can be controlled to count in either direction. Counters can have sequences other than the standard numbers, for example a BCD counter.

Counters are also not restricted to changing state on every clock cycle. An n-bit counter that changes state only after m clock pulses is called a divider or divide-by-m counter. There are still $2^n = m$ states; however, the output after p clock pulses is now p / m. Combining different divide-by-m counters can result in almost any desired count. For example, a base 12 counter can be made from a divide-by-2 and a divide-by-6 counter; a base 10 (decade) counter consists of a divide-by-2 and a BCD divide-by-5 counter.

The outputs of these counters are binary. To produce output in decimal form, the output of a counter would be provided to a binary-to-decimal decoder chip and/or an LED display.

4.5.3 Groups of Flip-Flops COUNTERS

Groups of flip-flops can be combined to make counters. Intuitively, a counter is a circuit that starts at state 0 and sequences up through states 1, 2, 3, to m, where m is the maximum number of states available. From state m, the next state will return the counter to 0. This describes the most common counter: the n-bit binary counter, with n outputs corresponding to $2^n = m$ states. Such a counter can be made from n flip-flops, as shown in Fig 4.21. This figure shows implementations for each of the types of synchronicity. Both circuits pass the data count from stage to stage. In the asynchronous counter, Fig 4.21A, the clock is also passed from stage to stage and the circuit is called ripple or ripple-carry.

The J-K flip-flop truth table shows that with PR (Preset) and CL (Clear) both positive, and therefore not effecting the operation, the flip-flop will toggle if J and K are tied to a logic 1. In Fig 4.21A the first stage has its J and K inputs permanently tied to a logic 1, and each succeeding stage has its J and K inputs tied to Q of the proceeding stage. This provides a direct ripple counter implementation.

Design of a synchronous counter is bit more

involved. It consists of determining, for a particular count, the conditions that will make the next stage change at the same clock edge when all the stages are changing.

To illustrate this, notice the binary counting table of Fig 4.21. The right-hand column represents the lowest stage of the counter. It alternates between 1 and 0 on every line. Thus, for the first stage the J and K inputs are tied to logic 1. This provides the alternation required by the counting table.

The middle column or second stage of the counter changes state right after the lower stage is a 1 (lines C, E and G). Thus if the Q output of the lowest stage is tied to the J and K inputs of the second stage, each time the output of the lowest stage is a 1 the second stage toggles on the next clock pulse.

Finally, the third column (third stage) toggles when both the first stage and the second stage are both 1s (line D). Thus by ANDing the Q outputs of the first two stages, and then connecting them to the J and K inputs of the third stage, the third stage will toggle whenever the first two stages are 1s.

There are formal methods for determining the wiring of synchronous counters. The illustration above is one manual method that may be used to design a counter of this type.

REGISTERS

Groups of flip-flops can be combined to make registers, usually implemented with D flip-flops. A register stores n bits of information, delivering that information in response to a clock pulse. Registers usually have asynchronous set to 1 and clear to 0 capabilities.

Storage Register

A storage register simply stores temporary information, for example, incoming information or intermediate results. The size is related to the basic size of information handled by a computer: 8 flip-flops for an 8-bit or byte register or 16 bits for a word register. Fig 4.22 shows a typical circuit and schematic symbols for an 8-bit storage register.

Shift Register

Shift registers also store information and provide it in response to a clock signal, but they handle their information differently: When a clock pulse occurs, instead of each flip-flop passing its result to the output, the flip-flops pass their data to each other, up and down the row. For example, in up mode, each flip-flop receives the output of the preceding flip-flop. A data bit starting in flip-flop D0 in a left

Fig 4.21 — Three-bit binary counter using J-K flip-flops: (A) asynchronous or ripple, (B) synchronous.

shifter would move to D1, then D2 and so on until it is shifted out of the register. If a 0 was input to the least significant bit, D0, on each clock pulse then, when the last data bit has been shifted out, the register contains all 0s.

Shift registers can be left shifters, right shifters or controlled to shift in either direction. The most general form, a *universal shift register*, has two control inputs for four states: Hold, Shift right, Shift left and Load. Most also have asynchronous inputs for preset, clear and parallel load. The primary use of shift registers is to convert parallel information to serial or vice versa. Additional uses for a shift register are to delay or synchronize data, and to multiply or divide a number by a factor 2^n . Data can be delayed simply by

taking advantage of the Hold feature of the register control inputs. Multiplication and division with shift registers is best explained by example: Suppose a 4-bit shift register currently has the value 1000 = 8. A right shift results in the new parallel output 0100 = 4 = $8 / 2$. A second right shift results in 0010 = 2 = $(8 / 2) / 2$. Together the 2 right shifts performed a division by 2^2 . In general, shifting right n times is equivalent to dividing by 2^n . Similarly, shifting left multiplies by 2^n . This can be useful to compiler writers to make a computer program run faster.

4.5.4 Multivibrators

Multivibrators are a general type of circuit

with three varieties: bistable, monostable and astable. The only truly digital multivibrator is bistable, having two stable states. The flip-flop is a *bistable multivibrator*: both of its two states are stable; it can be triggered from one stable state to the other by an external signal. The other two varieties of multivibrators are partly analog circuits and partly digital. While their output is one or more pulses, the internal operation is strictly analog.

MONOSTABLE MULTIVIBRATOR

A *monostable* or *one-shot* multivibrator has one energy-storing element in its feedback paths, resulting in one stable and one quasi-stable state. It can be switched, or *triggered*, to its quasi-stable state; then returns to the stable state after a time delay. Thus, when triggered, the one-shot multivibrator puts out a pulse of some duration, T .

A very common integrated circuit used for non-precision generation of a signal pulse is the 555 timer IC. Fig 4.23 shows a 555 connected as a one-shot multivibrator. The one-shot is activated by a negative-going pulse between the trigger input and ground. The trigger pulse causes the output (Q) to go positive and capacitor C to charge through resistor R. When the voltage across C reaches two-thirds of V_{CC} , the capacitor is quickly discharged to ground and the output returns to 0. The output remains at logic 1 for a time determined by

$$T = 1.1 RC$$

where:

- R = resistance in ohms, and
- C = capacitance in farads.

A very common, but again, non-precision application of this circuit is the generation of a delayed pulse. If there is a requirement

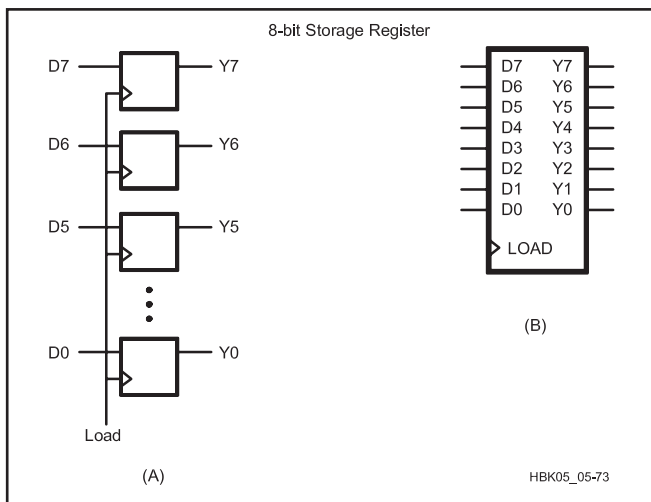

Fig 4.22 — An eight-bit storage register: (A) circuit and (B) schematic symbol.

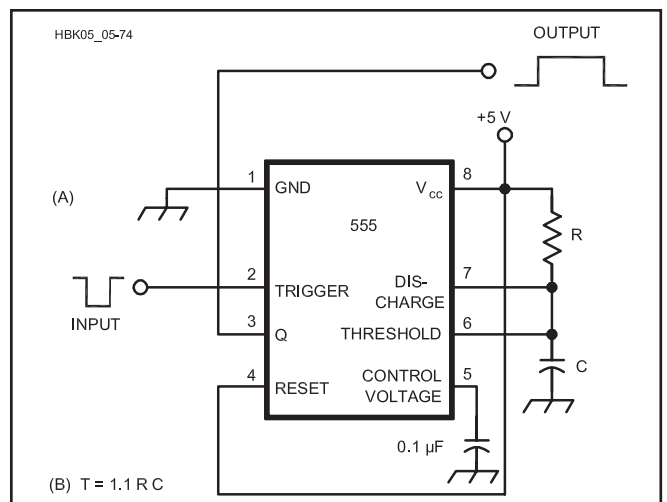

Fig 4.23 — (A) A 555 timer connected as a monostable multivibrator. (B) The equation to calculate values where T is the pulse duration in seconds, R is in ohms and C is in farads.

to generate a 50 μs pulse, but delayed from a trigger by 20 ms, two 555s might be used. The first 555, configured as an astable multivibrator, generates the 20-ms pulse, and the trailing edge of the 20-ms pulse is used to trigger a second 555 that in turn generates the 10 μs pulse. See the **Analog Basics** chapter for more information on the 555 timer and related circuits.

ASTABLE MULTIVIBRATOR

An *astable* or *free-running* multivibrator has two energy-storing elements in its feedback paths, resulting in two quasi-stable states. It continuously switches between these two states without external excitation. Thus, the astable multivibrator puts out a sequence of pulses. By properly selecting circuit components, these pulses can be of a desired frequency and width.

Fig 4.24 shows a 555 timer IC connected as an astable multivibrator. The capacitor C charges to two-thirds V_{CC} through R1 and R2 and discharges to one-third V_{CC} through R2. The ratio R1 : R2 sets the asserted high duty cycle of the pulse: t_{HIGH} / t_{PERIOD} . The output frequency is determined by:

$$f = \frac{1.46}{(R1 + 2 R2) C}$$

where:

- R1 and R2 are in ohms,
- C is in farads and
- f is in hertz.

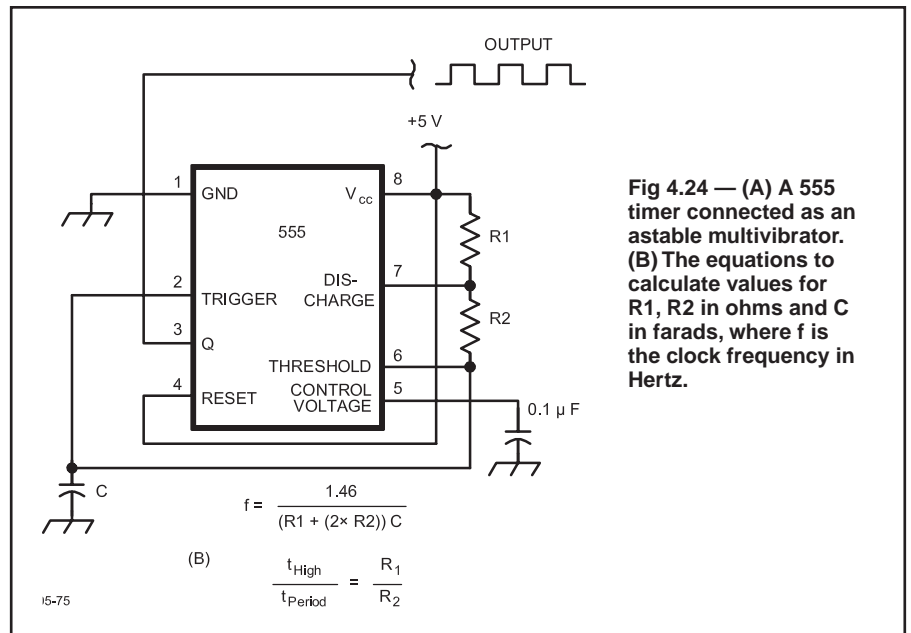

Fig 4.24 — (A) A 555 timer connected as an astable multivibrator. **(B)** The equations to calculate values for R1, R2 in ohms and C in farads, where f is the clock frequency in Hertz.

It may be difficult to produce a 50% duty cycle due to manufacturing tolerance for the resistors R1 and R2. One way to ensure a 50% duty cycle is to run the astable multivibrator at 2f and then divide by 2 with a toggle flip-flop.

Astable multivibrators, and the 555 integrated circuit in particular, are very often used to generate clock pulses. Although this

is a very inexpensive and minimum hardware approach, the penalty is stability with temperature. Since the frequency and the pulse dimensions are set by resistors and capacitors, drift with temperature and to some extent aging of components will result in changes with time. This is no different than the problem faced by designers of L-C controlled VFOs.

4.6 Digital Integrated Circuits

Integrated circuits (ICs) are the cornerstone of digital logic devices. Modern technology has enabled electronics to become smaller and smaller in size and less and less expensive. Much of today's complex digital equipment would be impossible to build with discrete transistors and discrete components.

An IC is a miniature electronic module of components and conductors manufactured as a single unit. All you see is a ceramic or black plastic package and the silver-colored pins sticking out. Inside the package is a piece of material, usually silicon, created (fabricated) in such a way that it conducts an electric current to perform logic functions, such as a gate, flip-flop or decoder.

As each generation of ICs surpassed the previous one, they became classified accord-

ing to the number of gates on a single chip. These classifications are roughly defined as:

- Small-scale integration (SSI):
10 or fewer gates on a chip.
- Medium-scale integration (MSI):
10-100 gates.
- Large-scale integration (LSI):
100-1000 gates.
- Very-large-scale integration (VLSI):
1000 or more gates.

Though SSI and MSI logic chips are still useful for building circuits to handle very simple tasks, it is more common to see them either used along with or completely replaced by programmable logic arrays and microcontrollers. In many cases you will see the smaller logic circuits referred to as "glue logic."

4.6.1 Comparing Logic Families

When selecting devices for a circuit, a designer is faced with choosing between many families and subfamilies of logic ICs. The determination of which logic subfamily is right for a specific application is based upon several desirable characteristics: logic speed, power consumption, fan-out, noise immunity and cost. From a practical viewpoint, the primary IC families available and in common use today are CMOS, with TTL a distant second place. Within these families, there are tradeoffs that can be made with respect to individual circuit capabilities, especially in the areas of speed and power consumption. Except under the most demanding circumstances, normal commercial

Fig 4.25 — Nonverting buffers used to increase fan-out: Gate A (fan-out = 2) is connected to two buffers, B and C, each with a fan-out of 2. Result is a total fan-out of 4.

grade temperature rating will do for amateur service.

FAN-OUT

Fan-out is a term with which you will need to become familiar when working with TTL logic families such as 7400, 74LS or 74S. A gate output can supply only a limited amount of current. Therefore, a single output can only drive a limited number of inputs. The measure of driving ability is called fan-out, expressed as the number of inputs (of the same subfamily) that can be driven by a single output. If a logic family that is otherwise desirable does not have sufficient fan-out, consider using noninverting buffers to increase fan-out, as shown by Fig 4.25.

Another approach is to use a CMOS logic family. These families typically have output drivers capable of sourcing or sinking 20 to 25 mA, and input current leakage in the microampere range. Thus, fan-out is seldom a problem when using these devices.

NOISE IMMUNITY

The noise margin was illustrated in Fig 4.2. The choice of voltage levels for the binary states determines the noise margin. If the gap is too small, a spurious signal can too easily produce the wrong state. Too large a gap, however, produces longer, slower transitions and thus decreased switching speeds.

Circuit impedance also plays a part in noise immunity, particularly if the noise is from external sources such as radio transmitters. At low impedances, more energy is needed to change a given voltage level than at higher impedances.

4.6.2 Bipolar Logic Families

Two broad categories of digital logic ICs are bipolar and metal-oxide semiconductor (MOS). Numerous manufacturing techniques have been developed to fabricate each type. Each surviving, commercially available family has its particular advantages and disadvantages and has found its own special niche in the market. The designer is cautioned, how-

ever, that sometimes this niche is simply the ongoing maintenance of old products. There are still very old logic families available for reasonable prices that would be considered quite obsolete and generally not suitable for new designs.

Bipolar semiconductor ICs usually employ NPN junction transistors. (Bipolar ICs can be manufactured using PNP transistors, but NPN transistors make faster circuits.) While early bipolar logic was faster and had higher power consumption than MOS logic, the speed difference has largely disappeared as manufacturing technology has developed.

There are several families of bipolar logic devices, and within some of these families there are subfamilies. The most-used bipolar logic family is transistor-transistor logic (TTL). Another bipolar logic family, Emitter Coupled Logic (ECL), has exceptionally high speed but high power consumption.

TRANSISTOR-TRANSISTOR LOGIC (TTL)

The TTL family saw widespread acceptance through the 1960s, 1970s and 1980s because it was fast compared to early MOS and CMOS logic, and has good noise immunity. It was by far the most commonly used logic family for a couple of decades. Though TTL logic is not in widespread use today for new designs, the device numbering system devised for TTL chips survives to this day for newer technologies. You will also often see TTL, especially the later low power, higher speed TTL subfamilies, in various equipment you may use and repair.

TTL Subfamilies

The original standard TTL used bipolar transistors and “totem-pole” outputs (see Fig 4.26A and B), which were a great improvement over the earlier diode-transistor logic (DTL) and resistor-transistor logic (RTL). Still, TTL logic consumed quite a bit of power

even at idle, and there were limits on how many inputs could be driven by a single output. Later versions used Schottky diodes to greatly improve switching speed, and reduced power requirements were introduced.

TTL IC identification numbers begin with either 54 or 74. The 54 prefix denotes an extended military temperature range of -55 to 125 °C, while 74 indicates a commercial temperature range of 0 to 70 °C. The next letters, in the middle of the TTL device number, indicate the TTL subfamily. Following the subfamily designation is a 2, 3 or 4-digit device-identification number. For example, a 7400 is a standard TTL NAND gate and a 74LS00 is a low-power Schottky NAND gate (The NAND gate is the workhorse TTL chip). A partial list of TTL subfamilies includes:

	74xx	standard TTL
H	74Hxx	High-speed
L	74Lxx	Low-power
S	74Sxx	Schottky
F	74Fxx	Fairchild Advanced Schottky
LS	74LSxx	Low-power Schottky
AS	74ASxx	Advanced Schottky
ALS	74ALSxx	Advanced Low-power Schottky

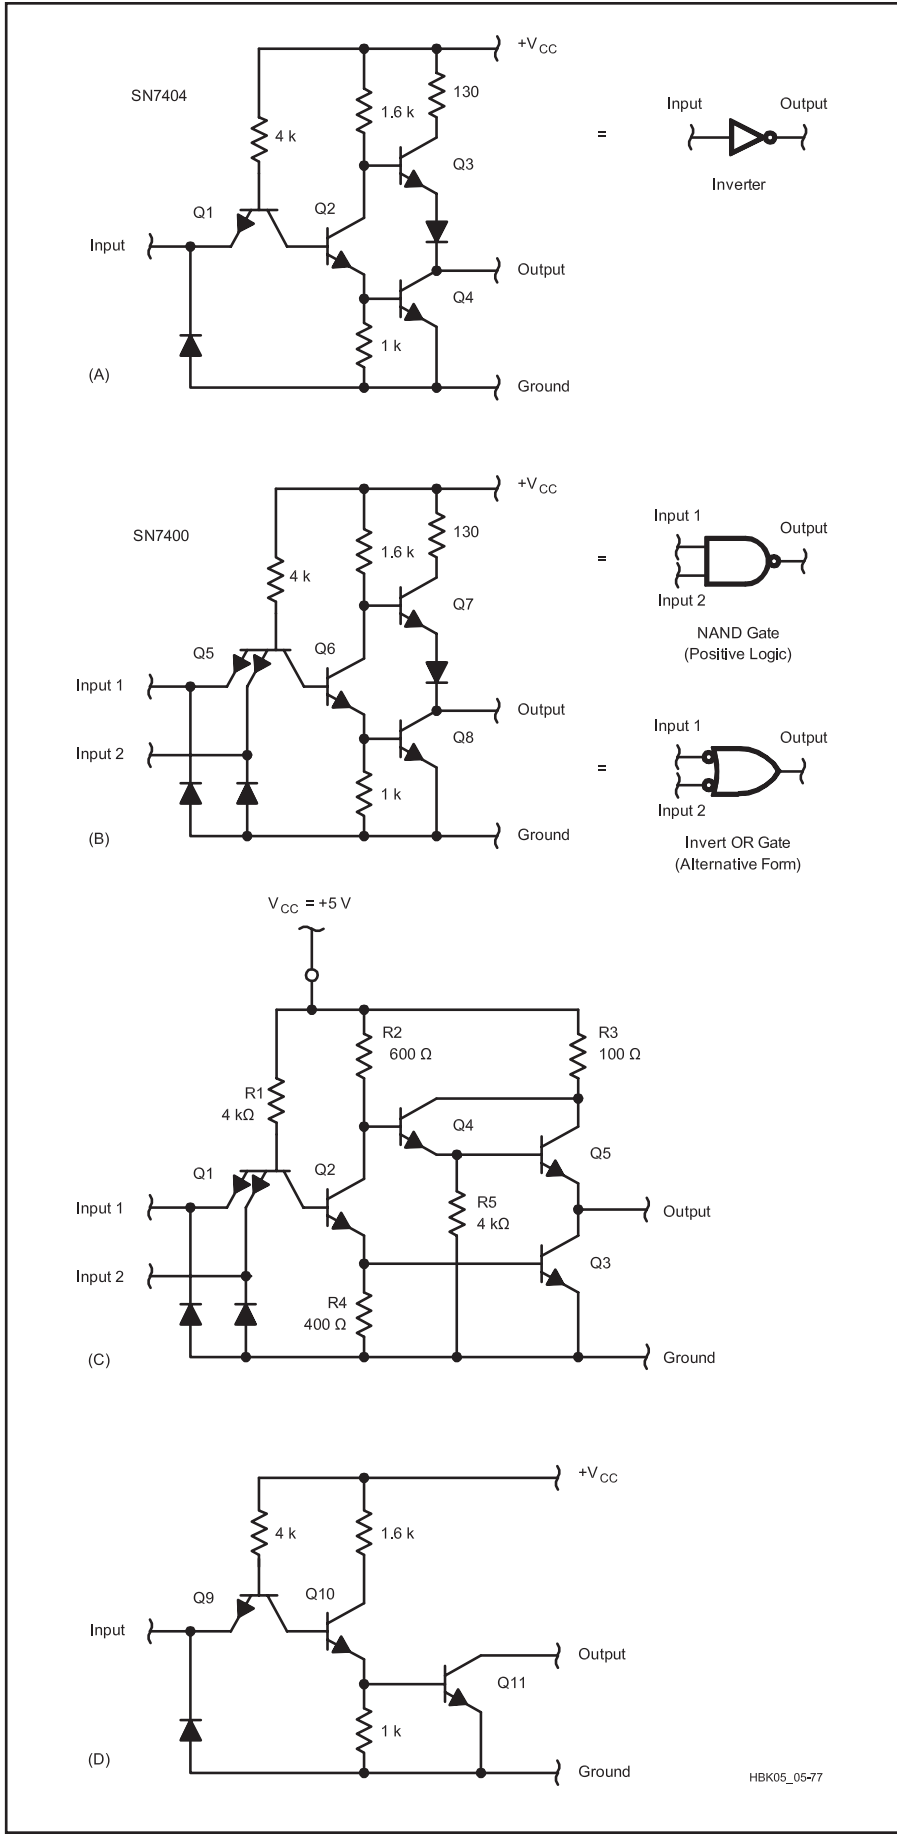

Each subfamily is a compromise between speed and power consumption. Table 5.9 shows some of these characteristics. Because the speed-power product is approximately constant, less power consumption generally results in lower speed and vice versa. The advanced low power Schottky devices (ALS, F) offer both increased speed and reduced power consumption. Historically, an additional consideration to the speed-versus-power trade-off has been the cost trade-off. For the amateur, this is not nearly the factor it once was as component costs are relatively low for the newer, faster, lower powered parts.

When a TTL gate changes state, the amount of current that it draws changes rapidly. These

Table 4.9
TTL and CMOS Subfamily Performance Characteristics

TTL Family	Propagation Delay (ns)	Per Gate Power Consumption (mW)	Speed Power Product (pico-joules)
Standard	9	10	90

ALS	5	1.3	6.5

CMOS Family	Operating with 4.5 < V _{CC} < 5.5 V	f=100 kHz	f=1 MHz	f=10 MHz	f=100 kHz	f=1 MHz	f=10 MHz
HC	18	0.0625	0.6025	6.0025	1.1	10.8	108
HCT	18	0.0625	0.6025	6.0025	1.1	10.8	108
AC	5.25	0.080	0.755	7.505	0.4	3.9	39
ACT	4.75	0.080	0.755	7.505	0.4	3.6	36

changes in current, called switching transients, appear on the power supply line and can cause false triggering of other devices. For this reason, the power bus should be adequately decoupled. For proper decoupling of TTL circuits, connect a 0.01 to 0.1 μF capacitor from V_{CC} to ground near each device to minimize the transient currents caused by device switching and magnetic coupling. These capacitors must be low-inductance, high-frequency RF capacitors (ceramic capacitors are preferred). In addition, a large-value (50 to 100 μF) capacitor should be connected from V_{CC} to ground somewhere on the board to accommodate the continually changing I_{CC} requirements of the total V_{CC} bus line. These are generally low-inductance tantalum capacitors.

Darlington and Open-Collector Outputs

Fig 4.26C and D show variations from the totem-pole configuration. They are the Darlington transistor pair and the open-collector configuration respectively.

The Darlington pair configuration replaces the single transistor Q4 with two transistors, Q4 and Q5. The effect is to provide more current-sourcing capability in the high state. This has two benefits: (1) the rise time is decreased and (2) the fan-out is increased.

Transistor(s) on the output in both the totem-pole and Darlington configurations provide active pull-up. Omitting the transistor(s) and providing an external resistor for passive pull-up gives the open-collector configuration. This configuration, unfortunately, results in slower rise time, since a relatively large external resistor must be used. The technique has some very useful applications, however: driving other devices, performing wired logic, busing and interfacing between logic devices.

Devices that need other than a 5-V supply can be driven with the open-collector output by substituting the device for the external resistor. Example devices include LEDs, relays and solenoids. Inductive devices like relay coils and solenoids need a protection diode across the coil. You must pay attention to the current ratings of open-collector outputs in such applications. You may need a switching transistor to drive some relays or other high-current loads.

Fig 4.26 — Example TTL circuits and their equivalent logic symbols: (A) an inverter and (B) a NAND gate, both with totem-pole outputs. (C) A NAND gate with a Darlington output. (D) A NAND gate with an open-collector output. (Indicated resistor values are typical. Identification of transistors is for text reference only. These are not discrete components but parts of the silicon die.)

Open-collector outputs can perform wired logic, rather than gated IC logic, by wire-ANDing the outputs. This can save the designer an AND gate, potentially simplifying the design. Wire-ANDed outputs are several open-collector outputs connected to a single external pull-up resistor. The overall output, then, will only be high when all pull-down transistors are OFF (all connected outputs are high), effectively performing an AND of the connected outputs. If any of the connected outputs are low, the output after the external resistor will be low. **Fig 4.27** illustrates the wire-ANDing of open-collector outputs.

The wire-ANDed concept can be applied to several devices sharing a common bus. At any time, all but one device has a high-impedance (off) output. The remaining device, enabled with control circuitry, drives the bus output.

Open-collector outputs are also useful for interfacing TTL gates to gates from other logic families. TTL outputs have a minimum high level of 2.4 V and a maximum low level of 0.4 V. When driving non-TTL circuits, a pull-up resistor (typically 2.2 k Ω) connected to the positive supply can raise the high level to 5 V. If a higher output voltage is needed, a pull-up resistor on an open-collector output can be connected to a positive supply greater than 5 V, so long as the chip output voltage and current maximums are not exceeded.

Three-State Outputs

While open-collector outputs can perform bus sharing, a more popular method is three-state output, or tristate, devices. The three states are low, high and high impedance, also called Hi-Z or *floating*. An output in the high-impedance state behaves as if it is disconnected from the circuit, except for possibly a small leakage current. Three-state devices have an additional disable input. When the

enable input is active, the device provides high and low outputs just as it would normally; when enable is inactive, the device goes into its high-impedance state.

A bus is a common set of wires, usually used for data transfer. A three-state bus has several three-state outputs wired together. With control circuitry, all devices on the bus but one have outputs in the high-impedance state. The remaining device is enabled, driving the bus with high and low outputs. Care should be taken to ensure only one of the output devices can be enabled at any time, since simultaneously connected high and low outputs may result in an incorrect logic voltage. (The condition when more than one driver is enabled at the same time is called *bus contention*.) Also, the large current drain from V_{CC} to ground through the high driver to the low driver can potentially damage the circuit or produce noise pulses that can affect overall system behavior.

Unused TTL Inputs

A design may result in the need for an n-input gate when only an n + m input gate is available. In this case, the recommended solution for extraneous inputs is to give the extra inputs a constant value that won't affect the output. A low input is easily provided by connecting the input to ground. A high input can be provided with either an inverter whose input is ground or with a pull-up resistor. The pull-up resistor is preferred rather than a direct connection to power because the resistor limits the current, thus protecting the circuit from transient voltages. Usually, a 1-k Ω to 5-k Ω resistor is used; a single 1-k Ω resistor can handle up to 10 inputs.

It's important to properly handle all inputs. Design analysis would show that an unconnected, or floating TTL input is usually high but can easily be changed low by only a small amount of capacitively-coupled noise.

4.6.3 Metal Oxide Semiconductor (MOS) Logic Families

While bipolar devices use junction transistors, MOS devices use field effect transistors (FETs). MOS is characterized by simple device structure, small size (high density) and ease of fabrication. MOS circuits use the NOR gate as the workhorse chip rather than the NAND. MOS families, specifically CMOS, are used extensively in most digital devices today because of their low power consumption and high speed.

P-CHANNEL MOS (PMOS)

The first MOS devices to be fabricated were PMOS, conducting electrical current by the flow of positive charges (holes). PMOS power consumption is much lower than that of bipolar logic, but its operating speed is also lower. The only extensive use of PMOS was in calculators and watches, where low speed is acceptable and low power consumption and low cost are desirable. PMOS was replaced by NMOS, which offered substantially higher switching speeds.

N-CHANNEL MOS (NMOS)

With improved fabrication technology, NMOS became feasible and provided improved performance and TTL compatibility. The speed of NMOS is at least twice that of PMOS, since electrons rather than holes carry the current. NMOS also has greater gain than PMOS and supports greater packaging density through the use of smaller transistors. NMOS has been almost completely obsolete by CMOS.

COMPLEMENTARY MOS (CMOS)

CMOS combines both P-channel and N-channel devices on the same substrate to achieve high noise immunity and low power consumption: less than 1 mW per gate and negligible power during standby. This accounts for the widespread use of CMOS in battery-operated equipment. The high impedance of CMOS gates makes them susceptible to electromagnetic interference, however, particularly if long traces are involved. Consider a trace $\frac{1}{4}$ -wavelength long between input and output. The output is a low-impedance point, hence the trace is effectively grounded at this point. You can get high RF potentials $\frac{1}{4}$ -wavelength away, which disturbs circuit operation.

A notable feature of CMOS devices is that the logic levels swing to within a few millivolts of the supply voltages. The input-switching threshold is approximately one half the supply voltage ($V_{DD} - V_{SS}$). This characteristic contributes to high noise immunity on the input signal or power supply lines. CMOS input-current drive requirements are

minuscule, so the fan-out is great, at least in low-speed systems. For high-speed systems, the input capacitance increases the dynamic power dissipation and limits the fan-out.

CMOS Subfamilies

There are a large number of CMOS subfamilies available. Like TTL, the original CMOS has largely been replaced by later subfamilies using improved technologies; in turn, these will be replaced with even newer families as technology evolves. The original family, called the 4000 series, has numbers beginning with 40 or 45 followed by two or three numbers to indicate the specific device. 4000B is second generation CMOS. When introduced, this family offered low power consumption but was fairly slow and not easy to interface with TTL.

Later CMOS subfamilies offer improved performance and, in some cases, TTL compatibility. For simplicity, the later subfamilies were given numbers similar to the TTL numbering system, with the same leading numbers, 54 or 74, followed by 1 to 4 letters indicating the subfamily and as many as 5 numbers indicating the specific device. The subfamily letters usually include a "C" to distinguish them as CMOS.

Following is a description of some of the CMOS device families available. As there are a substantial number of families offered by specific manufacturer, and there are new families being introduced frequently, this information is by no means exhaustive. A check of IC suppliers' and manufacturers' Web sites will provide the designer with a complete selection of choices to meet his or her requirements.

4000	4071B	Standard CMOS
C	74Cxx	CMOS versions of TTL

Largely obsolete today, devices in the 74C subfamily are pin and functional equivalents of many of the most popular parts in the 7400 TTL family. It may be possible to replace all TTLICs in a particular circuit with 74C-series CMOS, but this family should not be mixed with TTL in a circuit without careful design considerations. Devices in the C series are typically 50% faster than the 4000 series.

HC	74HCxx	High-speed CMOS
----	--------	-----------------

Devices in the 74HC subfamily have speed and drive capabilities similar to Low-power Schottky (LS) TTL but with better noise immunity and greatly reduced power consumption. High-speed refers to faster than the previous CMOS family, the 4000-series.

HCT	74HCTxx	High-Speed CMOS, TTL compatible
-----	---------	---------------------------------

Devices in this subfamily were designed to interface TTL to CMOS systems. The HCT inputs recognize TTL levels, while the outputs are CMOS compatible. HCT chips are

commonly used as lower powered, drop-in replacements for their pin compatible LS TTL counterparts.

AC	74ACxxxx	Advanced CMOS
----	----------	---------------

Devices in this family have reduced propagation delays, increased drive capabilities and can operate at higher speeds than standard CMOS. They are comparable to Advanced Low-power Schottky (ALS) TTL devices.

ACT	74ACTxxxx	Advanced CMOS, TTL compatible
-----	-----------	-------------------------------

This subfamily combines the improved performance of the AC series with TTL-compatible inputs.

AHCT	74AHCTxxxx	Advanced High Speed CMOS, TTL Compatible
------	------------	--

This subfamily is substantially faster than HC and HCT, but only slightly faster than ACT in switching speed. It has lower output drive capacity than AC/ACT.

New CMOS subfamilies are being introduced regularly. The current move is to lower voltage operation; where 5 V was the most common supply voltage until a few years ago, 3.3 V and lower supplies are becoming more common. Many newer microprocessors, micro-controllers and intelligent peripheral chips require 3.3 V logic.

LVC	74LVCxxxx	Low Voltage CMOS
-----	-----------	------------------

This subfamily uses a 3.3 V supply rather than 5 V. It offers low propagation delay (under 5 ns typical), extremely low supply current, robust output drive capabilities, and 5-V TTL compatible inputs.

ALVC	74ALVCxxxx	Advanced Low Voltage CMOS
------	------------	---------------------------

Even faster than LVC, this family offers propagation delays if under 3ns. Current demands are slightly higher, but still lower than 5V CMOS.

VCX	74VCXxxxx	Low voltage CMOS
-----	-----------	------------------

This family operates at supply voltages of

1.8 or 3.6 V. Offering high switching speeds and low propagation delays, it does not have TTL-compatible buffered inputs.

As with TTL, each CMOS subfamily has characteristics that may make it suitable or unsuitable for a particular design. You should consult the manufacturer's data books for complete information on each subfamily being considered.

CMOS Circuits

A simplified diagram of a CMOS logic inverter is shown in Fig 4.28. When the input is low, the resistance of Q2 is low so a high current flows from V_{CC} . Since Q1's resistance is high, the high current flows to the output. When the input is high, the opposite occurs: Q2's resistance is low, Q1's is high and the output is low. The diodes are to protect the circuit against static charges.

Special Considerations

Some of the diodes in the input- and output-protection circuits are an inherent part of the manufacturing process. Even with the protection circuits, however, CMOS ICs are susceptible to damage from static charges. To protect against damage from static, the pins should not be inserted in Styrofoam as is sometimes done with other components. Instead, a spongy conductive foam, usually black or pink in color, is available for this purpose. Before removing a CMOS IC from its protective material, make certain that your body is grounded. Touching nearly any large metal object before handling the ICs is probably adequate to drain any static charge off your body. Some people prefer to touch a grounded metal object or to use a conductive bracelet connected to the ground terminal of a three-wire ac outlet through a 10-M Ω resistor. Since wall outlets aren't always wired properly, you should measure the voltage between the ground terminal and any metal objects you might touch. Connecting yourself to ground through a 1-M Ω to 10-M Ω resistor will limit any current that might flow through your body.

Fig 4.28 — Internal structure of a CMOS inverter.

All CMOS inputs should be tied to an input signal. A positive supply voltage or ground is suitable if a constant input is desired. Undetermined CMOS inputs, even on unused gates, may cause gate outputs to oscillate. Oscillating gates draw high current, and may overheat and self destruct.

The low power consumption of CMOS ICs made them attractive for satellite applications, but standard CMOS devices proved to be sensitive to low levels of radiation — cosmic rays, gamma rays and X rays. Later, radiation-hardened CMOS ICs, able to tolerate 10^6 rads, made them suitable for space applications. (A rad is a unit of measurement for absorbed doses of ionizing radiation, equivalent to 10^{-2} joules per kilogram.)

SUMMARY

There are many types of logic ICs, each with its own advantages and disadvantages. Regardless of the application, consult up-to-date product specification sheets and manufacturer literature when designing logic circuits. IC data sheets, application notes, databooks and more are available from IC manufacturers via their Web sites. By using a search engine and entering a few key word specifications, you will locate application notes, tutorials and a host of other information.

4.6.4 Interfacing Logic Families

Each semiconductor logic family has its own advantages in particular applications. When a design mixes ICs from different logic families, the designer must account for the differing voltage and current requirements each logic family recognizes. The designer must ensure the appropriate interface exists between the point at which one logic family ends and another begins. Knowledge of the specific input/output (I/O) characteristics of each device is necessary, and knowledge of the general internal structure is desirable to ensure reliable digital interfaces. Typical internal structures have been illustrated for each common logic family. **Fig 4.29** illustrates the logic level changes for different TTL and CMOS families. Data sheets should be consulted for manufacturer's specifications.

Often more than one conversion scheme is possible, depending on whether the designer wishes to optimize power consumption or speed. Usually one quality must be traded off for the other. The following section discusses some specific logic conversions. Where an electrical connection between two logic systems isn't possible, an optoisolator can sometimes be used.

TTL DRIVING CMOS

TTL and low-power TTL can drive 74C

Fig 4.29 — Differences in logic levels for some TTL and CMOS families.

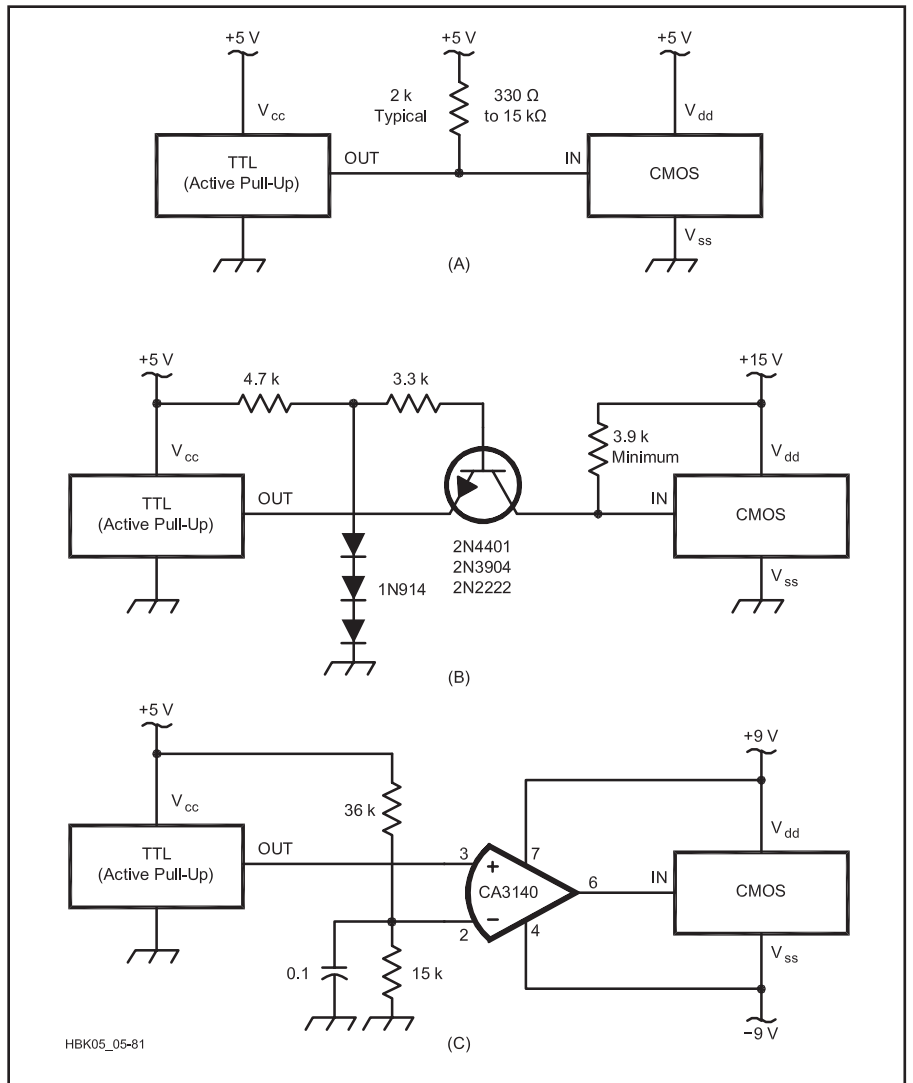

Fig 4.30 — TTL to CMOS interface circuits: (A) pull-up resistor, (B) common-base level shifter and (C) op amp configured as a comparator.

series CMOS directly over the commercial temperature range without an external pull-up resistor. However, they cannot drive 4000-series CMOS directly, and for HC-series devices, a pull-up resistor is recommended. The pull-up resistor, connected between the output of the TTL gate and V_{CC} as shown in Fig 4.30A, ensures proper operation and enough noise margin by making the high output equal to V_{DD} . Since the low output voltage will also be affected, the resistor value must be chosen with both desired high and low voltage ranges in mind. Resistor values in the range 1.5 k Ω to 4.7 k Ω should be suitable for all TTL families under worst conditions. A larger resistance reduces the maximum possible speed of the CMOS gate; a lower resistance generates a more favorable RC product but at the expense of increased power dissipation.

HCT-series and ACT-series CMOS devices were specifically designed to interface non-CMOS devices to a CMOS system. An HCT device acts as a simple buffer between the non-CMOS (usually TTL) and CMOS device and may be combined with a logic function if a suitable HCT device is available.

When the CMOS device is operating from a power supply other than +5 V, the TTL interface is more complex. One fairly simple technique uses a TTL open-collector output connected to the CMOS input, with a pull-up resistor from the CMOS input to the CMOS power supply. Another method, shown in Fig 4.30B, is a common-base level shifter. The level shifter translates a TTL output signal to a +15 V CMOS signal while preserving the full noise immunity of both gates. An excellent converter from TTL to CMOS using dual power supplies is to configure an operational amplifier as a comparator, as shown in Fig 4.30C. An FET op amp is shown because its output voltage can usually swing closer to the rails (+ and - supply voltages) than a bipolar device.

CMOS DRIVING TTL

Certain CMOS devices (including most modern 5 V powered CMOS logic families) can drive TTL loads directly. The output voltages of CMOS are compatible with the input requirements of TTL, but the input-current requirement of TTL limits the number of TTL loads that a CMOS device can drive from a single output (the fan-out).

Interfacing CMOS to TTL is a bit more complicated when the CMOS is operating at a voltage other than +5 V. One technique is shown in Fig 4.31A. The diode blocks the high voltage from the CMOS gate when it is in the high output state. A germanium diode is preferred because its lower forward-voltage drop provides higher noise immunity for the TTL device in the low state. The 68-k Ω resistor pulls the input high when the diode is reverse biased.

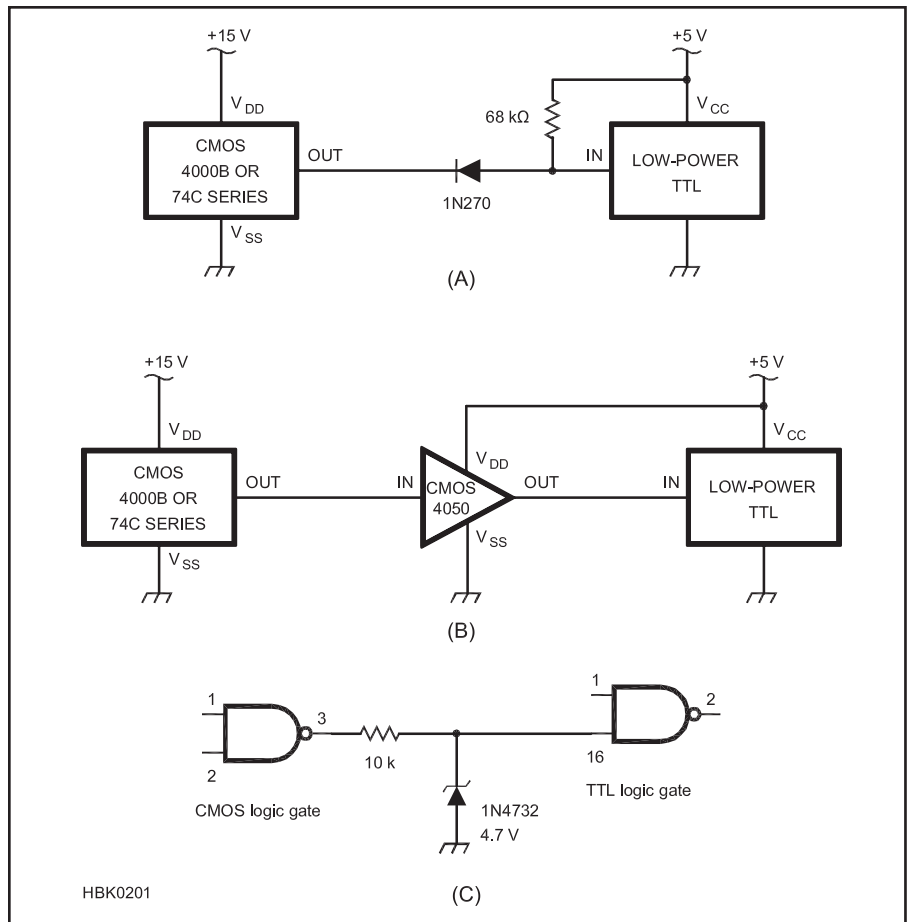

Fig 4.31 — CMOS to TTL interface circuits. (A) blocking diode chosen when different supply voltages are used. The diode is not necessary if both devices operate with a +5 V supply. (B) CMOS noninverting buffer IC. (C) Resistor/Zener circuit clamps the voltage to the TTL input at 4.7 V.

A simple resistor/Zener circuit, shown in Fig. 4.31C, can also be used. This clamps the voltage to the TTL input at 4.7 V.

There are two CMOS devices specifically designed to interface CMOS to TTL when TTL is using a lower supply voltage. The CD4050 is a noninverting buffer that allows its input high voltage to exceed the supply voltage. This capability allows the CD4050 to be connected directly between the CMOS and TTL devices, as shown in Fig 4.31B. The CD4049 is an inverting buffer that has the same capabilities as the CD4050.

5 V DRIVING 3.3 V LOGIC

Low voltage logic operating with 3.3 to 3.6 V supplies is becoming more and more common. Some of these logic families have 5 V tolerant inputs and can be driven directly by TTL levels; others require buffering to keep inputs at or below the supply voltage. Output levels may or may not be sufficient to drive TTL level inputs reliably under all conditions. The use of TTL compatible buffers (74LVC, 74ALVC) on input signals is a safe way to drive these devices. Since the low logic volt-

ages are compatible, a simple Zener clamp arrangement may also be sufficient.

3.3 V DRIVING 5 V LOGIC

Output voltages of most 3.3 V logic families are sufficient to drive the inputs of TTL-level devices. In some cases, the high level output voltage of a 3.3 V powered device may approach the lower end of the TTL level device's input range. In these cases, a pull-up resistor to 3.3 V will usually be sufficient. It is also possible to use an IC or transistor buffer.

4.6.5 Programmable Logic

As digital logic designs became more and more complex, the size and power consumption of their implementations grew. PLDs (*Programmable Logic Devices*) were introduced to allow the designer to produce application-specific logic without the expense and delay of fabricating custom chips. As explained earlier, the design of a logic circuit begins with a description; this description is used to determine an equation; then the equation is expanded to components. With

programmable logic we can shortcut this process by implementing the equations themselves, programming them into a generic array of gates.

Several families of programmable logic devices have been introduced over the years. The earliest were Programmable Array Logic (PAL) chips, consisting of an array of gates whose inputs, interconnections and outputs

could be configured by blowing internal fuses according to a specific design. PALs were followed by Generic Array Logic (GALs), which have more gates and more flexible I/O pin logic. GALs are also erasable and reprogrammable.

Later developments led to the Field Programmable Gate Array (FPGA) and other programmable logic arrays. These devices

can contain anywhere from several hundred to millions of logic gates, and up to more than a thousand I/O pins. The connections between gates, and thus the device's function, is determined by complex program code. PLDs can be made to replace large numbers of individual SSI, MSI and even LSI chips, up to and including entire microprocessor cores.

4.7 Analog-Digital Interfacing

Quite often, logic circuits must either drive or be driven from non-logic sources. A very common requirement is sensing the presence or absence of a high (as compared to +5 V) voltage or perhaps turning on or off a 120 V ac device or moving the motor in an antenna rotator. A similar problem occurs when two different units in the shack must be interfaced because induced ac voltages or ground loops can cause problems with the desired signals.

A slow speed but safe way to interface such circuits is to use a relay. This provides absolute isolation between the logic circuits and the load. **Fig 4.32A** shows the correct way to provide this connection. The relay coil is selected to draw less than the available current from the driving logic circuit. The diode, most often a 1N914 or equivalent switching diode, prevents the inductive load from back-biasing the logic circuit and possibly destroying it.

It is often not possible to find a relay that meets the load requirements *and* has a coil that can be driven directly from the logic output. **Fig 4.32B** shows two methods of using transistors to allow the use of higher power relays with logic gates.

Electro-optical couplers such as optoisolators and solid state relays can also be used for this circuit interfacing. **Fig 4.32C** uses an optoisolator to interface two sets of logic circuits that must be kept electrically isolated, and **Fig 4.32D** uses a solid state relay to control an ac line supply to a high current load. Note that this example uses a solid state relay with internal current limiting on the input side; the LED input has an impedance of approximately 300 Ω . Some devices may need a series resistor to set the LED current; always consult the device data sheet to avoid exceeding device limits of the relay or the processor's I/O pin. See the **Analog Basics** chapter for more information on optoisolators.

For safely using signals with voltages higher than logic levels as inputs, the same simple resistor and Zener diode circuit similar to that shown in **Fig 4.31C** can be used to clamp the input voltage to an acceptable level. Care

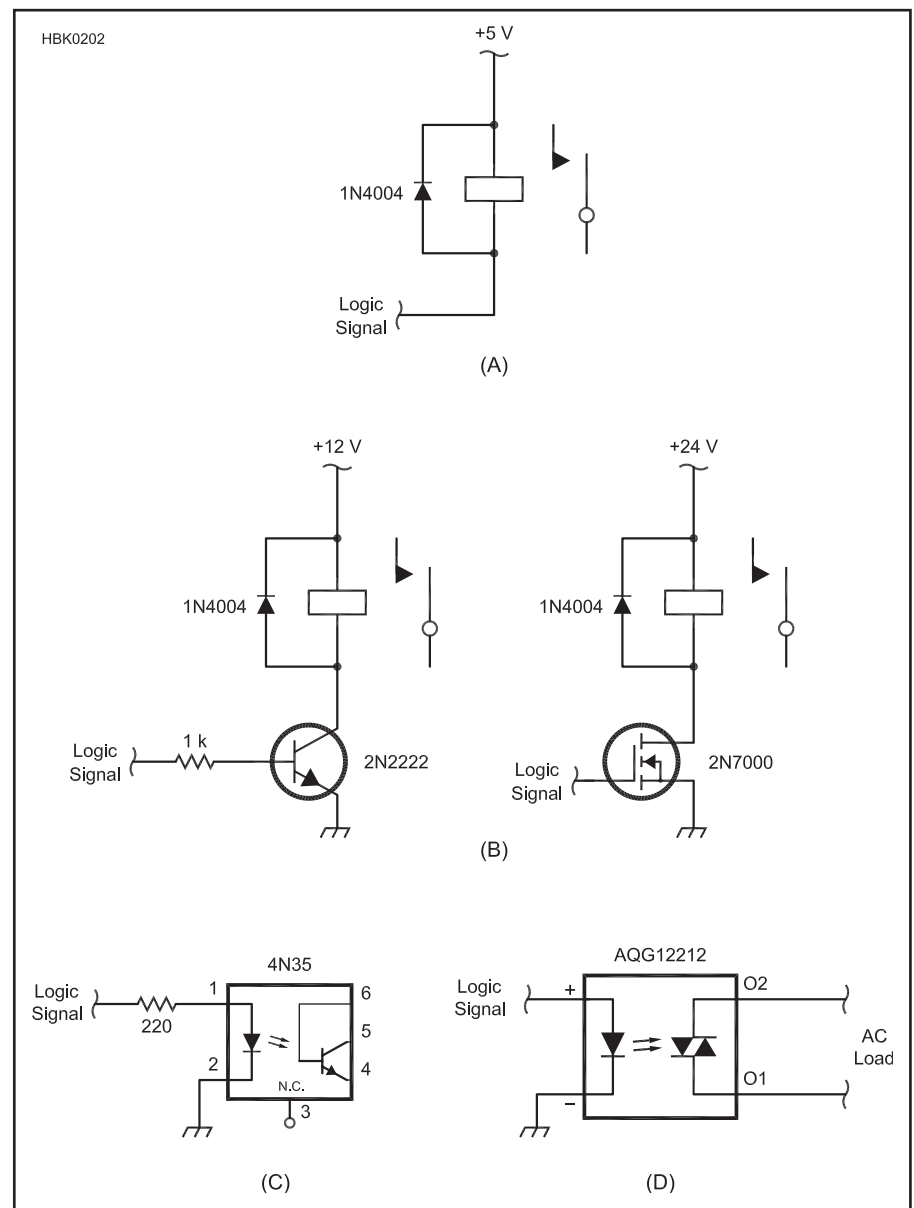

Fig 4.32— Interface circuits for logic driving real-world loads. (A) driving a relay from a logic output; (B) using a bipolar transistor or MOSFET to boost current capacity; (C) using an optoisolator for electrical isolation; (D) using a solid-state relay for switching ac loads.

must be used to choose a resistor value that will not load the input signal unacceptably.

4.7.1 Analog-Digital Converters

Of course not all signals in the real world are digital. It is often desirable to know the exact voltage of an analog sensor, for example, or to measure the level of something — light, water, current or some other input. Similarly, an analog output can be quite useful for controlling or indicating things that are better left in the analog domain. For this reason we have two types of converters. The analog-to-digital converter (ADC) and digital-to-analog converter (DAC) handle these tasks for us, and they are often fairly easy to use. Additional information on ADCs and DACs may be found in the **Analog Basics** chapter.

ADC AND DAC DIGITAL INTERFACES

Interfaces for ADC and DAC chips are generally classed as serial or parallel. Serial interfaces can vary in speed, complexity and the number of wires required for operation. A serial interface has the advantage of requiring a small number of processor I/O pins to accommodate data of any length. Whether your ADC is providing 8, 10 or 12 bits, the same small number of I/O signals are used. Some of the most common serial interfaces used for ADC and DAC chips are as follows:

Serial Peripheral Interconnect (SPI). This four-wire, synchronous bus and protocol use a common CLK signal, plus data lines for

master-to-slave (Master Out-Slave In, or MOSI) and slave-to-master (Master In-Slave Out, or MISO). Multiple devices can be used by providing each with its own Slave Select (SS) signal. Speeds can range up to 70 Mbit/s, depending on the capabilities of the master and slave devices.

Microwire. This earlier predecessor to SPI implements a half-duplex subset of SPI using the same signals.

Inter-IC Communication (I2C) bus. Originally developed by Philips, this synchronous two-wire bus and protocol use a pair of open-drain lines, Serial Clock (SCL) and Serial Data (SDA). Communication is controlled by a master node, though there may be more than one master attached to the bus. Many peripheral devices can be attached to an I2C bus; a device address is sent by the master to initiate communication with a slave. Speeds range from 10 kbit/s (low speed) to 100 kbit/s (standard) to 400 kbit/s (high speed) and higher.

Parallel interfaces generally have eight or more data lines, plus a chip select, read/write and interrupt controls. The read and write signals may be separate, or may be a single read/write signal — low for WR, and high for RD, for example, or vice versa. The interrupt signal can be used to indicate the end of a conversion cycle to the CPU. In this way the processor can tell the converter to start a conversion, then continue processing until the conversion is complete. This can allow more processing to be done without waiting idly for the ADC or DAC to complete its conversion.

PROGRAMMING AND COMMUNICATION

Many ADC chips have multiplexed inputs that allow you to use one chip to sample and digitize more than one analog input. In these devices, there is a single converter but several inputs that can be internally switched. Additionally, it is common to be able to program the inputs as single-ended or differential. In the case of the popular ADC0832, for example, you can use its two analog input pins as two separate inputs, or as a single differential input. The ADC0838 expands this to eight single-ended or four differential inputs. In the case of the ADC0832, modes can be mixed. This allows the use of various combinations of single-ended and differential inputs, as needed.

Programming and selecting the inputs is done by sending a series of bits from the processor to the ADC at the beginning of the conversion cycle. **Fig 4.33** shows a diagram of the signal timing used with the ADC0834 ADC. In the case of the ADC0834, a series of four bits are sent by the CPU to the ADC to select single ended or differential mode, the polarity of the input, and which of the four inputs (or two input pairs) is to be selected. Immediately following the fourth bit, the ADC starts its conversion and starts sending the resulting data to the CPU. Other chips in this family and many from different manufacturers use a similar scheme; the number of program bits sent by the CPU depends on the number of inputs present.

Some chips are also configurable for data format as well. For example, a 12 bit ADC

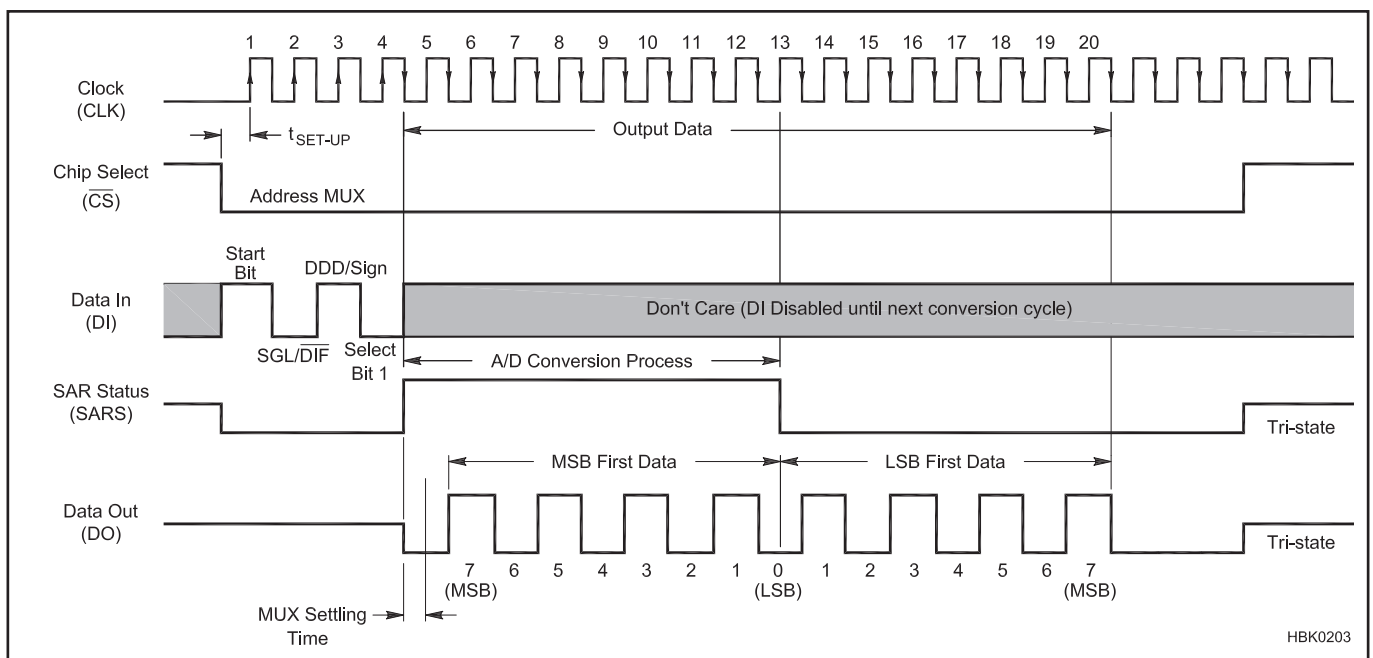

Fig 4.33 — ADC0834 timing diagram. Much more information about this device is available from the National Semiconductor datasheet.

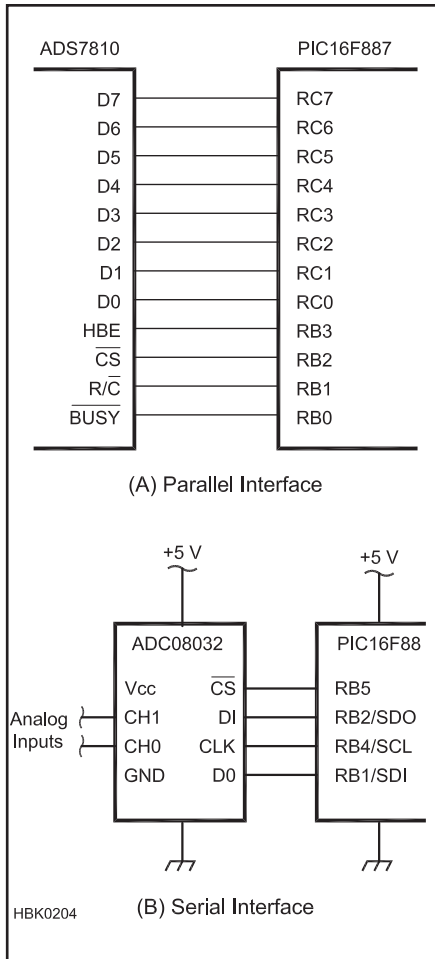

Fig 4.34 — A/D converter to microcontroller interfacing: (A) parallel; (B) serial.

may be programmable to send a sign bit for a total of 13 data bits rather than 12. Data may also be sent LSB first or MSB first. Some chips are configurable for either parallel or serial data transfer; this selection is generally made by pulling a pin or pins high or low to select the mode. In all cases, a careful reading of the device data sheet is your best bet for successful integration of the converter into your project.

INTERFACING TO YOUR MICROCONTROLLER

Probably the simplest way to interface an external ADC to your microcontroller is by using a parallel interface. In this case, one simply manipulates the I/O pins from the CPU to start the conversion, then reads the resulting data from the data lines. This method is often less desirable than a serial connection, though, due to the limited number of I/O pins usually available. **Fig 4.34A** shows an example of a parallel interface between a 12 bit ADC (the ADS7810) and a PIC microcontroller (the PIC16F887). In this example, only eight data lines are used for twelve data bits. The HBE signal is used to gate the four high order bits onto the data lines after the low order bits have been read. This saves four I/O pins on the microcontroller.

Serial connections save I/O pins, allow the use of physically smaller IC packages, and can be quite easy to implement. **Fig 4.34B** shows an example of a serial interface. If your CPU has a hardware SPI/Microwire interface built in, communication with the ADC can be quite simple from a program standpoint. Simply send the program word, if required, and read the resulting data — either one or

two bytes, depending on the ADC resolution. If you do not have built-in hardware SPI, the program code to “bit-bang” the interface is fairly simple to implement. (See www.dlpdesign.com/images/bit-bang-usb.pdf for more information on bit-bang.)

Note that **Fig 4.34B** shows separate grounds for the processor and ADC. This is required to keep switching noise and transients from affecting the accuracy of readings. A separate analog supply is also recommended. The analog supply should be well filtered using a combination of smaller ceramic or monolithic, and bulk tantalum or other low-ESR capacitors. This should be done for the analog supply and reference voltage supplies. The more noise you can eliminate from the analog supply, the more reliable your readings will be.

MICROCONTROLLERS WITH BUILT-IN CONVERTERS

It is not at all unusual to find microcontrollers with built-in analog-to-digital converters, complete with multiplexers, analog supply pins and V_{REF} inputs. For example, many Microchip PIC processors are equipped with 10 bit ADCs, and have 5, 8 or more pins that can be configured as multiplexed analog inputs. A few also have digital-to-analog, though this is not nearly as common. While these devices can be extremely useful, there are some limitations. Reference voltages are generally limited to the device’s supply voltage. Internal CPU-generated noise may also somewhat limit the usefulness of the converter. With careful attention to device specifications and limitations, though, a built-in ADC may meet the needs of a wide range of uses.

4.8 Microcontroller Overview

This section surveys microcontroller characteristics and applications as they pertain to typical Amateur Radio projects and equipment. The reader interested in using microcontrollers is directed to the many books and Internet resources that exist for learning how to apply microcontrollers. Manufacturer websites such as Microchip (www.microchip.com), Freescale (www.freescale.com) and Atmel (www.atmel.com) are a good place to start. There are also a number of message boards, forums and email lists devoted to specific processor families, such as the PICList (www.piclist.com) or the Arduino User Forum (<http://arduino.cc/forum>). Local users groups are often active in large cities. Online communities of microprocessor users are very fluid — use Internet search engines to find current resources.

4.8.1 Selecting a Microcontroller

There are a number of microcontroller families available from several manufactures, each with its own advantages and disadvantages. At the time of this writing, the more popular options for amateur use come from Microchip (PIC product line), Atmel (AVR, ATmega, 8051 and other product lines), Freescale (68HC11, HC08, HC16 and other product lines), and many manufacturers who are building chips based on the venerable Intel 8051 architecture. In addition to these you will see and hear of the Texas Instruments MSP430, ARM, and many others.

Designing projects using microcontrollers can range from relatively simple to quite complex. On the simpler end of the scale are several products intended to bring microcontroller based design ability to people who would otherwise not be able to use these devices. Various breadboard kits and development systems are available to simplify hardware development and program downloading. The following three systems are particular popular:

- Arduino (www.arduino.cc) — based on an AVR microcontroller, Arduino boards are available with a variety of capabilities and interfaces. Add-on modules called “shields” are added to interfaces provided on the Arduino board. Software is written in C or C++ and downloaded to the microcontroller. The manufacturer provides free development software.

- Parallax BASIC Stamp (www.parallax.com) — a single-board system containing a PIC microcontroller preloaded with PBASIC. Software is written in an editor program on the PC and then downloaded.

- PICAXE — a variety of PIC microcontroller with a special form of BASIC. Various sizes of microcontrollers are available with different numbers of I/O pins and clock speeds. The user is responsible for building the circuit board that supports the microcontroller.

In each of these cases, the user does not necessarily need to have a deep understanding of the details of the microcontroller or its operation. The circuit can be designed with attention paid to keeping signal levels within the limits of the device. Then, one simply writes a program to perform the functions required. To be sure, there are trade-offs. The built-in firmware required to allow the user to write a program may be in a simple language such as BASIC that takes up space and processor cycles, so execution speed is not as fast and programs are somewhat limited.

The BASIC Stamp and PICAXE use specific variants of the PIC microcontroller, so if you need features that are not present in those chips you will need to take a different approach. Still, these can be extremely valuable tools that the average amateur can use with very little time and money invested.

There is a very broad range of microcontrollers available to meet nearly any need. Available devices include 8 bit, 16 bit and 32 bit processors with internal program memory ranging from 512 words up to 256 kbytes and more. At the low end are very low cost, physically small devices (down to 8 pin ICs) that can perform relatively simple tasks with ease. Larger, faster processors may include more memory, more I/O pins, and specialized peripherals. Some of the more common features are ADCs, DACs, pulse width modulation (PWM) outputs, USB interface hardware or digital signal processing.

I/O REQUIREMENTS

Selecting a microcontroller for a new project involves evaluating your requirements and prior experience. First, evaluate the number of inputs and outputs you are likely to need. If, for example, you need to sample an analog voltage and two switch closures and generate a serial data stream, you will need one analog input and three or more digital I/O pins. Depending on memory requirements, even some of the smallest devices will fit the bill. For a more elaborate design, you may need to scan a 4×4 key switch matrix, drive an LCD module with a parallel interface, control a number of LEDs and interface to a PC through a USB port. In this case, the number of I/O pins needed will eliminate a large number of devices from consideration.

CPU SIZE, PERFORMANCE AND MEMORY

If you are a computer user, you are used to seeing 32 bit and 64 bit microprocessors, many with more than one CPU core on the same chip. In the world of embedded microcontrollers, things are a little different. Instead of handling an operating system and a large number of different programs, the microcontroller only has to execute one program and is completely dedicated to that task. Unless you require very high speed I/O, need very intensive processing or will be using DSP, a simple 8 bit processor may be more than sufficient. There are dozens of ham related products that use embedded controllers — iambic keyers, APRS transponders, repeater controllers, antenna rotator controls and many other accessories that all use simple 8 bit processors with surprisingly small amounts of program memory. On the other hand, if you are designing a new rig or antenna tuner that will require DSP, chances are you may need a more robust processor.

If you are unsure of what your project will require, you may want to pick a processor family that has scalable, pin-compatible members. For example, Microchip offers processors ranging from 8 bit and 5 million instructions per second (MIPS) with 7 kbytes of program memory, to 16 bit with 48 kbytes of program memory at 30 MIPS. All are pin-compatible, so if you find you need more speed, more memory or more built-in peripherals, you can drop in a different processor without changing the hardware.

Also take into account the physical packaging. Some products are available in through-hole, dual inline (DIP) packages; others are available only in surface mount versions. This can make a difference if you lack the equipment, expertise or desire to work with surface mount components.

SPECIALIZED PERIPHERALS

Will you need a USB interface? Analog inputs? DSP? Precision timekeeping? It may be easier to select a processor that has the features you need built in. On the other hand, it is relatively easy to add an external real-time clock, ADC or DAC, and it takes only a few I/O pins. There are several USB interface chips available that will handle communication with your PC, and present an asynchronous serial data interface to the microcontroller. This can save a lot of firmware development time and frustration.

HARDWARE COST AND DEVELOPMENT TOOLS

The cost of the actual microcontroller may be a factor, or it may not. If you are building a

one-off project for your own use, there is not much difference between using a \$3 chip and a \$30 chip with a built-in BASIC interpreter. The difference in time and effort to develop the firmware may make it well worth the extra money for the easier-to-use solution. If you plan to manufacture your device for a larger

audience, the cost difference may lead you to make a different choice.

Take into account the cost of the software and hardware tools needed for development. Does the manufacturer offer a free set of firmware development tools, or will you have to spend extra money for an assembler or

compiler? Is there a low cost development kit available with the PC interface you need? Does the device require a simple PC interface to program, or a more expensive dedicated programmer? Do you have any previous experience with the processor family, or will it be a completely new effort for you?

4.9 Personal Computer Interfaces

This section provides an overview of the personal computer (PC) digital interfaces used in the amateur station. Detailed information on using these interfaces is available online, especially in users groups and specialized forums for specific software and hardware applications. This book's chapters on **DSP and Software Radio Design**, **Digital Modes**, and the CD-ROM chapter **Digital Communications** provide more information on specific applications and techniques. The **Station Accessories** chapter includes PC interface construction projects, as well.

4.9.1 Parallel vs Serial Signaling

To communicate a word to someone across the room, you could hold up flash cards displaying the letters of the word. If you hold up four flash cards, each with a letter on it, all at once, then you are transmitting in parallel. If, instead, you hold up each of the flashcards one at a time, then you are transmitting in serial. *Parallel* means all the bits in a group are handled exactly at the same time. *Serial* means each of the bits is sent in turn over a single channel or wire, according to an agreed sequence. **Fig 4.35** illustrates parallel and serial signaling.

Both parallel and serial signaling are appropriate for certain circumstances. Parallel signaling is faster, since all bits are transmitted simultaneously, but each bit needs its own conductor, which can be expensive. Parallel signaling is more likely to be used for internal communications. For spanning longer distances, such as to an external device, serial signaling is more appropriate. Each bit is sent in turn, so communication is slower, but it also is less expensive, since fewer channels are needed between the devices.

Most amateur digital communications use serial transmission to minimize cost and complexity. The number of channels needed for signaling also depends on the operational mode. One channel is required per bit for simplex (one-way, from sender to receiver only) and for half-duplex (two-way communication, but only one person can talk at a time), but two channels per bit

are needed for full-duplex (simultaneous communications in both directions).

PARALLEL I/O INTERFACING

Fig 4.36 shows an example of a parallel input/output interface, similar to the parallel printer ports once common in PCs. Typically, they have eight data lines and one or more handshaking lines. *Handshaking* involves a number of functions to coordinate the data

transfer. For example, the READY line indicates that data are available on all eight data lines. If only the READY line is used, however, the receiver may not be able to keep up with the data. Thus, the STROBE line is added so the receiver can determine when the transmitter is ready for the next character.

Interfacing to the parallel port is very simple and can be done in many languages and under many operating systems. It is an easy way to get a PC to act as a controller in the shack and around the home, with from 8 to 12 independent input or output wires. You can get an old computer either virtually free or for just a few dollars and use it exclusively as a controller. (New computers usually do not have a parallel port.)

By searching the Internet for a combination of "parallel port interface" and the language of your choice (for example, Visual BASIC or C), you can find detailed interfacing and programming instructions. It is a good and relatively simple place to "roll your own," compared to the protocol requirements of interfacing with the serial port or USB.

For more information, including practical circuits, see "Interfacing to the Parallel Port" by Paul Danzer, N111, on the CD-ROM included with this book.

SERIAL I/O INTERFACING

Serial input/output interfacing is more complex than parallel, since the data must be transmitted based on an agreed sequence.

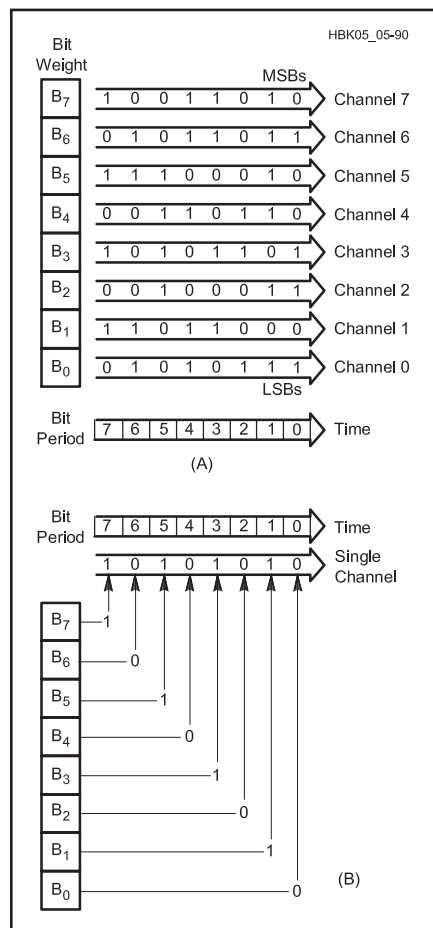

Fig 4.35 — Parallel (A) and serial (B) signaling. Parallel signaling in this example uses 8 channels and is capable of transferring 8 bits per bit period. Serial transfer only uses 1 channel and can send only 1 bit per bit period.

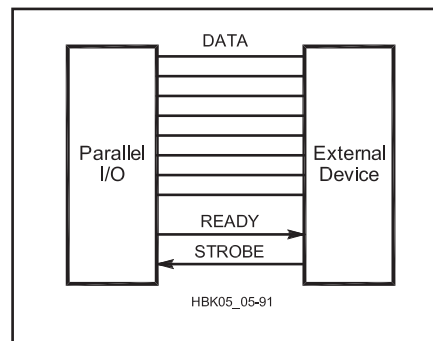

Fig 4.36 — Parallel interface with READY and STROBE handshaking lines.

For example, transmitting the 8 bits (b7, b6, . . . b0) of a word includes specifying whether the least significant bit, b0, or the most significant bit, b7, is sent first. Fortunately, a number of standards have been developed to define the agreed sequence, or encoding scheme.

In order to use a serial interface between a computer and a serial device such as a modem, printer or a new transceiver, several things must be set the same on both ends of the connection. The first is the data rate, the choices for which are usually limited to specific values between 300 and 115200 bits per second for historical reasons. The next is the data format — 7 or 8 bits, and with even, odd or no parity. Finally, both devices must be using the same handshaking method. The usual choices are RTS/CTS, DSR/DTR, or XON/XOFF. The first two use extra signals (and therefore extra wires) to indicate when the transmitting device has data to send, and when the receiving device is able to accept data. In the third method, XON/XOFF, the device receiving data will send an XOFF control character to the transmitting device to indicate that it can no longer accept data. When the transmitting device sees the XOFF it stops sending until it receives an XON from the other end. Each method has its advantages and disadvantages. For example, XON/XOFF needs no extra wires, but response is not instantaneous. Both ends must have some data buffer space and logic to support the handshake.

4.9.2 Standard Data Interfaces

This section covers a set of common data interfaces used in the amateur station. See the **Component Data and References** chapter for details on computer connector pinouts.

SIGNALING LEVELS

Inside equipment and for short runs of wire between equipment, the normal practice is to use neutral keying; that is, simply to key a voltage such as +5 V on and off. In neutral keying, the off condition is considered to be 0 V. Over longer runs of wire, the line is viewed as a transmission line, with distributed inductance and capacitance. It takes longer to make the transition from 0 to 1 or vice versa because of the additional inductance and capacitance. This decreases the maximum speed at which data can be transferred on the wire and also may cause the 1s and 0s to be different lengths, called bias distortion. Also, longer lines are more likely to pick up noise, which can make it difficult for the receiver to decide exactly when the transition takes place. Because of these problems, bipolar keying is used on longer lines. Bipolar keying uses one polarity (for example +) for a logical 1 and the other (– in this example) for a 0. This means

that the decision threshold at the receiver is 0 V. Any positive voltage is taken as a 1 and any negative voltage as a 0.

EIA-RS-232

The serial bus protocol EIA-RS-232 addresses this issue (however, a Mark “1” is a negative voltage and a Space “0” is positive). Generally called RS-232, this protocol defines connectors and voltages between data terminal equipment (DTE) such as a PC, and data communications equipment (DCE), such as a modem or TNC.

The connector is the DB-25 (25 pin), or DB-9 (9 pin) version — though RS-232 interfaces have also been implemented using nonstandard connectors such as RJ45, 3.5 mm audio plugs and many others. Signaling voltages are defined between +3 V and +25 V for logic “0” and between –3 V and –25 V for logic “1.” Although the top data rate addressed in the specification is only 20 kbit/s, speeds of up to 115 kbit/s are commonly used. Communications distances of hundreds of meters are possible at reasonable data rates.

Since neutral keying is usually used inside equipment and bipolar keying for lines leaving equipment, signals must be converted between bipolar and neutral. Discrete level shifters or op amp circuits may perform this task, or low cost specialized IC line drivers and receivers are available.

UNIVERSAL SERIAL BUS (USB)

USB is a computer standard for an intelligent serial data transfer protocol, and it has become the standard for nearly all connections between a PC and its external peripherals. It has largely replaced serial, parallel, keyboard and mouse ports as well as SCSI and numerous other buses in consumer PCs.

In addition to higher speed than RS-232 and parallel ports, USB offers reasonable power availability to its loads, or functions. Under certain circumstances, up to 127 hubs and functions may connect to a single computer. USB requires that each function have on-board intelligence and that it negotiate with the host for power and bandwidth allocation. USB also has the major advantage of hot-pluggability — the PC need not reboot when new functions are added.

The USB connectors use four-conductor cable, with two bidirectional, differential data lines, power, and ground. Approximately 5 V at 100 mA is allowed per function, with up to 500 mA available if the host system has the capability. This means that relatively sophisticated devices, such as modems, small video cameras, or hand-held scanners may operate from the bus without additional power supplies. It has also become common to use USB for connecting and charging a wide range

of devices such as cellular phones, cameras and GPS units. When a USB connecting cable is used, proper connections and proper flow are ensured by using a rectangular (USB “A”) connector on the host and a different connector (USB “B”, Mini-B or Micro-B) on the attached function.

There are currently two USB standards in general use. USB 1.1, somewhat obsolete but common in PCs just a few years old, is capable of 12 megabits per second (12 Mbit/s). USB 2.0 is the later standard and is rated up to 480 Mbit/s. Most USB 2.0 ports will allow the use of older USB 1.1 devices — that is, they are backward compatible. However maximum cable lengths and available power to devices may be affected. USB 3.0 uses additional wires and some new connectors to enable communication at up to 5 Gbit/s in its SuperSpeed configuration.

Older PCs that have just one or two USB ports can have additional ports by adding an inexpensive USB port expander, commonly called a USB hub. Some units obtain their power from the host computer’s USB port, and distribute only the USB signals along with the remaining power available from the host. Others come with a small power supply that provides the normal power to each new USB port.

If the PC does not have any USB ports, an expansion card can be used to add USB ports. It is quite common to see new personal computers without any serial or parallel ports, with USB replacing these functions. If you need to use your older serial or parallel peripheral devices with these “legacy-free” PC systems, adapter cables are available to connect them to USB ports.

ETHERNET

For wired networks, 100BaseT or “fast Ethernet” has been the standard for a number of years, with low cost hubs and switches commonly available. The 100BaseT systems are rated to 100 Mbit/s and use unshielded, twisted-pair Category 5 network cable. Each computer on the network connects to a central hub or switch.

More recently, 1000BaseT (gigabit Ethernet, or GigE) and is quickly replacing 100BaseT even at the consumer level. Gigabit Ethernet also uses Cat 5 cable, though Cat 5e or Cat 6 is often recommended. Explanation of the MBaseN and Category N terminology can be found in many available networking books.

Mutual interference with ham station operation is not uncommon. A 10 Mbit/s signal, if all bit positions are filled, means that unshielded wire is carrying 10 MHz and various harmonics of 10 MHz around the shack. When digital words are going through the network, any number of frequencies may

be present on the wires and the wires may be very susceptible to pick-up from HF, VHF and UHF signals. In addition, cable and DSL modems may not only transmit various frequencies (especially on VHF) but lose data when a few hundred watts on a ham band is present. Some RF in the shack that can normally be ignored can easily bring down a network. Unfortunately, it is also common for this equipment to have “noisy” switching power supplies that can wreak havoc on a ham’s sensitive receiver. See the **RF Interference** chapter for more information on dealing with RFI from networking equipment.

WIRELESS NETWORKS — WIFI

The other technology commonly found in home and office networks is IEEE 802.11 wireless. These networks use low-power, spread spectrum transceivers operating in the 2.4 and 5.2-5.8 GHz range to transfer data at nominal rates up to 54 Mbit/s and higher. Older equipment used the 801.11b protocol at 11 Mbit/s; newer gear commonly found at low prices uses 802.11g at 54 Mbit/s maximum data rate. The 802.11n protocol supports data rates up to several hundred megabits per second in the 2.4 and 5 GHz ranges.

These data rates are the maximum under ideal conditions, and it is not uncommon to see links running at significantly lower speeds as the *wireless access point* (WAP) and the wireless adapter dynamically adapt to the

conditions. Still, performance is adequate for most uses, and the lack of network cabling makes wireless networking attractive in many situations.

Wireless networks actually appear to be less susceptible to mutual interference, since they are not connected to long runs of unshielded wire that easily act as both transmitting and receiving antennas. The frequency bands used for wireless networks are reasonably far removed from normal ham operations at frequencies below 2.4 GHz, but a high power VHF or UHF station may interfere with such a network. Also, some of the channels used for 802.11b and 802.11g network equipment fall within the amateur spectrum allocation in the 2.4 GHz band.

CABLE REPLACEMENT — BLUETOOTH AND ZIGBEE

A number of low power, short range data links have been created to replace cable based interfaces such as USB and RS-232. These are digital protocols that use unlicensed spectrum in the ISM bands. Two of the most popular as of early 2013 are Bluetooth (www.bluetooth.com) and Zigbee (www.zigbee.org). Most technologies of this type are either initially or permanently developed as implementations of an IEEE 802.x standard.

Bluetooth data links operate in the 2.4 GHz band and are primarily used for streaming audio and high speed digital links up to

several megabits per second. Bluetooth links use frequency-hopping spread-spectrum technology. It can also support personal area networks (piconets or PANs) at various levels of security. Up to seven devices can share a Bluetooth interface with a host. A process called synchronization is used to associate the various devices.

Zigbee is designed for ad-hoc mesh networking applications and operates in the 902 MHz ISM band in North America. Zigbee’s maximum data rate is 250 kbit/sec. Because of the lower data rate, most Zigbee applications are designed for control and monitoring applications.

REPLACING COM AND LPT PC INTERFACES

USB-to-serial and USB-to-parallel adapters are relatively inexpensive and easy to find. Note, however, that not all of them support all of the handshaking signals we may require, and some may have delays or inadequate drivers. Be prepared to try several different brands to find one that works with your equipment. Users groups for specific equipment or software are good resources to find out what brands and models of port replacement accessories are compatible and operate properly. While they are becoming less common, there is also still a market for add-in PCI bus cards to add serial, parallel and other ports to desktop computers.

4.10 Glossary of Digital Electronics Terms

AND gate — A logic circuit whose output is 1 only when all of its inputs are 1.

Astable (free-running) multivibrator — A circuit that alternates between two unstable states. This circuit could be considered as an oscillator that produces square waves.

Asynchronous flip-flop — A circuit, also called a *latch*, that changes output state depending on the data inputs, without requiring a clock signal.

Binary — A base-2 number system used in digital electronics that uses the symbols 0 and 1.

Binary coded decimal (BCD) — A simple method for converting binary values to and from decimal for inputs and outputs for user-oriented digital systems. BCD was widely used in the days of 7-segment LED displays but is not common today.

Bistable multivibrator — Another name for a flip-flop circuit that has two stable output states.

Boolean algebra — The mathematical system used to describe and design binary used digital circuits, named after George Boole.

Bus — A set of wires through which data is routed internally within computers and other digital devices.

Clock — A signal that toggles at a regular rate. Clock control is the most common method of synchronizing logic circuits.

Combinational logic — A type of circuit element in which the output depends on the present inputs. (Also see **Sequential logic**.)

Complementary metal-oxide semiconductor (CMOS) — A type of construction used to make digital integrated circuits. CMOS is composed of both N-channel and P-channel MOS devices on the same chip.

Counter (divider, divide-by-n counter) — A circuit that is able to change from one state to the next each time it receives an input signal. A counter produces an

output signal every time a predetermined number of input signals have been received.

Decimal — The base-10 number system we use every day that uses the symbols 0 through 9.

DeMorgan’s Theorem — In Boolean algebra, a way to simplify the complement of a large expression or to enable a designer to interchange a number of equivalent gates.

Digital IC — An integrated circuit whose output is either on (1) or off (0).

Dynamic (edge-triggered) input — A control signal that allows a circuit to change state only when the control signal changes from unasserted to asserted.

Exclusive OR gate — A logic circuit whose output is 1 when either of two inputs is 1 and whose output is 0 when neither input is 1 or when both inputs are 1.

Fan-out — The ability of a logic element

to drive or feed several other logic elements.

Field Programmable Gate Array (FPGA)

— A type of programmable logic array that can contain several hundred to millions of logic gates and up to 1000 or more I/O pins.

FireWire (IEEE-1394) — A very high speed serial protocol capable of up to 400 Mbit/s of sustained transfer.

Flip-flop (bistable multivibrator) — A circuit that has two stable output states, and which can change from one state to the other when the proper input signals are detected.

Gate — A combinational logic element with two or more inputs and one output. The output state depends upon the state of the inputs.

Handshaking — Functions to coordinate data transfer.

Hexadecimal — A base-16 number system widely used in computer systems that uses the 0,1,2,3,4,5,6,7,8,9,A,B,C,D,E,F.

Integrated circuit — A device composed of many bipolar or field-effect transistors manufactured on the same chip, or wafer, of silicon.

Inverter — A logic circuit with one input and one output. The output is 1 when the input is 0, and the output is 0 when the input is 1.

Latch — Another name for a bistable multivibrator (flip-flop) circuit. The term latch reminds us that this circuit serves as a memory unit, storing a bit of information.

Linear IC — An integrated circuit whose output voltage is a linear (straight line) representation of its input voltage.

Logic probe — A simple piece of test equipment used to indicate high or low

logic states (voltage levels) in digital-electronic circuits.

Microcontroller — A “computer on a chip” that usually consists of a relatively small microprocessor along with some amount of program memory, data memory, input/output ports and often some specialized peripheral devices.

Monostable multivibrator (one shot) — A circuit that has one stable state. It can be forced into an unstable state for a time determined by external components, but it will revert to the stable state after that time.

NAND (NOT AND) gate — A logic circuit whose output is 0 only when both inputs are 1.

Noninverter — A logic circuit with one input and one output, and whose output state is the same as the input state (0 or 1). Sometimes called a *noninverting buffer*.

NOR (NOT OR) gate — A logic circuit whose output is 0 if either input is 1.

OR gate — A logic circuit whose output is 1 when either input is 1.

Parallel — A digital signaling method in which all the bits in a group are handled exactly at the same time.

Programmable logic device (PLD) — A device that includes a generic array of gates that can be controlled by program code. PLDs can be made to replace large numbers of individual ICs.

Propagation delay — The time delay between providing an input to a digital circuit and seeing a response at the output.

Register — A set of latches or flip-flops storing an n-bit number.

RS-232 — The most common serial bus protocol.

RS-422 — A serial protocol similar to RS-232, but employing fully differential data lines.

Serial — A digital signaling method in which each bit is sent in turn over a single channel or wire, according to an agreed sequence.

Sequential logic — A type of circuit element in which the output depends on the present inputs, the previous sequence of inputs and often a clock signal. (Also see **Combinational logic**.)

Square wave — A periodic waveform that alternates between two values, and spends an equal time at each level. It is made up of sine waves at a fundamental frequency and all odd harmonics.

Static (level-triggered, or gated) input — A control signal that allows the circuit to change state whenever the control signal is at its active or asserted level.

Synchronous flip-flop — A circuit whose output state depends on the data inputs, but that will change output state only when it detects the proper clock signal.

Transition region — The undefined region between the two binary states. Also known as the *noise margin*.

Transition time — The time it takes a digital circuit to change state. The transition from a 0 to a 1 state is called the *rise time*, and the transition from a 1 to a 0 state is called the *fall time*.

Tri-state gate — A gate with one additional control lead. When enabled, the gate operates normally; when not enabled, the output goes to a high impedance.

Truth table — A chart showing the outputs for all possible input combinations to a digital circuit.

Universal serial bus (USB) — A computer standard for an intelligent serial data transfer protocol.

RF Techniques

This chapter is a compendium of material from ARRL publications and other sources. It assumes the reader is familiar with the concepts introduced in the **Electrical Fundamentals** and **Analog Basics** chapters. The topics and techniques discussed here are associated with the special demands of circuit design in the HF and VHF ranges. The material is collected from previous editions of this book written by Leonard Kay, K1NU; *Introduction to Radio Frequency Design* by Wes Hayward, W7ZOI; and *Experimental Methods in RF Design* by Wes Hayward, W7ZOI, Rick Campbell, KK7B, and Bob Larkin, W7PUA. Material on ferrites is drawn from publications by Jim Brown, K9YC. The section on Noise was written by Paul Wade, W1GHZ, with contributions from Joe Taylor, K1JT. The editor was Ward Silver, NØAX.

Chapter 5 — CD-ROM Content

- “Reflections on the Smith Chart” by Wes Hayward, W7ZOI
- Tuned Networks
- “Simplified Design of Impedance-Matching Networks,” Parts I through III by George Grammer, W1DF (SK)
- *LTSpice* simulation files for Section 5.3, Effects of Parasitic Characteristics

5.1 Introduction

When is an inductor not an inductor? When it’s a capacitor! This statement may seem odd, but it suggests the main message of this chapter. In the earlier chapter, **Electrical Fundamentals**, the basic components of electronic circuits were introduced. As you may know from experience, those simple component pictures are ideal. That is, an ideal component (or element) by definition behaves exactly like the mathematical equations that describe it, and only in that fashion. For example, the current through an ideal capacitor is equal to the capacitance times the rate of change of the voltage across it without consideration of the materials or techniques by which a real capacitor is manufactured.

It is often said that, “Parasitics are anything you don’t want,” meaning that the component is exhibiting some behavior that detracts from or compromises its intended use. Real components only approximate ideal components, although sometimes quite closely. Any deviation from ideal behavior a component exhibits is called *non-ideal* or *parasitic*. The important thing to realize is that *every* component has parasitic aspects that become significant when it is used in certain ways. This chapter deals with parasitic effects that are commonly encountered at radio frequencies.

Knowing to what extent and under what conditions real components cease to behave like their ideal counterparts, and what can be done to account for these behaviors, allows the circuit designer or technician to work with circuits at radio frequencies. We will explore how and why the real components behave differently from ideal components, how we can account for those differences when analyzing circuits and how to select components to minimize, or exploit, non-ideal behaviors.

5.2 Lumped-Element versus Distributed Characteristics

Most electronic circuits that we use every day are inherently and mathematically considered to be composed of *lumped elements*. That is, we assume each component acts at a single point in space, and the wires that connect these lumped elements are assumed to be perfect conductors (with zero resistance and insignificant length). This concept is illustrated in **Fig 5.1**. These assumptions are perfectly reasonable for many applications, but they have limits. Lumped element models break down when:

- Circuit impedance is so low that the small, but non-zero, resistance in the wires is important. (A significant portion of the circuit power may be lost to heat in the conductors.)
- Operating frequency is high enough that the length of the connecting wires is a significant fraction (>0.1) of the wavelength causing the propagation delay along the conductor or radiation from it to affect the circuit in which it is used.
- Transmission lines are used as conductors. (Their characteristic impedance is usually significant, and impedances connected to them are transformed as a function of the line length. See the **Transmission Lines** chapter for more information.)

Effects such as these are called *distributed*, and we talk of *distributed elements* or effects to contrast them to lumped elements.

Fig 5.1 — The lumped element concept. Ideally, the circuit at A is assumed to be as shown at B, where the components are isolated points connected by perfect conductors. Many components exhibit nonideal behavior when these assumptions no longer hold.

To illustrate the differences between lumped and distributed elements, consider the two resistors in Fig 5.2, which are both 12 inches long. The resistor at A is a uniform rod of carbon. The second “resistor” B is made of two 6-inch pieces of silver rod (or other highly conductive material), with a small resistor soldered between them. Now imagine connecting the two probes of an ohmmeter to each of the two resistors, as in the figure. Starting with the probes at the far ends, as we slide the probes toward the center, the carbon rod will display a constantly decreasing resistance on the ohmmeter. This represents a distributed resistance. On the other hand, the ohmmeter connected to the other 12-inch “resistor” will display a constant resistance as long as one probe remains on each side of the small resistance and as long as we neglect the resistance of the silver rods! This represents a lumped resistance connected by perfect conductors.

Lumped elements also have the very desirable property that they introduce no phase shift

Fig 5.2 — Distributed (A) and lumped (B) resistances. See text for discussion.

resulting from propagation delay through the element. (Although combinations of lumped elements can produce phase shifts by virtue of their R , L and C properties.) Consider a lumped element that is carrying a sinusoidal current, as in Fig 5.3A. Since the element has negligible length, there is no phase difference in the current between the two sides of the element — *no matter how high the frequency* — precisely *because* the element length is negligible. If the physical length of the element were long, say 0.25 wavelength (0.25λ) as shown in Fig 5.3B, the current phase would *not* be the same from end to end. In this instance, the current is delayed by 90 electrical degrees as it moves along

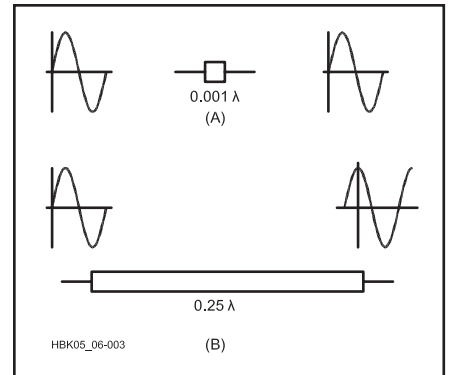

Fig 5.3 — The effects of distributed resistance on the phase of a sinusoidal current. There is no phase delay between ends of a lumped element.

the element. The amount of phase difference depends on the circuit’s electrical length.

Because the relationship between the physical size of a circuit and the wavelength of an ac current present in the circuit will vary as the frequency of the ac signal varies, the ideas of lumped and distributed effects actually occupy two ends of a spectrum. At HF (30 MHz and below), where $\lambda \geq 10$ m, the lumped element concept is almost always valid. In the UHF and microwave region (300 MHz and above), where $\lambda \leq 1$ m and physical component size can represent a significant fraction of a wavelength, nearly all components and wiring exhibits distributed effects to one degree or another. From roughly 30 to 300 MHz, whether the distributed effects are significant must be considered on a case-by-case basis.

Of course, if we could make resistors, capacitors, inductors and so on, very small, we could treat them as lumped elements at much higher frequencies. For example, surface-mount components, which are manufactured in very small, leadless packages, can be used at much higher frequencies than leaded components and with fewer non-ideal effects.

It is for these reasons that circuits and equipment are often specified to work within specific frequency ranges. Outside of these ranges the designer’s assumptions about the physical characteristics of the components and the methods and materials of the circuit’s assembly become increasingly invalid. At frequencies sufficiently removed from the design range, circuit behavior often changes in unpredictable ways.

5.3 Effects of Parasitic Characteristics

At HF and above (where we do much of our circuit design) several other considerations become very important, in some cases dominant, in the models we use to describe our components. To understand what happens to circuits at RF we turn to a brief discussion of some electromagnetic and microwave theory concepts.

Parasitic effects due to component leads, packaging, leakage and so on are relatively common to all components. When working at frequencies where many or all of the parasitics become important, a complex but completely general model such as that in **Fig 5.4** can be used for just about any component, with the actual component placed in the box marked *. Parasitic capacitance, C_p , and leakage conductance, G_L , appear in parallel across the device, while series resistance, R_s , and parasitic inductance, L_s , appear in series with it. Package capacitance, C_{pkg} , appears as an additional capacitance in parallel across the whole device.

These small parasitics can significantly affect frequency responses of RF circuits. Either take steps to minimize or eliminate them, or use simple circuit theory to predict and anticipate changes. This maze of effects may seem overwhelming, but remember that it is very seldom necessary to consider all parasitics at all frequencies and for all applications. The **Computer-Aided Circuit Design** chapter shows how to incorporate the effect of multiple parasitics into circuit design and performance modeling. Files for the *LTSpice* simulation package that include parasitic characteristics for a resistor, capacitor and inductor are provided on the CD-ROM that comes with this *Handbook*.

5.3.1 Parasitic Inductance

Maxwell's equations — the basic laws of electromagnetism that govern the propagation of electromagnetic waves and the operation of all electronic components — tell us that any wire carrying a current that changes with time (one example is a sine wave) develops a changing magnetic field around it. This changing magnetic field in turn induces an opposing voltage, or *back EMF*, on the wire. The back EMF is proportional to how fast the current changes (see **Fig 5.5**).

We exploit this phenomenon when we make an inductor. The reason we typically form inductors in the shape of a coil is to concentrate the magnetic field and thereby maximize the inductance for a given physical size. However, *all* wires carrying varying currents have these inductive properties. This includes the wires we use to connect our circuits, and even the *leads* of capacitors, resistors and so on. The inductance of a straight, round,

Fig 5.4 — A general model for electrical components at VHF frequencies and above. The box marked * represents the component itself. See text for discussion.

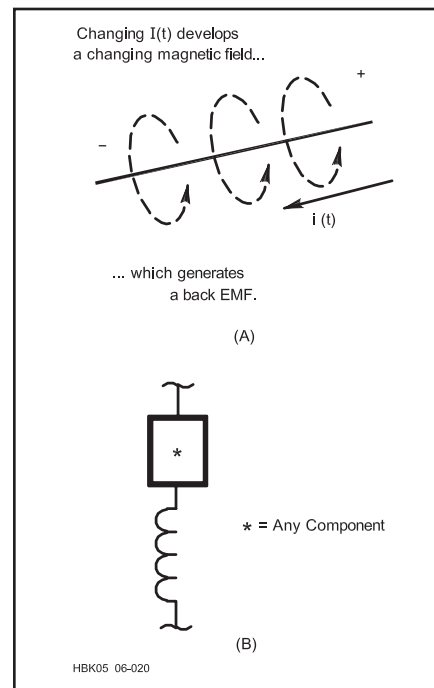

Fig 5.5 — Inductive consequences of Maxwell's equations. At A, any wire carrying a changing current develops a voltage difference along it. This can be mathematically described as an effective inductance. B adds parasitic inductance to a generic component model.

Fig 5.6 — A plot of inductance vs length for straight conductors in several wire sizes.

nonmagnetic wire in free space is given by:

$$L = 0.00508 b \left[\ln \left(\frac{2b}{a} \right) - 0.75 \right] \quad (1)$$

where

- L = inductance, in μH
- a = wire radius, in inches
- b = wire length, in inches
- ln = natural logarithm ($2.303 \times \log_{10}$)

Skin effect (discussed below) changes this formula slightly at VHF and above. As the frequency approaches infinity, the value 0.75 in the above equation increases to approach 1. This effect usually causes a change of no more than a few percent.

As an example, let's find the inductance of a typical #18 wire (diameter = 0.0403 inch and a = 0.0201) that is 4 inches long (b = 4):

$$L = 0.00508 (4) \left[\ln \left(\frac{8}{0.0201} \right) - 0.75 \right]$$

$$= 0.0203 [5.98 - 0.75] = 0.106 \mu\text{H}$$

Wire of this diameter has an inductance of about 25 nH per inch of length. In circuits operating at VHF and higher frequencies, including high-speed digital circuits, the inductance of component leads can become significant. (The #24 AWG wire typically used for component leads has an inductance on the order of 20 nH per inch.) At these frequencies, lead inductance can affect circuit behavior, making the circuit hard to reproduce or repair.

Good design and construction practice is to minimize the effects of lead inductance by using surface-mount components or trimming the leads to be as short as possible.

The impact of reactance due to parasitic inductance is usually very small; at AF or LF, parasitic inductive reactance of most components is practically zero. To use this example, the reactance of a 0.106 μH inductor even at 10 MHz is only 6.6 Ω . Fig 5.6 shows a graph of the inductance for wires of various gauges (radii) as a function of length. Whether the reactance is significant or not depends on the application and the frequency of use.

We can represent parasitic inductance in component models by adding an inductor of appropriate value in series with the component since the wire leads are in series with the element. This (among other reasons) is why minimizing lead lengths and interconnecting wires becomes very important when designing circuits for VHF and above.

PARASITIC INDUCTANCE IN RESISTORS

The basic construction of common resistor types is shown in Fig 5.7. The primary parasitic effect associated with resistors is parasitic inductance. (Some parasitic capacitance exists between the leads or electrodes due to packaging.) Fig 5.8 shows some more accurate circuit models for resistors at low to medium frequencies. The type of resistor with the most parasitic inductance are wire-wound resistors, essentially inductors used as resistors. Their

use is therefore limited to dc or low-frequency ac applications where their reactance is negligible. Remember that this inductance will also affect switching transient waveforms, even at dc, because the component will act as an RL circuit. The inductive effects of wire-wound resistors begin to become significant in the audio range above a few kHz.

As an example, consider a 1- Ω wire-wound resistor formed from 300 turns of #24 wire closely-wound in a single layer 6.3 inches long on a 0.5-inch diameter form. What is its approximate inductance? From the inductance formula for air-wound coils in the **Electrical Fundamentals** chapter:

$$L = \frac{d^2 n^2}{18d + 40l} = \frac{0.5^2 \times 300^2}{(18 \times 0.5) + (40 \times 6.3)} = 86 \mu\text{H}$$

If we want the inductive reactance to be less than 10% of the resistor value, then this resistor cannot be used above $f = 0.1 / (2\pi \times 86 \mu\text{H}) = 185 \text{ Hz}$! Real wire-wound resistors have multiple windings layered over each other to minimize both size and parasitic inductance (by winding each layer in opposite directions, much of the inductance is canceled). If we assume a five-layer winding, the length is reduced to 1.8 inches and the inductance to approximately 17 μH , so the resistor can then be used below 937 Hz. (This has the effect of increasing the resistor's parasitic capacitance, however.)

The resistance of certain types of tubular film resistors is controlled by inscribing a spiral path through the film on the inside of the tube. This creates a small inductance that may be significant at and above the higher audio frequencies.

NON-INDUCTIVE RESISTORS

The resistors with the least amount of parasitic inductance are the bulk resistors, such as carbon-composition, metal-oxide, and ceramic resistors. These resistors are made from a single linear cylinder, tube or block of resis-

Fig 5.7 — The electrical characteristics of different resistor types are strongly affected by their construction. Reactance from parasitic inductance and capacitance strongly impacts the resistor's behavior at RF.

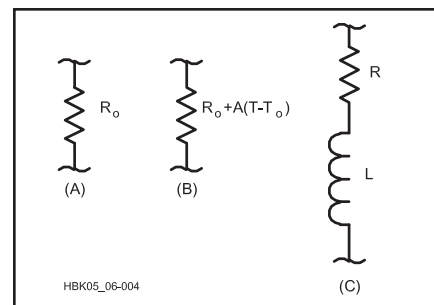

Fig 5.8 — Circuit models for resistors. The wire-wound model with associated inductance is shown at C. B includes the effect of temperature (T). For designs at VHF and higher frequencies, the model at C could be used with L representing lead inductance.

tive material so that inductance is minimized. Each type of resistor has a maximum usable frequency, above which parasitic capacitance and inductance begin to become significant. Review the manufacturer's data sheet for the component to learn about its performance at high frequencies.

Some resistors advertised as “noninductive” are actually wire-wound resistors with a special winding technique that minimizes inductance. These resistors are intended for use at audio frequencies and are not suitable for use at RF. If you are not sure, ask the vendor if the resistors are suitable for use in RF circuits.

Because resistors are manufactured with an insulating coating, it can be difficult to determine their internal structure and thus estimate their parasitic inductance. In cases where a surplus or used component is to be included, it is recommended that you test the component with an impedance meter or make some other type of reactance measurement if you are unable to access the manufacturer's specifications for the resistor.

PARASITIC INDUCTANCE IN CAPACITORS

The size and shape of a capacitor's plates and the leads used to connect them to circuits create parasitic inductance, often referred to as *equivalent series inductance* (ESL) by capacitor manufacturers. **Figs 5.9** and **5.10** show reasonable models for capacitors that are good up to VHF.

Fig 5.11 shows a roll-type capacitor made of two strips of very thin metal foil and separated by a dielectric. After leads are attached to the foil strips, the sandwich is rolled up and either placed in a metal can or coated with plastic. *Radial leads* both stick out of one end of the roll and *axial leads* from both ends along the roll's axis. Because of the rolled strips, the ESL is high. Electrolytic and many types of film capacitors are made with roll construction. As a result, they are generally not useful in RF circuits.

In the stack capacitor, thin sheets of dielectric are coated on one side with a thin metal layer. A stack of the sheets is placed under pressure and heated to make a single solid unit. Metal side caps with leads attached contact the metal layers. The ESL of stack capacitors is very low and so they are useful at high frequencies. Ceramic and mica capacitors are the most common stack-style capacitor.

Parallel-plate air and vacuum capacitors used at RF have relatively low parasitic inductance, but transmitting capacitors made to withstand high voltages and current are large enough that parasitic inductance becomes significant, limiting their use to low-VHF and lower frequencies. Adjustable capacitors (air variables and compression or piston trimmer

Fig 5.9 — A simple capacitor model for frequencies well below self-resonance.

Fig 5.11 — Two common types of capacitor construction. (A) Roll construction uses two strips of foil separated by a strip of dielectric. (B) Stack construction layers dielectric material (such as ceramic or film), one side coated with metal. Leads are attached and the assembly coated with epoxy resin.

capacitors) for tuning low-power circuits are much smaller and so have correspondingly lower parasitic inductance.

It is difficult for a single capacitor to work well over a very wide frequency range, so capacitors are often placed in parallel as discussed in the section below on Bypassing and Decoupling. It is often suggested that different types of capacitors be connected in parallel to avoid the effects of parasitic inductance at different frequencies, but without testing and careful modeling the results are often unpredictable or even counterproductive as the referenced discussion shows.

5.3.2 Parasitic Capacitance

Maxwell's equations also tell us that if the voltage between any two points changes with time, a displacement current is generated between these points as illustrated in **Fig 5.12**. This *displacement current* results from the propagation of the electromagnetic field between the two points and is not to be confused with *conduction current*, which is the movement of electrons. Displacement current is directly proportional to the rate at which the voltage is changing.

When a capacitor is connected to an ac voltage source, a steady ac current can flow because taken together, conduction current and displacement current “complete the loop” from the positive source terminal, across the plates of the capacitor, and back to the negative terminal.

In general, parasitic capacitance shows up *wherever* the voltage between two points is changing with time, because the laws of electromagnetics require a displacement current to flow. Since this phenomenon

Fig 5.12 — Capacitive consequences of Maxwell's equations. A: Any changing voltage between two points, for example along a bent wire, generates a displacement current running between them. This can be mathematically described as an effective capacitance. B adds parasitic capacitance to a generic component model.

represents an *additional* current path from one point in space to another, we can add this parasitic capacitance to our component models by adding a capacitor of appropriate value in *parallel* with the component. These parasitic capacitances are typically less than 1 pF, so that below VHF they can be treated as open circuits (infinite reactances) and thus neglected.

PACKAGE CAPACITANCE

Another source of capacitance, also in the 1-pF range and therefore important only at VHF and above, is the packaging of the com-

Fig 5.13 — Unexpected stray capacitance. The mounting tab of TO-220 transistors is often connected to one of the device leads. Because one lead is connected to the chassis, small capacitances from the other lead to the chassis appear as additional package capacitance at the device. Similar capacitance can appear at any device with a conductive package.

ponent itself. For example, a power transistor packaged in a TO-220 case (see **Fig 5.13**), often has either the emitter or collector connected to the metal tab itself. This introduces an extra *inter-electrode capacitance* across the junctions.

The copper traces on a PC board also create capacitance with the circuit components, to other traces, and to power and ground planes. Double-sided PC boards have a certain capacitance per square inch between the layers of copper on each side of the board. (Multi-layer PC boards have higher values of capacitance due to the smaller separation between layers.) It is possible to create capacitors by leaving unetched areas of copper on both sides of the board. The dielectric constant of inexpensive PC board materials intended for use at low-frequencies is not well-controlled, however, leading to significant variations in capacitance. For this reason, the copper on one side of a double-sided board should be completely removed under frequency-determining circuits such as VFOs.

Stray capacitance (a general term used for any "extra" capacitance that exists due to physical construction) appears in any circuit where two metal surfaces exist at different voltages. Such effects can be modeled as an extra capacitor in parallel with the given points in the circuit. A rough value can be obtained with the parallel-plate formula given in the chapter on **Electrical Fundamentals**. Similar to parasitic inductance, *any* circuit component that has wires attached to it, or is fabricated from wire, or is near or attached to metal, will have a parasitic capacitance associated with it, which again, becomes important only at RF.

Stray capacitance can be difficult to account for in circuit design because it exists *between* components and other circuit structures, depending on the physical orientation of the component. Its presence may allow signals to flow in ways that disrupt the normal operation of a circuit and may have a greater affect in a high-impedance circuit because the capacitive reactance may be a greater percentage of the circuit impedance. Also, because stray capacitance often appears in parallel with the circuit, the stray capacitor may bypass more of the desired signal at higher frequencies. Careful physical design of an RF circuit and selection of components can minimize the effects of stray capacitance.

5.3.3 Inductors at Radio Frequencies

Inductors are perhaps the component with the most significant parasitic effects. Where there are many different varieties of form for capacitors and resistors, most inductors are fundamentally similar: a coil of wire on a tubular or toroidal form. As such, they are

affected by both parasitic resistance and capacitance as shown in the simple inductor model of **Fig 5.14**.

While the leakage conductance of a capacitor is usually negligible, the series resistance of an inductor often is not. This is caused by the long lengths of thin wire needed to create typical inductance values used in RF circuits and the skin effect (discussed below). Consider a typical air-core inductor, with $L = 33 \mu\text{H}$ and a minimum Q of 30 measured at 2.5 MHz. This would indicate a series resistance of $R_s = 2\pi fL/Q = 17 \Omega$ that could significantly alter the bandwidth of a circuit. The skin effect also results in parasitic resistance in the upper HF ranges and above. To minimize losses due to the skin effect, inductors at these frequencies, particularly those intended for use in transmitters and amplifiers and that are expected to carry significant currents, are often made from large-diameter wire or tubing or even flat strap to maximize the surface area for current flow. For coils with many turns for which large conductors are impractical, *Litz wire* is sometimes used. Litz wire is made of many fine insulated strands woven together, each with a diameter smaller than the skin depth at the expected frequency of use, thus presenting a larger surface area than a solid wire or normal stranded wire.

If an inductor is wound on a magnetic core, the core itself can have losses that are treated as parasitic resistance. Each type of core — iron, powdered iron or ferrite — has a frequency range over which it is designed for maximum efficiency. Outside of that range, the core may have significant losses, raising the parasitic resistance of the inductor.

Parasitic capacitance is a particular concern

Fig 5.14 — General model for inductor with parasitic capacitance and resistance. The parasitic capacitance represents the cumulative effect of the capacitance between the different turns of wire. Parasitic resistance, R_s , depends on frequency due to the skin effect. R_p represents leakage resistance. At low frequencies, parasitic capacitance, C_p , can be neglected.

Fig 5.15 — Coils exhibit distributed capacitance as explained in the text. The graph at B shows how distributed capacitance resonates with the inductance. Below resonance, the reactance is predominantly inductive which increases as frequency increases. However, above resonance, the reactance becomes predominantly capacitive which decreases as frequency increases.

for inductors because of their construction. Consider the inductor in **Fig 5.15**. If this coil has n turns, then the ac voltage between identical points of two neighboring turns is $1/n$ times the ac voltage across the entire coil. When this voltage changes due to an ac current passing through the coil, the effect is that of many small capacitors acting in parallel with the inductance of the coil. Thus, in addition to the capacitance resulting from the leads, inductors have higher parasitic capacitance due to their physical shape.

These various effects illustrate why inductor construction has such a large effect on performance. As an example, assume you're working on a project that requires you to wind a $5 \mu\text{H}$ inductor. Looking at the coil inductance formula in the **Electrical Fundamentals** chapter, it comes to mind that many combinations of length and diameter could yield the desired inductance. If you happen to have both 0.5 and 1-inch coil forms, why should you select one over the other? To eliminate some other variables, let's make both coils 1 inch long, close-wound, and give them 1-inch leads on each end.

Let's calculate the number of turns required for each. On a 0.5-inch-diameter form:

$$n = \frac{\sqrt{L(18d + 40l)}}{d} = \frac{\sqrt{5 [(18 \times 0.5) + (40 \times 1)]}}{0.5} = 31.3 \text{ turns}$$

This means coil 1 will be made from #20 AWG wire (29.9 turns per inch). Coil 2, on the 1-inch form, yields

$$n = \frac{\sqrt{5 [(18 \times 1) + (40 \times 1)]}}{1} = 17 \text{ turns}$$

which requires #15 AWG wire in order to be close-wound.

What are the series resistances associated with each? For coil 1, the total wire length is 2 inches + $(31.3 \times \pi \times 0.5) = 51$ inches, which at $10.1 \Omega / 1000 \text{ ft}$ gives $R_s = 0.043 \Omega$ at dc. Coil 2 has a total wire length of 2 inches + $(17.0 \times \pi \times 1) = 55$ inches, which at $3.18 \Omega / 1000 \text{ ft}$ gives a dc resistance of $R_s = 0.015 \Omega$, or about $1/3$ that of coil 1. Furthermore, at RF, coil 1 will begin to suffer from skin effect at a frequency about 3 times lower than coil 2 because of its smaller conductor diameter. Therefore, if Q were the sole consideration, it would be

Fig 5.16 — Unshielded coils in close proximity should be mounted perpendicular to each other to minimize coupling.

better to use the larger diameter coil.

Q is not the only concern, however. Such coils are often placed in shielded enclosures. A common rule of thumb says that to prevent the enclosure from affecting the inductor, the enclosure should be at least one coil diameter from the coil on all sides. That is, $3 \times 3 \times 2$ inches for the large coil and $1.5 \times 1.5 \times 1.5$ for the small coil, a volume difference of over 500%.

INDUCTOR COUPLING

Mutual inductance (see the **Electrical Fundamentals** chapter) will also have an effect on the resonant frequency and Q of RF circuits. For this reason, inductors in frequency-critical circuits should always be shielded, either by constructing compartments for each circuit block or through the use of can-mounted coils. Another helpful technique to minimize coupling is to mount nearby coils with their axes perpendicular as in **Fig 5.16**.

Fig 5.17 — Result of light coupling ($k = 0.05$) between two identical circuits of Fig 5.19A on their frequency responses.

As an example, assume we build an oscillator circuit that has both input and output resonant circuits. If we are careful to keep the two coils in these circuits uncoupled, the frequency response of either of the two circuits is that of the solid line in **Fig 5.17**.

If the two coils are coupled either through careless placement or improper shielding, the resonant frequency and Q will be affected. The dashed line in Fig 5.17 shows the frequency response that results from a coupling coefficient of $k = 0.05$, a reasonable value for air-wound inductors mounted perpendicularly in close proximity on a circuit chassis. Note the resonant frequency shifted from 10.06 to 9.82 MHz, or 2.4%. The Q has gone up slightly from 30.0 to 30.8 as a result of the slightly higher inductive reactance at the resonant frequency.

5.3.4 Skin Effect

The resistance of a conductor to ac is different than its value for dc because of the way ac fields interact with the conductor. As a result, thick, near-perfect conductors (such as metals) conduct ac only to a certain *skin depth*, δ , inversely proportional to the square root of the frequency of the current. Called the *skin effect*, this decreases the effective cross-section of the conductor at high frequencies and thus increases its resistance.

$$\delta = \frac{1}{\sqrt{\pi f \mu \sigma}} \quad (2)$$

where

μ is the conductor's permeability, and
 σ is the conducting material's conductance.

The increase in resistance caused by the skin effect is insignificant at and below audio frequencies, but beginning around 1 MHz (depending on the size of the conductor) it is so pronounced that practically all the current flows in a very thin layer near the conductor's surface. For example, at 10 MHz, the skin depth of a copper conductor is about 0.02 mm (0.00079 inch). For this reason, at RF a hollow tube and a solid rod of the same diameter and made of the same metal will have the same resistance and the RF resistance of a conductor is often much higher than its dc resistance. A rough estimate of the frequency above which a nonmagnetic wire (one made of nonferrous metal) will begin to show appreciable skin effect can be calculated from

$$f = \frac{124}{d^2} \quad (3)$$

where

f = frequency, in MHz
 d = diameter in mils (a mil is 0.001 inch)

Above this frequency, increase the resis-

tance of the wire by $10\times$ for every 2 decades of frequency (roughly $3.2\times$ for every decade). For example, say we wish to find the RF resistance of a 2-inch length of #18 AWG copper wire at 100 MHz. From the wire tables in the **Component Data and References** chapter, we see that this wire has a dc resistance of 2 inches \times 6.386 Ω /1000 ft = 1.06 m Ω . From the above formula, the frequency is found to be $124 / 40.3^2 = 76$ kHz. Since 100 MHz is roughly three decades above this (100 kHz to 100 MHz), the RF resistance will be approximately $1.06 \text{ m}\Omega \times 3.2^3 = 1.06 \text{ m}\Omega \times 32.8 = 34.8 \text{ m}\Omega$. Again, values calculated in this manner are approximate and should be used qualitatively — like when you want an answer to a question such as, “Can I neglect the RF resistance of this length of connecting wire at 100 MHz?” Several useful charts regarding skin effect are available in *Reference Data for Engineers*, listed in the References section of this chapter.

Losses associated with skin effect can be reduced by increasing the surface area of the conductor carrying the RF current. Flat, solid strap and tubing are often used for that reason. In addition, because the current-carrying layer is so thin at UHF and microwave frequencies, a thin highly conductive layer at the surface of the conductor, such as silver plating, can lower resistance. Silver plating is too thin to improve HF conductivity significantly, however.

5.3.5 RF Heating

RF current often causes component heating problems where the same level of dc or low frequency ac current may not. These losses result from both the skin effect and from dielectric losses in insulating material, such as a capacitor dielectric.

An example is the tank circuit of an RF oscillator. If several small capacitors are connected in parallel to achieve a desired capacitance, skin effect will be reduced and the total surface area available for heat dissipation will be increased, thus significantly reducing the RF heating effects as compared to a single large capacitor. This technique can be applied to any similar situation; the general idea is to divide the heating among as many components as possible.

An example is shown in the circuit block in **Fig 5.18**, which is representative of the input tank circuit used in many HF VFOs. Along with L, C_{main} , C_{trim} , C1 and C3 set the oscillator frequency. Therefore, temperature effects are critical in these components. By using several capacitors in parallel, the RF current (and resultant heating, which is proportional to the square of the current) is reduced in each component. Parallel combinations are used for the feedback capacitors for the same reason.

Fig 5.18 — A tank circuit of the type commonly used in VFOs. Several capacitors are used in parallel to distribute the RF current, which reduces temperature effects.

At high power levels, losses due to RF heating — either from resistive or dielectric losses — can be significant. Insulating materials may exhibit dielectric losses even though they are excellent insulators. For example, nylon plastic insulators may work very well at low frequencies, but being quite lossy at and above VHF, they are unsuitable for use in RF circuits at those frequencies. To determine whether material is suitable for use as an insulator at RF, a quick test can be made by heating the material in a microwave oven for a few seconds and measuring its temperature rise. (Take care to avoid placing parts or materials containing any metal in the microwave!) Insulating materials that heat up are lossy and thus unsuitable for use in RF circuits.

5.3.6 Effect on Q

Recall from the **Electrical Fundamentals** chapter that circuit Q, a useful figure of merit for tuned RLC circuits, can be defined in several ways:

$$Q = \frac{X_L \text{ or } X_C}{R} \quad (4)$$

$$= \frac{\text{energy stored per cycle}}{\text{energy dissipated per cycle}}$$

Q is also related to the bandwidth of a tuned circuit's response by

$$Q = \frac{f_0}{\text{BW}_{3\text{dB}}} \quad (5)$$

Parasitic inductance, capacitance and resistance can significantly alter the performance and characteristics of a tuned circuit if the design frequency is close to the self-resonant frequencies of the components.

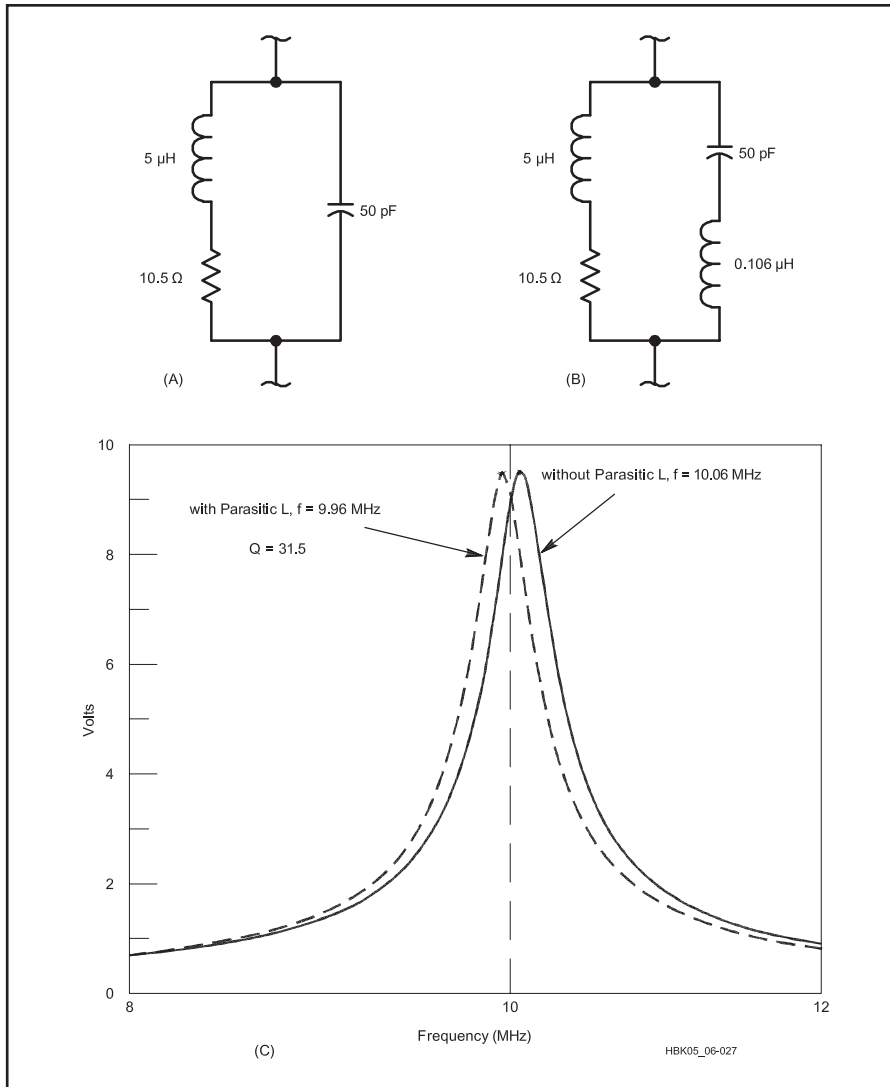

Fig 5.19 — A is a tank circuit, neglecting parasitics. B is the same circuit including L_p on capacitor. C is the frequency response curves for A and B. The solid line represents the unaltered circuit (also see Fig 5.17) while the dashed line shows the effects of adding parasitic inductance.

As an example, consider the resonant circuit of **Fig 5.19A**, which could represent the frequency-determining resonant circuit of an oscillator. Neglecting any parasitics,

$$f_0 = \frac{1}{2\pi\sqrt{LC}} = 10.07 \text{ MHz}$$

As in many practical cases, assume the resistance arises entirely from the inductor series resistance. The data sheet for the inductor specified a minimum Q of 30, so assuming $Q = 30$ yields an R value of

$$\frac{X_L}{Q} = \frac{2\pi(10.06 \text{ MHz})(5 \mu\text{H})}{30} = 10.5 \Omega$$

Next, let's include the parasitic inductance of the capacitor (Fig 5.19B). A reasonable assumption is that this capacitor has the same physical size as the example from the sec-

tion on Parasitic Inductance for which we calculated $L_s = 0.106 \mu\text{H}$. This would give the capacitor a self-resonant frequency of 434 MHz — well above our frequency of interest. However, the added parasitic inductance does account for an extra $0.106/5.0 = 2\%$ inductance. Since this circuit is no longer strictly series or parallel, we must convert it to an equivalent form before calculating the new f_0 .

An easier and faster way is to *simulate* the altered circuit by computer. This analysis was performed on a desktop computer using *SPICE*, a standard circuit simulation program described in the **Computer-Aided Circuit Design** chapter. The voltage response of the circuit (given an input current of 1 mA) was calculated as a function of frequency for both cases, with and without parasit-

ics. The results are shown in the plot in Fig 5.19C, where we can see that the parasitic circuit has an f_0 of 9.96 MHz (a shift of 1%) and a Q (measured from the -3 dB points) of 31.5. For comparison, the simulation of the unaltered circuit does in fact show $f_0 = 10.06$ MHz and $Q = 30$.

5.3.7 Self-Resonance

Because of parasitic effects, a capacitor or inductor — all by itself — exhibits the properties of a resonant RLC circuit at frequencies for which the parasitic effects are significant. Figs 5.10 and 5.14 illustrate RF models for the capacitor and inductor, which are based on the general model in Fig 5.4, leaving out the packaging capacitance. Note the slight difference in configuration; the pairs C_p - R_p and L_s - R_s are in series in the capacitor but in parallel in the inductor. This is because of the different physical structure of the components.

At some sufficiently high frequency, both inductors and capacitors become *self-resonant* when the parasitic reactance cancels or equals the intended reactance, creating a series-resonant circuit. Similar to a series-resonant circuit made of discrete components, above the self-resonant frequency a capacitor will appear inductive, and an inductor will appear capacitive.

For an example, let's calculate the approximate self-resonant frequency of a 470-pF capacitor whose leads are made from #20 AWG wire (0.032-inch diameter), with a total length of 1 inch. Using equation 1, we calculate the approximate parasitic inductance

$$L (\mu\text{H}) = 0.00508 (1) \left[\ln \left(\frac{2(1)}{(0.032/2)} \right) - 0.75 \right] = 0.021 \mu\text{H}$$

and the self-resonant frequency is roughly

$$f = \frac{1}{2\pi\sqrt{LC}} = 50.7 \text{ MHz}$$

Similarly, an inductor can also have a parallel self-resonance.

The purpose of making these calculations is to provide a feel for actual component values. They could be used as a rough design guideline, but should not be used quantitatively. Other factors such as lead orientation, shielding and so on, can alter the parasitic effects to a large extent. Large-value capacitors tend to have higher parasitic inductances (and therefore a lower self-resonant frequency) than small-value capacitors.

Self-resonance becomes critically important at VHF and UHF because the self-resonant frequency of many common components is at or below the frequency where the component will be used. In this case, either special techniques can be used to construct

components to operate at these frequencies, by reducing the parasitic effects, or else the idea of lumped elements must be abandoned altogether in favor of microwave techniques such as striplines and waveguides.

5.3.8 Dielectric Breakdown and Arcing

Anyone who has ever seen an arc form across a transmitting capacitor's plates, seen static discharges jump across an antenna insulator or touched a metal doorknob on a dry day has experienced the effects of dielectric breakdown.

In the ideal world, we could take any two conductors and put as large a voltage as we want across them, no matter how close together they are. In the real world, there is a voltage limit (*dielectric strength*, measured in kV/cm and determined by the insulating material between the two conductors) above which the insulator will break down.

Because they are charged particles, the electrons in the atoms of a dielectric material feel an attractive force when placed in an electric field. If the field is sufficiently strong, the force will strip the electron from the atom. This electron is available to conduct current, and furthermore, it is traveling at an extremely high velocity. It is very likely that this electron will hit another atom, and free another electron. Before long, there are many stripped electrons producing a large current, forming an *arc*. When this happens, we say the dielectric has suffered *breakdown*. Arcing in RF circuits is most common in transmitters and transmission line components where high voltages are common, but it is possible anywhere two components at significantly

different voltage levels are closely spaced.

If the dielectric is liquid or gas, it will repair itself when the applied voltage is removed and the molecules in the dielectric return to their normal state. A solid dielectric, however, cannot repair itself because its molecules are fixed in place and the low-resistance path created by the arc is permanent. A good example of this is a CMOS integrated circuit. When exposed to the very high voltages associated with static electricity, the electric field across the very thin gate oxide layer exceeds the dielectric strength of silicon dioxide, and the device is permanently damaged by the resulting hole created in the oxide layer.

The breakdown voltage of a dielectric layer depends on its composition and thickness (see **Table 5.1**). The variation with thickness is not linear; doubling the thickness does not quite double the breakdown voltage. Breakdown voltage is also a function of geometry: Because of electromagnetic considerations, the breakdown voltage between two conductors separated by a fixed distance is less if the surfaces are pointed or sharp-edged than if they are smooth or rounded. Therefore, a simple way to help prevent breakdown in many projects is to file and smooth the edges of conductors. (See the **Power Sources** and **RF Power Amplifier** chapters for additional information on high voltage applications.)

Capacitors are, by nature, the component most often associated with dielectric failure. To prevent damage, the working voltage of a capacitor — and there are separate dc and ac ratings — should ideally be two or three times the expected maximum voltage in the circuit. Capacitors that are not air-insulated or have a *self-healing dielectric* should be replaced if a dielectric breakdown occurs.

Resistors and inductors also have voltage ratings associated with breakdown of their insulating coating. High-value resistors, in particular, can be bypassed by leakage current flowing along the surface of the resistor. High-voltage resistors often have elongated bodies to create a long *leakage path* to present a high resistance to leakage current. Cleaning the bodies of resistors and inductors in high-voltage circuits helps prevent arcs from forming and minimizes leakage current.

5.3.9 Radiative Losses

Any conductor placed in an electromagnetic field will have a current induced in it. We put this principle to good use when we make an antenna. The unwelcome side of this law of nature is the phrase “any conductor”; even conductors we don't intend to act as antennas will respond this way.

Fortunately, the efficiency of such “antennas” varies with conductor length. They will be of importance only if their length is a significant fraction of a wavelength. When we

make an antenna, we usually choose a length on the order of $\lambda/2$. Therefore, when we *don't* want an antenna, we should be sure that the conductor length is *much less* than $\lambda/2$, no more than 0.1λ . This will ensure a very low-efficiency antenna. This is why even unpaired 60-Hz power lines do not lose a significant fraction of the power they carry — at 60 Hz, 0.1λ is about 300 miles!

In addition, we can use shielded cables. Such cables do allow some penetration of EM fields if the shield is not solid, but even 95% coverage is usually sufficient, especially if some sort of RF choke is used to reduce shield current.

Radiative losses and coupling can also be reduced by using twisted or parallel pairs of conductors — the fields tend to cancel. In some applications, such as audio cables, this may work better than shielding. Critical stages such as tuned circuits should be placed in shielded compartments where possible.

This argument also applies to large components — remember that a component or long wire can both radiate and receive RF energy. Measures that reduce radiative losses will also reduce unwanted RF pickup. See the **RF Interference** chapter for more information.

5.3.10 Bypassing and Decoupling

BYPASSING

Circuit models showing ac behavior often show ground connections that are not at dc ground. Bias voltages and currents are neglected in order to show how the circuit responds to ac signals. Rather, those points are “signal grounded” through bypass capacitors. Obtaining an effective bypass can be difficult and is often the route to design difficulty. The problem is parasitic inductance. Although we label and model parts as “capacitors,” a more complete model is needed. The better model is a series RLC circuit, shown in **Fig 5.20**. Capacitance is close to the marked value while inductance is a small value that grows with component lead length. Resistance is a loss term, usually controlled by the Q of the parasitic inductor. Even a leadless SMT (surface-mount technology) component will display inductance commensurate with its dimensions. As shown in the Parasitic Inductance section, wire component leads have an inductance of about 1 nH per mm of length (20-25 nH per inch).

Bypass capacitor characteristics can be measured in the home lab with the test setup of **Fig 5.21**. **Fig 5.22** shows a test fixture with an installed 470-pF leaded capacitor. The fixture is used with a signal generator and spectrum analyzer to evaluate capacitors. Relatively long capacitor leads were required to interface to the BNC connectors,

Table 5.1
Dielectric Constants and Breakdown Voltages

Material	Dielectric Constant*	Puncture Voltage**
Aisimag 196	5.7	240
Bakelite	4.4-5.4	240
Bakelite, mica filled	4.7	325-375

Fig 5.22 — Test fixture for measuring self-resonant frequency of capacitors.

even though the capacitor itself was small. The signal generator was tuned over its range while examining the spectrum analyzer response, showing a minimum at the series resonant frequency. Parasitic inductance is calculated from this frequency. The C value was measured with a low-frequency LC meter. Additional test instruments and techniques are discussed in the **Test Equipment and Measurement** chapter.

The measured 470-pF capacitor is modeled as 485 pF in series with an inductance of 7.7 nH. The L is larger than we would see with shorter leads. A 0.25-inch 470-pF ceramic disk capacitor with zero lead length will show a typical inductance closer to 3 nH. The measured capacitor Q was 28 at its self-resonance of 82 MHz but is higher at lower frequency. Data from a similar measurement, but with a network analyzer is shown in **Fig 5.23**. Two 470-pF capacitors are measured, one surface mounted and the other a leaded part with 0.1-inch leads.

It is often suggested that the bandwidth for bypassing can be extended by paralleling a capacitor that works well at one frequency with another to accommodate a different

part of the spectrum. Hence, paralleling the 470 pF with a 0.01- μ F capacitor should extend the bypassing to lower frequencies. The calculations are shown in the plots of **Fig 5.24**. The results are terrible! While the low frequency bypassing is indeed improved, a high impedance response is created at 63 MHz. This complicated behavior is again the result of inductance. Each capacitor was assumed to have a series inductance of 7 nH. A parallel resonance is approximately formed between the L of the larger capacitor and the C of the smaller. The Smith Chart plot shows us that the impedance is nearly 50 Ω at 63 MHz. Impedance would be even higher with greater capacitor Q.

Bypassing can be improved by paralleling capacitors. However, the capacitors should be approximately identical. **Fig 5.25** shows the result of paralleling two capacitors of about the same value. They differ slightly at 390 and 560 pF, creating a hint of resonance. This appears as a small perturbation in the reactance plot and a tiny loop on the Smith Chart. These

anomalies disappear as the C values become equal. Generally, paralleling is the scheme that produces the best bypassing. The ideal solution is to place an SMT capacitor on each side of a printed circuit trace or wire at a point that is to be bypassed.

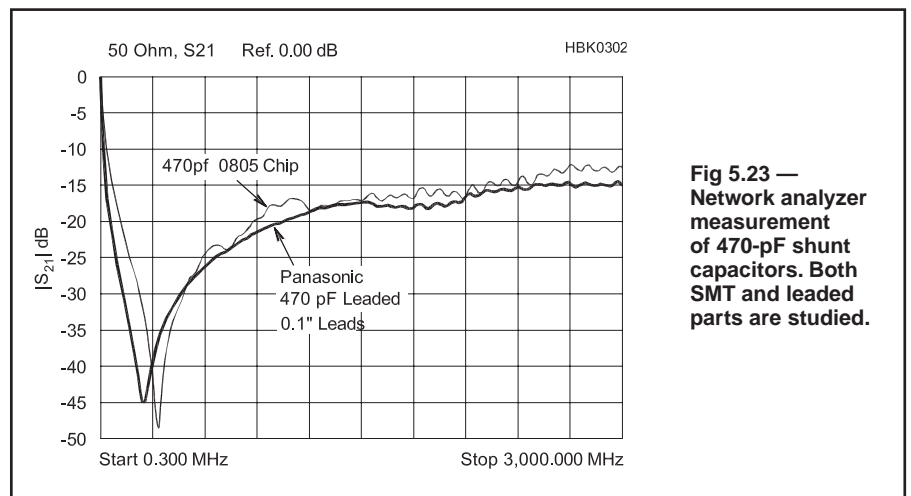

Matched capacitor pairs form an effective bypass over a reasonable frequency range. Two 0.01- μ F disk capacitors have a reactance magnitude less than 5 Ω from 2 to 265 MHz. A pair of the 0.1- μ F capacitors was even better, producing the same bypassing impedance from 0.2 to 318 MHz. The 0.1- μ F capacitors are chip-style components with attached wire leads. Even better results can be obtained with multi-layer ceramic chip capacitors. Construction with multiple layers creates an integrated paralleling.

Some applications (for example, IF amplifiers) require effective bypassing at even lower frequencies. Modern tantalum electrolytic capacitors are surprisingly effective through the RF spectrum while offering high enough C to be useful at audio. In critical applications, however, the parts should be tested to be sure of their effectiveness.

DECOUPLING

The bypass capacitor usually serves a dual role, first creating the low impedance needed to generate a “signal” ground. It also becomes part of a decoupling low-pass filter that passes dc while attenuating signals. The attenuation must function in both directions, suppressing noise in the power supply that might reach an amplifier while keeping amplifier signals from reaching the power supply. A low-pass filter is formed with alternating series and parallel component connections. A parallel bypass is followed by a series impedance, ideally a resistor.

Additional shunt elements can then be added, although this must be done with care. An inductor between shunt capacitors should have high inductance. It will resonate with the

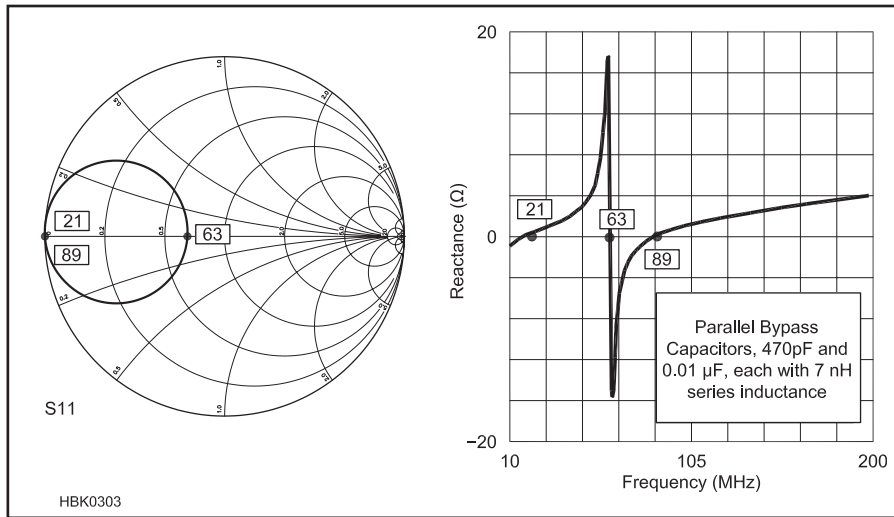

Fig 5.24 — The classic technique of paralleling bypass capacitors of two values, here 470 pF and 0.01 μF. This is a terrible bypass! See text.

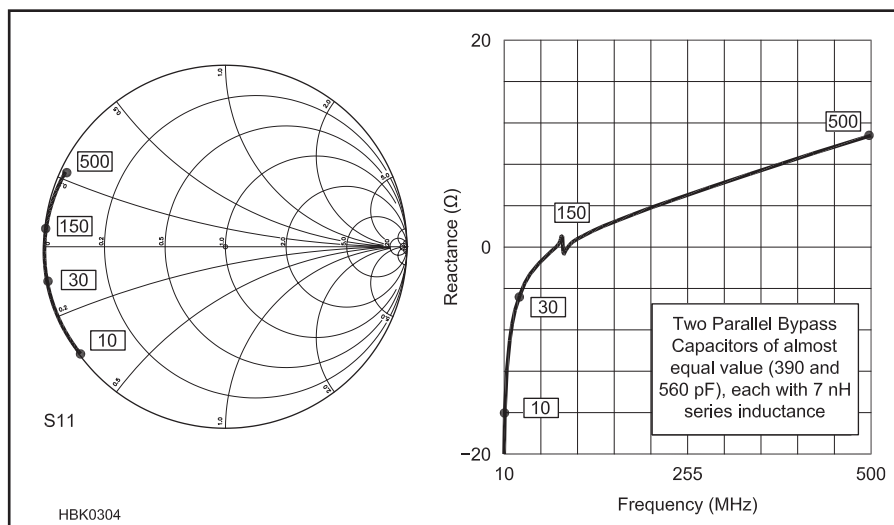

Fig 5.25 — Paralleling bypass capacitors of nearly the same value. This results in improved bypassing without complicating resonances.

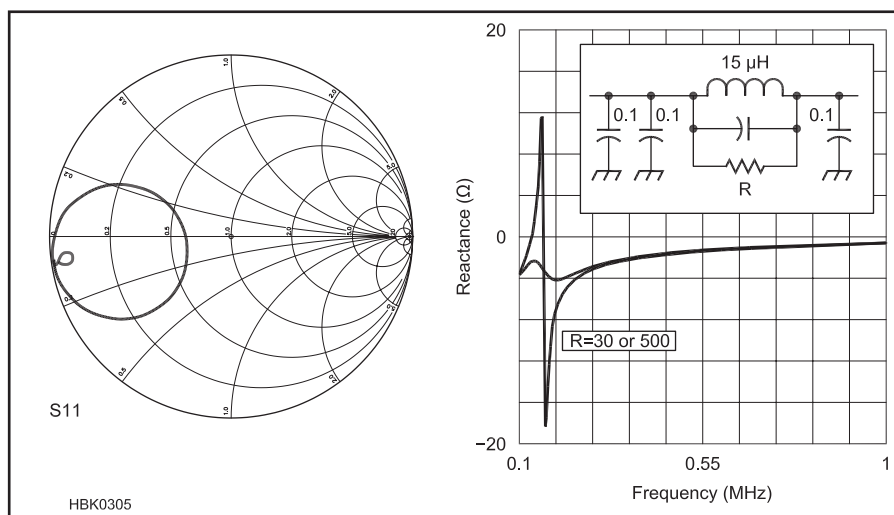

Fig 5.26 — Two different resistor values parallel a decoupling choke. The lower, 30-Ω value is more effective. See text.

shunt capacitors to create high impedances just like those that came from parasitic inductance in the bypasses. This makes it desirable to have an inductance that is high enough that any resonance is below the band of interest. But series inductors have their own problems; they have parasitic capacitance, creating their own self-resonance. As an example, a pair of typical RF chokes (RFCs) were measured (now as series elements) as described earlier. A 2.7-μH molded choke was parallel resonant at 200 MHz, indicating a parallel capacitance of 0.24 pF. The Q at 20 MHz was 52. A 15-μH molded choke was parallel resonant at 47 MHz, yielding a parallel C of 0.79 pF. This part had a Q of 44 at 8 MHz.

Large inductors can be fabricated from series connections of smaller ones. The best wideband performance will result only when all inductors in a chain have about the same value. The reasons for this (and the mathematics that describe the behavior) are identical with those for paralleling identical capacitors.

Low inductor Q is often useful in decoupling applications, encouraging us to use inductors with ferrite cores. Inductors using the Fair-Rite Type #43 material have low Q in the 4 to 10 range over the HF spectrum. One can also create low-Q circuits by paralleling a series inductor of modest Q with a resistor.

Fig 5.26 shows a decoupling network and the resulting impedance when viewed from the “bypass” end. The 15-μH RFC resonates with a 0.1-μF capacitor to destroy the bypass effect just above 0.1 MHz. A low-value parallel resistor fixes the problem.

A major reason for careful wideband bypassing and decoupling is the potential for amplifier oscillation. Instability that allows oscillations is usually suppressed by low impedance terminations. The base and collector (or gate and drain) should both “see” low impedances to ensure stability. But that must be true at all frequencies where the device can produce gain. It is never enough to merely consider the operating frequency for the amplifier. A parallel resonance in the base or collector circuits can be a disaster. When wideband bypassing is not possible, negative feedback that enhances wideband stability is often used.

Emitter bypassing is often a critical application. As demonstrated in the **Analog Basics** chapter, a few extra ohms of impedance in the emitter circuit can drastically alter amplifier performance. A parallel-resonant emitter bypass could be a profound difficulty while a series-resonant one can be especially effective.

Capacitors also appear in circuits as blocking elements. A blocking capacitor, for example, appears between stages, creating a near short circuit for ac signals while accommodating different dc voltages on the two sides. A blocking capacitor is not as critical

as a bypass, for the impedances on either side will usually be higher than that of the block.

With parasitic effects having the potential to strongly affect circuit performance, the circuit designer must account for them wherever they are significant. The additional complexity of including parasitic elements can result in a design too complex to be analyzed manually. Clearly, detailed modeling is the answer to component selection and the control of parasitic effects.

5.3.11 Effects on Filter Performance

LC bandpass filters perform a critical function in determining the performance of a typical RF system such as a receiver. An input filter, usually a bandpass, restricts the frequency range that the receiver must process. Transmitters use LC filters to reduce harmonic output. Audio and LF filters may also use LC elements. The LC filters we refer to in this section are narrow with a bandwidth from 1 to 20% of the center frequency. Even narrower filters are built with resonators having higher Q ; the quartz crystal filter discussed in the **RF and AF Filters** chapter is used where bandwidths of less than a part per thousand are possible. The basic concepts that we examine with LC circuits will transfer to the crystal filter.

LOSSES IN FILTERS AND Q

The key elements in narrow filters are tuned circuits made from inductor-capacitor pairs, quartz crystals, or transmission line sections. These resonators share the property that they store energy, but they have losses. A chime is an example. Striking the chime with a hammer produces the waveform of **Fig 5.27**. The rate at which the amplitude decreases with time after the hammer strike is determined by the filter's Q , which is discussed in the chapter on **Analog Basics**. The higher the Q , the longer it takes for the sound to disappear. The oscillator amplitude would not decrease if it were not for the losses that expend energy stored in the resonator. The mere act of observing the oscillation will cause some energy to be dissipated.

Fig 5.27 — The amplitude of a chime's ring after being struck by a hammer. Units are arbitrary.

A chime is an acoustic resonator, but the same behavior occurs in electric resonators. A pulse input to an LC circuit causes it to ring; losses cause the amplitude to diminish. The most obvious loss in an LC circuit is conductor resistance, including that in the inductor wire. This resistance is higher than the dc value owing to the skin effect, which forces high frequency current toward the conductor surface. Other losses might result from hysteresis losses in an inductor core or dielectric losses in a capacitor.

An inductor is modeled as an ideal part with a series or a parallel resistance. The resistance will depend on the Q if the inductor was part of a resonator with that quality. The two resistances are shown in **Fig 5.28**.

$$R_{\text{Series}} = \frac{2\pi f L}{Q} \quad \text{and}$$

$$R_{\text{Parallel}} = Q \times 2\pi f L \quad (6)$$

The higher the inductor Q , the smaller the series resistance, or the larger the parallel resistance is needed to model that Q . It does not matter which configuration is used. The Q of a resonator is related to the bandwidth of the tuned circuit by

Fig 5.28 — Inductor Q may be modeled with either a series or a parallel resistance.

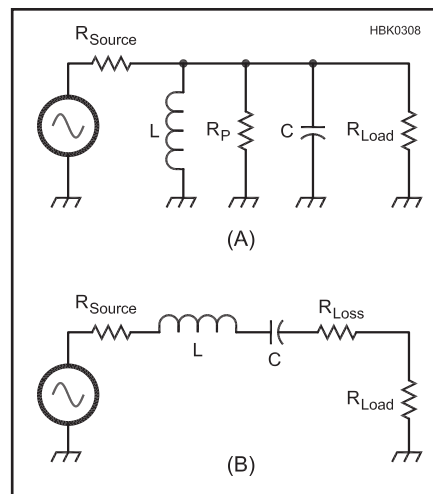

Fig 5.29 — Two simple forms of the single-tuned circuit.

$$BW = \frac{f_c}{Q} \quad (7)$$

where f_c is the tuned circuit's center frequency. This is also the Q of an inductor in a tuned circuit if the capacitor is lossless.

The single-tuned circuit is presented in two different forms in **Fig 5.29**. In the top, a parallel tuned circuit consisting of L and C has loss modeled by three resistors. The resistor R_p is the parallel loss resistance representing the non-ideal nature of the inductor. (Another might be included to represent capacitor losses.) But the LC is here paralleled by three resistors: the source, the load and the loss element. R_p would disappear if the tuned circuit was built from perfect components. The source and load remain; they represent the source resistance that must be present if power is available and a load resistance that must be included if power is to be extracted.

Equation 6 and 7 can be applied in several ways. If the resonator is evaluated with only its intrinsic loss resistance (in either series or parallel form) the resulting Q is called the *unloaded Q* , or Q_u . If, however, the net resistance is used, which is the parallel combination of the load, the source, and the loss in the parallel tuned circuit, the resulting Q is called the *loaded Q* , Q_L . If we were working with the series tuned circuit form, the loaded Q would be related to the total series R .

Consider an example, a parallel tuned circuit (**Fig 5.29A**) with a $2\text{-}\mu\text{H}$ inductor tuned to 5 MHz with a 507-pF capacitor. Assume the parallel loss resistor was 12.57 k Ω . The unloaded Q calculated from equation 6 is 200. The unloaded bandwidth would be 5 MHz/200 = 25 kHz. Assume that the source and load resistors were equal, each 2 k Ω . The net resistance paralleling the LC would then be the combination of the three resistors, 926 Ω . The loaded Q becomes 14.7 with a loaded bandwidth of 339 kHz. The loaded Q is also the filter Q , for it describes the bandwidth of the single-tuned circuit, the simplest of band-pass filters.

This filter also has *insertion loss (IL)*. This is illustrated in **Fig 5.30** which shows the

Fig 5.30 — Simplified parallel tuned circuit at resonance. The effect of loss is illustrated by removing the parallel-LC combination which at resonance has infinite impedance.

parallel-resonant LC combination removed (at resonance, the LC combination has infinite impedance), leaving only the loss resistance of 12.57 k Ω . We use an arbitrary open circuit source voltage of 2. The available power to a load is then 1 V across a resistance equaling the 2-k Ω source. If the resonator had no internal losses, this available power would be delivered to the 2-k Ω load. However, the loss R parallels the load, causing the output voltage to be 0.926 V, a bit less than the ideal 1 V. Calculation of the output power into the 2-k Ω load resistance and the available power shows that the insertion loss is 0.67 dB.

This exercise illustrates two vital points that are general for all bandpass filters. First, the bandwidth of any filter must always be larger than the unloaded bandwidth of the resonators used to build the filter. Second, any filter built from real-world components will have an insertion loss. The closer the Q of the filter approaches the unloaded resonator Q, the greater the insertion loss becomes. A parallel tuned circuit illustrated these ideas; the series tuned filter would have produced identical results. Generally, the insertion loss of a single-tuned circuit relates to loaded and unloaded Q by

$$IL(\text{dB}) = -20 \log \left(1 - \frac{Q_L}{Q_U} \right) \quad (8)$$

Fig 5.31 — Test setup for measuring the Q of a resonator. The source and load impedances, R_O , are assumed to be identical. The two coupling capacitors are adjusted to be equal to each other. The output signal is measured with an appropriate ac voltmeter, an oscilloscope or a spectrum analyzer.

The Q of a tuned LC circuit is easily measured with a signal generator of known output impedance (usually 50 Ω) and a sensitive detector, again with a known impedance level, often equal to that of the generator. The test configuration is shown in **Fig 5.31**. It uses equal loads and equal capacitors to couple from the terminations to the resonator. Equal capacitors, C1 and C2 guarantees that each termination contributes equally to the resonator parallel load resistance. The voltmeter across the load is calibrated in dB.

To begin measurement we remove the tuned circuit and replace it with a direct connection from generator to load. The available

power delivered to the load is calculated after the voltage is measured. The resonator is then inserted between the generator and load, and the generator is tuned for a peak. The measured power is less than that available from the source, with the difference being the insertion loss for the simple filter. Capacitors C1 and C2 are adjusted until the loss is 30 dB or more. With loss this high, the intrinsic loss resistance of the resonator will dominate the loss. The generator is now tuned first to one side of the peak, and then to the other, noting the frequencies where the response is lower than the peak by 3 dB. The unloaded bandwidth, ΔF , is the difference between the two 3 dB frequencies. The unloaded Q is calculated as

$$Q_U = \frac{F}{\Delta F} \quad (9)$$

This method for Q measurement is quite universal, being effective for audio tuned circuits, simple LC RF circuits, VHF helical resonators, or microwave resonators. The form of the variable capacitors, C1 and C2, may be different for the various parts of the spectrum, but the concepts are general. Indeed, it is not even important how the coupling occurs. The Q measurement normally determines an unloaded value, but loaded values are also of interest when testing filters.

5.4 Semiconductor Circuits at RF

The models used in the **Analog Basics** chapter are reasonably accurate at low frequencies, and they are of some use at RF, but more sophisticated models are required for consistent results at higher frequencies. This section notes several areas in which the simple models must be enhanced. Circuit design using models accurate at RF, particularly for large signals, is performed today using design software as described in the **Computer-Aided Circuit Design** chapter of this book. In-depth discussions of the elements of RF circuit design appear in Hayward's *Introduction to Radio Frequency Design*, an excellent text for the beginning RF designer (see the References section).

5.4.1 The Diode at High Frequencies

A DIODE AC MODEL

At high frequencies, the diode's behavior becomes less like a switch, especially for small signals that do not cause the diode's operating point to move by large amounts.

In this case, the diode's small-signal dynamic behavior becomes important.

Fig 5.32 shows a simple resistor-diode circuit to which is applied a dc bias voltage plus an ac signal. Assuming that the voltage drop across the diode is 0.6 V and R_f is negligible, we can calculate the bias current to be $I = (5 - 0.6) / 1 \text{ k}\Omega = 4.4 \text{ mA}$. This point is marked on the diodes I-V curve in **Fig 5.32**. If we draw a line tangent to this point, as shown, the slope of this line represents the *dynamic resistance* of the diode, R_d , experienced by a small ac signal. At room temperature, dynamic resistance is approximately

$$R_d = \frac{25}{I} \Omega \quad (10)$$

where I is the diode current in mA. Note that this resistance changes with bias current and should not be confused with the dc forward resistance discussed in the **Analog Basics** chapter, which has a similar value but represents a different concept. **Fig 5.33** shows a low-frequency ac model for the diode, including the dynamic resistance and junction

capacitance. This model should only be used when the diode's dc operating parameters can be neglected.

SWITCHING TIME

If you change the polarity of a signal applied to the ideal diode, current flow stops or starts instantaneously. Current in a real diode cannot do this, as a finite amount of time is required to move electrons and holes in or out of the diode as it changes states. Effectively, the diode junction capacitance, C_j , in **Fig 5.33** must be charged or discharged. As a result, diodes have a maximum useful frequency when used in switching applications.

The operation of diode switching circuits can often be modeled by the circuit in **Fig 5.34**. The approximate switching time (in seconds) for this circuit is given by

$$t_s = \tau_p \left(\frac{V_1}{R_1} \right) = \tau_p \frac{I_1}{I_2} \left(\frac{V_2}{R_2} \right) \quad (11)$$

Fig 5.32 — A simple resistor-diode circuit used to illustrate dynamic resistance. The ac input voltage “sees” a diode resistance whose value is the slope of the line at the Q-point, shown in B.

Fig 5.33 — An ac model for diodes. R_d is the dynamic resistance and C_j is the junction capacitance.

where τ_p is the minority carrier lifetime of the diode, a material constant determined during manufacture, on the order of 1 ms. I_1 and I_2 are currents that flow during the switching process. The minimum time in which a diode can switch from one state to the other and back again is therefore $2\tau_s$, and thus the maximum usable switching frequency is $f_{sw} \text{ (Hz)} = \frac{1}{2\tau_s}$. It is usually a good idea to stay below this by a factor of two. Diode data sheets usually give

Fig 5.34 — Circuit used for computation of diode switching time.

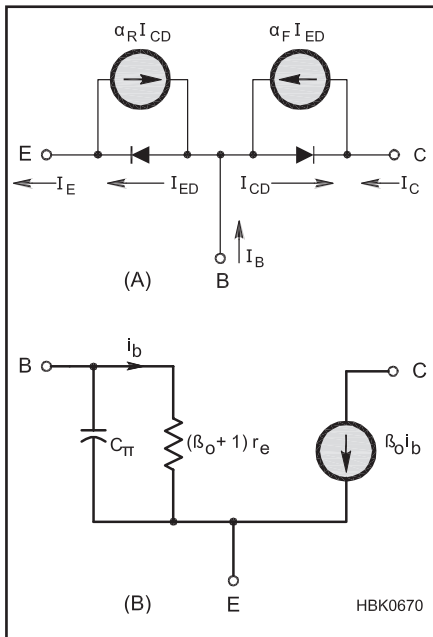

Fig 5.35 — (A) The Ebers-Moll model of the bipolar junction transistor (BJT) is used at dc and low frequencies when the transistor is in its active region. (B) The hybrid-pi model includes frequency dependence.

typical switching times and show the circuit used to measure them.

Note that f_{sw} depends on the forward and reverse currents, determined by I_1 and I_2 (or equivalently V_1 , V_2 , R_1 , and R_2). Within a reasonable range, the switching time can be reduced by manipulating these currents. Of course, the maximum power that other circuit elements can handle places an upper limit on switching currents.

5.4.2 The Transistor at High Frequencies

The development and selection of suitable models for active devices at RF is an involved and nuanced process. This section presents a few of the models used for bipolar junction transistors (BJT) and field-effect transistors (FET) as examples of the issues involved. For more information on model details, start with the *SPICE* home page at bwrc.eecs.berkeley.edu/classes/icbook/spice and the user’s manual for the simulation software you intend to use.

GAIN VERSUS FREQUENCY

The circuit design equations in **Analog Basics** generally assumed that current gain in the bipolar transistor was independent of frequency. As signal frequency increases, however, current gain decreases. The low-frequency current gain, β_0 , is constant through the audio spectrum, but it eventually decreases, and at some high frequency it will drop by a factor of 2 for each doubling of signal frequency. (The h-parameter $[h_{FE}]$ is often substituted for β at dc and h_{FE} for ac current gain. H-parameters are discussed later in this chapter.) A transistor’s frequency vs current gain relationship is specified by its *gain-bandwidth product*, or F_T , the frequency at which the current gain is 1. Common transistors for lower RF applications might have $\beta_0 = 100$ and $F_T = 500$ MHz. The frequency at which current gain equals β_0 is called F_b and is related to F_T by $F_b = F_T / \beta_0$.

The *Ebers-Moll model* for the bipolar transistor, shown in **Fig 5.35A**, is a “large signal model.” It is used when the transistor is in its active mode and gives good results for dc collector and emitter currents. This would be a good model to use when designing a pass-transistor voltage regulator circuit, for example.

The frequency dependence of current gain is modeled by adding a capacitor across the base resistor of **Fig 5.35B**, the *hybrid-pi* model results. The capacitor’s reactance should equal the low-frequency input resistance, $(\beta + 1)r_e$, at F_b . This simulates a frequency-dependent current gain.

Similar considerations affect the transconductance of FETs as the gate-to-source and gate-to-drain capacitances act to reduce high-frequency gain. Instead of F_T , most FETs designed for amplifier use specify input and output transconductance, susceptance, and power gain at different frequencies.

Recognizing that transistor gain varies with frequency, it is important to know the conditions under which the simpler model is useful. Calculations show that the simple model is valid, with $\beta = F_T / F$, for frequencies well above F_b . The approximation worsens, however, as the operating frequency (f_0) approaches F_T .

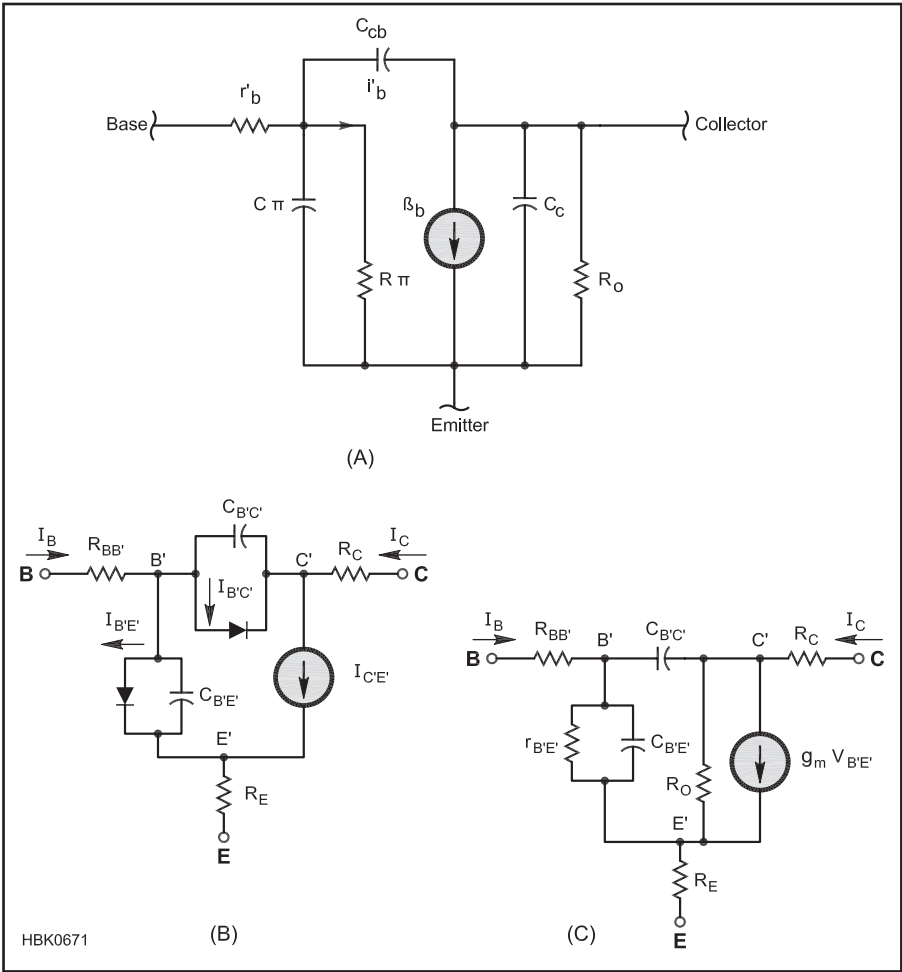

Fig 5.36 — High-frequency models for the bipolar junction transistor. (A) An improved version of the hybrid-pi model including additional device capacitances. (B) is the large-signal Gummel-Poon model used at dc and low-frequencies — the standard used for bipolar transistors by simulators based on SPICE3 and (C) is the small-signal ac version.

SMALL-SIGNAL DESIGN AT RF

The simplified hybrid-pi model of Fig 5.35B is often suitable for non-critical designs, but **Fig 5.36A** shows a better small-signal model for RF design that expands on the hybrid-pi. Consider the physical aspects of a real transistor: There is some capacitance across each of the PN junctions (C_{cb} and C_p) and capacitance from collector to emitter (C_c). There are also capacitances between the device leads (C_e , C_b and C_c). There is a resistance in each current path, emitter to base and collector. From emitter to base, there is r_{π} from the hybrid-pi model and r'_b , the “base spreading” resistance. From emitter to collector is R_o , the output resistance. The leads that attach the silicon die to the external circuit present three inductances.

Manual circuit analysis with this model is best tackled with the aid of a computer and specialized software. Other methods are presented in Hayward’s *Introduction to Radio Frequency Design*. Surprisingly accurate results may be obtained, even at RF, from the simple models. Simple models also give a better “feel” for device characteristics that might be obscured by the mathematics of a more rigorous treatment. Use the simplest model that describes the important features of the device and circuit at hand.

The *Gummel-Poon model* shown in Figs 5.36B and 5.36C is the standard used by simulation software based on SPICE3. By adding additional parasitic elements, such as lead inductance and lead-to-package capacitances, the small-signal ac model can be used accurately at high frequencies. Note how the ac model becomes progressively more sophisticated from Fig 5.35A through 5.36C.

HIGH FREQUENCY FET MODELS

At low frequencies the FET can be treated as a simple current source controlled by the gate-to-source voltage as in Fig 3.49 in the **Analog Basics** chapter. As frequency increases, the inter-electrode capacitances become significant and must be included, such as in the model in **Fig 5.37A**. As with the BJT,

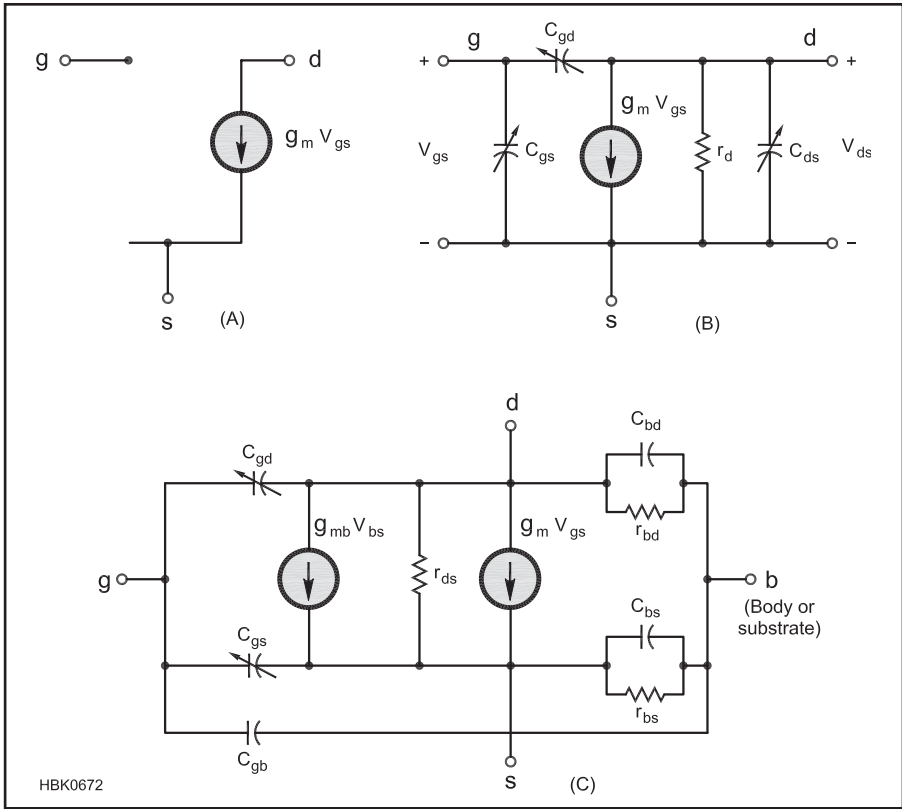

Fig 5.37 — Small-signal models for the field-effect transistor (FET). (A) is a simple low-frequency model. (B) is a common SPICE3 large-signal model and (C) is a typical high-frequency model for the JFET.

separate models are used for small-signal and large-signal applications. Fig 5.37B shows a small-signal *SPICE3* simulation model for the JFET. All of the model's capacitances vary with temperature and device operating characteristics. Fig 5.37C shows a typical high-frequency MOSFET model used by *SPICE3* (there are several) that includes the effect of the body or substrate elements.

The advances in CMOS integrated circuit technology have resulted in transistors (and capacitors and inductors) with sufficient performance for use in RF design work. In fact, most radio transceivers for cellular telephones, wireless LANs and similar high-volume applications are implemented almost exclusively in CMOS technology due to the high integration available. MOSFET RF design principles are similar to BJT and JFET designs, and most circuit simulators provide good models for MOSFET devices. These additional techniques are enabled by the excellent device matching available in IC technology and the ability to integrate additional circuitry at low incremental cost.

PARASITIC ELEMENTS AND NOISE

For accurate RF simulation the effects of additional parasitic elements must be included. The most significant is lead inductance — generally inserted in series with the device's external connections. Lead-to-package and lead-to-lead capacitances are also included in most high-frequency simulations. Depending on the simulation package used, the user may be required to install these parasitic elements as separate circuit elements or the simulator or manufacturer may provide special models for high-frequency simulation.

Simulation of device noise is not covered here, but many simulator packages include separate noise models for various active devices. Review the simulator's documentation for information about how to include noise in your simulation.

5.4.3 Amplifier Classes

The class of operation of an amplifier is determined by the fraction of a drive cycle during which conduction occurs in the amplifying device or for switchmode devices. (Switchmode amplifiers use different criteria.) The Class A amplifier conducts for 100% of the cycle. It is characterized by constant flow of supply current, regardless of the strength of the driving signal. Most of the amplifiers we use for RF applications and many audio circuits in receivers operate in Class A.

A Class B amplifier conducts for 50% of the cycle, which is 180 degrees if we examine the circuit with regard to a driving sine wave. A Class B amplifier draws no dc current when no input signal is applied, but current begins to flow with any input, growing with the input

strength. A Class B amplifier can display good *envelope linearity*, meaning that the output amplitude at the drive frequency changes linearly with the input signal. The total absence of current flow for half of the drive cycle will create harmonics of the signal drive.

A Class C amplifier is one that conducts for less than half of a cycle. No current flows without drive. Application of a small drive produces no output and no current flow. Only after a threshold is reached does the device begin to conduct and provide output. A bipolar transistor with no source of bias for the base typically operates in Class C.

The large-signal models discussed earlier are suitable for the analysis of all amplifier classes. Small-signal models are generally reserved for Class A amplifiers. The most common power amplifier class is a cross between Class A and B — the Class AB amplifier that conducts for more than half of each cycle. A Class AB amplifier at low drive levels is indistinguishable from a Class A design. However, increasing drive produces greater collector (or drain) current and greater output.

Amplifier class letter designators for vacuum tube amplifiers were augmented with a numeric subscript. A Class AB₁ amplifier operates in AB, but with no grid current flowing. A Class AB₂ amplifier's grid is driven positive with respect to the cathode and so some grid current flows. In solid-state amplifiers, which have no grids, no numeric subscripts are used.

While wide-bandwidth Class A and Class B amplifiers are common, most circuits operating in Class C and higher are tuned at the output. The tuning accomplishes two things. First, it allows different terminations to exist for different frequencies. For example, a resistive load could be presented at the drive frequency while presenting a short circuit at some or all harmonics. The second consequence of tuning is that reactive loads can be created and presented to the amplifier collector or drain. This then provides independent control of current and voltage waveforms.

While not as common as A, B, and C, Class D and E amplifiers are of increasing interest. The Class D circuit is a balanced (two transistor) switching format where the input is driven hard enough to produce square wave collector waveforms. Class E amplifiers usually use a single switching device with output tuning that allows high current to flow in the device only when the output voltage is low. Other "switching amplifier" class designators refer to the various techniques of controlling the switched currents and voltages.

Class A and AB amplifiers are capable of good envelope linearity, so they are the most common formats used in the output of SSB amplifiers. Class B and, predominantly, Class C amplifiers are used for CW and FM

applications, but lack the envelope linearity needed for SSB.

Efficiency varies considerably between amplifier class. The Class A amplifier can reach a collector efficiency of 50%, but no higher, with much lower values being typical. Class AB amplifiers are capable of higher efficiency, although the wideband circuits popular in HF transceivers typically offer only 30% at full power. A Class C amplifier is capable of efficiencies approaching 100% as the conduction cycle becomes small, with common values of 50 to 75%. Both Class D and E are capable of 90% and higher efficiency. An engineering text treating power amplifier details is Krauss, Bostian, and Raab's *Solid State Radio Engineering*. A landmark paper by a Cal Tech group led by David Rutledge, KN6EK, targeted to the home experimenter, *High-Efficiency Class-E Power Amplifiers*, was presented in *QST* for May and June, 1997.

5.4.4 RF Amplifiers with Feedback

The feedback amplifier appears frequently in amateur RF circuits. This is a circuit with two forms of negative feedback with (usually) a single transistor to obtain wide bandwidth, well-controlled gain and well-controlled, stable input and output resistances. Several of these amplifiers can be cascaded to form a high gain circuit that is both stable and predictable.

The small-signal schematic for the feedback amplifier is shown in Fig 5.38 without bias components or power supply details. The design begins with an NPN transistor biased for a stable dc current. Gain is reduced with emitter degeneration, increasing input resistance while decreasing gain. Additional feedback is then added with a parallel feedback resistor, R_f, between the collector and base. This is much like the resistor between an op-amp output and the inverting input which reduces gain and *decreases* input resistance.

Several additional circuits are presented

Fig 5.38 — Small-signal circuit for a feedback amplifier.

Fig 5.39 — A practical feedback amplifier. Components marked with “B” are predominantly for biasing. The 50-Ω output termination is transformed to 200 Ω at the collector. A typical RF transformer is 10 bifilar turns of #28 on a FT-37-43 ferrite toroid. The inductance of one of the two windings should have a reactance of around 250 Ω at the lowest frequency of operation.

Fig 5.40 — A variation of the feedback amplifier with a 50-Ω output termination at the collector.

showing practical forms of the feedback amplifier. **Fig 5.39** shows a complete circuit. The base is biased with a resistive divider from the collector. However, much of the resistor is bypassed, leaving only R_f active for actual signal feedback. Emitter degeneration is ac-coupled to the emitter. The resistor R_E dominates the degeneration since R_E is normally much smaller than the emitter bias resistor. Components that are predominantly used for biasing are marked with “B.” This amplifier would normally be terminated in 50 Ω at both the input and output. The transformer has the effect of making the 50-Ω load “look like” a

Fig 5.41 — This form of the feedback amplifier uses an arbitrary transformer. Feedback is isolated from bias components.

Fig 5.42 — A feedback amplifier with feedback from the output transformer tap. This is common, but can produce unstable results.

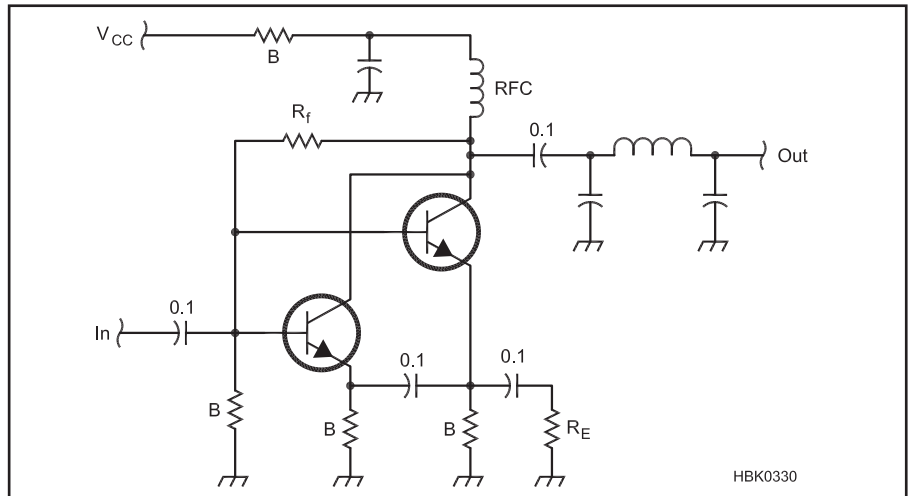

Fig 5.43 — Feedback amplifier with two parallel transistors.

larger load value, $R_L = 200 \Omega$ to the collector. This is a common and useful value for many HF applications.

Fig 5.40 differs from **Fig 5.39** in two places. First, the collector is biased through an RF choke instead of a transformer. The collector circuit then “sees” 50 Ω when that load is connected. Second, the emitter degeneration is in series with the bias, instead of the earlier parallel connection. Either scheme works well, although the parallel configuration affords experimental flexibility with isolation between setting degeneration and biasing. Amplifiers without an output transformer are not constrained by degraded transformer performance and often offer constant or “flat” gain to several GHz.

The variation of **Fig 5.41** may well be the most general. It uses an arbitrary transformer to match the collector. Biasing is traditional

and does not interact with the feedback.

Feedback is obtained directly from the output tap in the circuit of **Fig 5.42**. While this scheme is common, it is less desirable than the others, for the transformer is part of the feedback loop. This could lead to instabilities. Normally, the parallel feedback tends to stabilize the amplifiers.

The circuit of **Fig 5.43** has several features. Two transistors are used, each with a separate emitter biasing resistor. However, ac coupling causes the pair to operate as a single device with degeneration set by R_E . The parallel feedback resistor, R_f , is both a signal feedback element and part of the bias divider. This constrains the values slightly. Finally, an arbitrary output load can be presented to the composite collector through a π -type matching network. This provides some low pass filtering, but constrains the amplifier bandwidth.

5.5 Ferrite Materials

Ferrites are ceramics consisting of various metal oxides formulated to have very high permeability. Iron, manganese, manganese zinc (MnZn), and nickel zinc (NiZn) are the most commonly used oxides. Ferrite cores and beads are available in many styles, as shown in Fig 5.44. Wires and cables are then passed through them or wound on them.

When ferrite surrounds a conductor, the high permeability of the material provides a much easier path for magnetic flux set up by current flow in the conductor than if the wire were surrounded only by air. The short length of wire passing through the ferrite will thus see its self-inductance “magnified” by the relative permeability of the ferrite. The ferrites used for suppression are soft ferrites — that is, they are not permanent magnets.

Recalling the definition in the **Electrical Fundamentals** chapter, permeability (μ) is the characteristic of a material that quantifies the ease with which it supports a magnetic field. Relative permeability is the ratio of the permeability of the material to the permeability of free space. The relative permeability of nonmagnetic materials like air, copper, and aluminum is 1, while magnetic materials have a relative permeability much greater than 1. Typical values (measured at power frequencies) for stainless steel, steel and mu-metal are on the order of 500, 1000 and 20,000 respectively. Various ferrites have values from the low tens to several thousand. The permeability of these materials changes with frequency and this affects their suitability for use as an inductor’s magnetic core or as a means of providing EMI suppression.

Manufacturers vary the chemical composition (the *mix* or *material “type”*) and the dimensions of ferrites to achieve the desired electrical performance characteristics. It is important to select a mix with permeability and loss characteristics that are appropriate for the intended frequency range and application. (The **Component Data and References** chapter includes tables showing the data for different

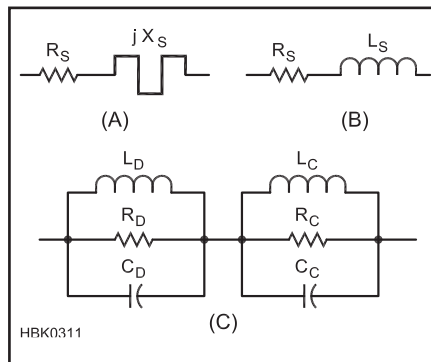

Fig 5.45 — Equivalent circuits for ferrite material. (A) shows the equivalent series circuit specified by the data sheet. (B) shows an over-simplified equivalent circuit for a ferrite choke. (C) shows a better equivalent circuit for a ferrite choke.

types of ferrite and powdered-iron cores and appropriate frequency ranges for each.)

Fair-Rite Products Corp. supplies most of the ferrite materials used by amateurs, and their website (www.fair-rite.com) includes extensive technical data on both the materials and the many parts made from those materials. Much can be learned from the study of this data, the most extensive of any manufacturer. The website includes two detailed application notes on the use of ferrite materials, *How to Choose Ferrite Components for EMI Suppression* and *Use of Ferrites in Broadband Transformers*.

5.5.1 Ferrite Permeability and Frequency

Product data sheets characterize ferrite materials used as chokes by graphing their series equivalent impedance, and chokes are usually analyzed as if their equivalent circuit had only a series resistance and inductance, as shown in Figs 5.45A and 5.45B. (Fig 5.45 presents small-signal equivalent circuits. Is-

Fig 5.46 — Permeability of a typical ferrite material, Fair-Rite Type #61 (A) and of Type #43 material (B). (Based on product data published by Fair-Rite Products Corp.)

Fig 5.44 — Ferrites are made in many forms. Beads are cylinders with small center holes so that they can be slid over wires or cables. Toroidal cores are more ring-like so that the wire or cable can be passed through the center hole multiple times. Snap-on or split cores are made to be clamped over cables too large to be wound around the core or for a bead to be installed.

sues of temperature and saturation at high power levels are not addressed in this section.) The actual equivalent circuit is closer to Fig 5.45C. The presence of both inductance and capacitance creates resonances visible in the graphs of impedance versus frequency as discussed below. One resonance is created by the pair $L_D C_D$ and the other by $L_C C_C$.

Fig 5.46A graphs the permeabilities μ'_s and μ''_s for Fair-Rite Type #61 ferrite material (Fair-Rite products are identified by a material “Type” and a number), one of the many mix choices available. This material is recommended for use in inductive applications below 25 MHz and for EMI suppression at frequencies above 200 MHz.

For the simple series equivalent circuit of Fig 5.45A and B, the permeability constant for ferrite is actually complex; $\mu = \mu'_s + j \mu''_s$. In this equation, μ'_s represents the component of permeability defining ordinary inductance, and μ''_s describes the component that affects losses in the material. You can see that up to approximately 20 MHz, μ'_s is nearly constant, meaning that an inductor wound on a core of this material will have a stable inductance. Below about 15 MHz, the chart shows that μ''_s is much smaller than μ'_s , so that losses are small, making this material good for high power inductors and transformers in this frequency range.

Above 15 MHz, μ''_s increases rapidly and so do the material’s associated losses, peaking between 300 and 400 MHz. That makes the inductor very lossy at those frequencies and good for suppressing EMI by absorbing energy in the unwanted signal. **Fig 5.47** shows the manufacturer’s impedance data for one “turn” of wire through a cylindrical ferrite bead (a straight wire passing through the bead) made of mix #61 with the expected peak in impedance above 200 MHz. Interestingly,

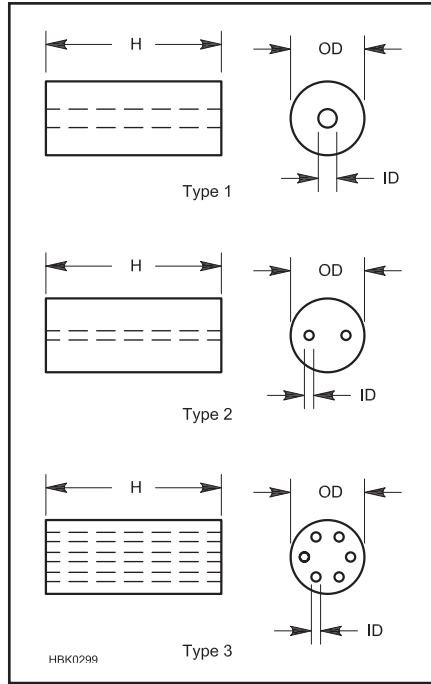

Fig 5.49 — Typical one-piece ferrite bead configurations. Component leads or cables can be inserted through beads one or more times to create inductance and loss as described in the text.

X_L goes below the graph above resonance, but it isn’t zero. The negative reactance is created by the capacitors in Fig 5.45C.

The Type #43 mix (see Fig 5.46B) used for the beads of **Fig 5.48** is optimized for suppression

Fig 5.50 — A ferrite choke consisting of multiple turns of cable wound on a 2.4-in. OD x 1.4-in. ID x 0.5-in. toroid core.

at VHF (30-300 MHz). Type #43 material’s μ'_s is much higher than type #61, meaning that fewer turns are required to achieve the needed inductance. But μ''_s for #43 remains significant even at low frequencies, limiting its usefulness for inductor and transformer cores that must handle high power. The figure shows the impedance data for several beads of different lengths. The longer the bead, the higher the impedance. The same effect can be obtained by stringing multiple beads together on the same wire or cable.

5.5.2 Resonances of Ferrite Cores

Below resonance, the impedance of a wire passing through a ferrite cylinder is proportional to the length of the cylinder. Fig 5.48

Fig 5.51 — Impedance of multi-turn choke wound on a Fair-Rite Type #43 core as shown in Fig 5.50. Type #43 material is optimized for use as a choke for the VHF range. (Measured data)

Fig 5.52 — Impedance of multi-turn choke wound on a Fair-Rite Type #78 core as shown in Fig 5.50. Type #78 material is optimized for use as a choke below 2 MHz. (Measured data)

Fig 5.53 — Series reactive component of the chokes of Fig 5.52. (Measured data)

shows the impedance of a family of beads that differ primarily in their length. There are also small differences in their cross section, which is why the resonant frequency shifts slightly as discussed below. Fig 5.49 shows some typical ferrite bead configurations.

Like all inductors, the impedance of a fer-

rite choke below resonance is approximately proportional to the square of the number of turns passing through the core. Fig 5.50 shows a multi-turn choke wound on a 2.4-inch OD × 1.4-inch ID × 0.5-inch ferrite toroid core. Fig 5.51 is measured data for the choke in Fig 5.50 made of ferrite optimized for the VHF

range (30-300 MHz). The data of Fig 5.52 are for toroids of the same size, but wound on a material optimized for use below 2 MHz.

We'll study the $L_D C_D$ resonance first. A classic text (*Soft Ferrites, Properties and Applications*, by E. C. Snelling, published in 1969), shows that there is a dimensional resonance within the ferrite related to the velocity of propagation (V_p) within the ferrite and standing waves that are set up in the cross-sectional dimensions of the core. In general, for any given material, the smaller the core, the higher will be the frequency of this resonance, and to a first approximation, the resonant frequency will double if the core dimension is halved. In Fig 5.45C, L_D and C_D account for this dimensional resonance, and R_D for losses within the ferrite. R_D is mostly due to eddy currents (and some hysteresis) in the core.

Now it's time to account for R_C , L_C and C_C . Note that there are two sets of resonances for the chokes wound around the Type #78 material (Fig 5.52), but only one set for the choke of Fig 5.51. For both materials, the upper resonance starts just below 1 GHz for a single turn and moves down in frequency as the number of turns is increased. Fig 5.53, the reactance for the chokes of Fig 5.52, also shows both sets of resonances. That's why the equivalent circuit must include two parallel resonances!

The difference between these materials that accounts for this behavior is their chemical composition (the mix). Type #78 is a MnZn ferrite, while Type #43 is a NiZn ferrite. The velocity of propagation (V_p) in NiZn ferrites is roughly two orders of magnitude higher than for MnZn, and, at those higher frequencies, there is too much loss to allow the standing waves that establish dimensional resonance to exist.

To understand what's happening, we'll return to our first order equivalent circuit of a ferrite choke (Fig 5.45C). L_C , and R_C , and C_C are the inductance, resistance, (including the effect of the μ of the ferrite), and stray capacitance associated with the wire that passes through the ferrite. This resonance moves down in frequency with more turns because both L and C increase with more turns. The dimensional resonance does not move, since it depends only on the dimensions V_p of the ferrite.

What is the source of C_C if there's no "coil," only a single wire passing through a cylinder? It's the parasitic capacitance from the wire at one end of the cylinder to the wire at the other end, with the ferrite acting as the dielectric. Yes, it's a very small capacitance, but you can see the resonance it causes in the measured data and on the data sheet.

5.5.3 Ferrite Series and Parallel Equivalent Circuits

Let's talk briefly about series and parallel equivalent circuits. Many impedance analyzers express the impedance between their ter-

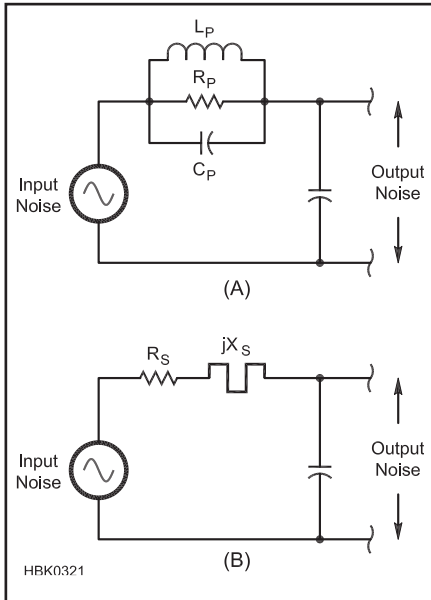

Fig 5.54 — At A, the series element of the divider is a parallel-resonant circuit. At B, the series element of the divider is the series-equivalent circuit used by ferrite data sheets.

minals as Z with a phase angle, and the series equivalent R_S and X_S . They could just have easily expressed that same impedance using the parallel equivalent R_P and X_P but R_P and X_P will have values that are numerically different from R_S and X_S . (See the section on series-parallel impedance transformation in the **Electrical Fundamentals** chapter.)

It is important to remember that in a series circuit, the larger value of R_S and X_S has the greatest influence, while in a parallel circuit, the smaller value of R_P and X_P is dominant. In other words, for R_P to dominate, R_P must be small.

Both expressions of the impedance (series or parallel) are correct at any given frequency, but whether the series or parallel representation is most useful will depend on the physics of the device being measured and how that device is used in a circuit. We've just seen, for example, that the parallel equivalent circuit is a more realistic representation of a ferrite choke — the values of R_P , L_P , and C_P will come much closer to remaining constant as frequency changes than if we use the series equivalent. (R_P , L_P and C_P won't be precisely constant though, because the physical properties of all ferrites — permeability, resistivity and permittivity — all vary with frequency.)

Fig 5.55 — At A, the impedance of multi-turn chokes on a Type #31 2.4-in. OD toroidal core. At B, the equivalent series resistance of the chokes of (A). (Measured data)

But virtually all product data for ferrite chokes is presented as the series equivalent R_S and X_S . Why? First, because it's easy to measure and understand, second, because we tend to forget there is stray capacitance, and third because ferrite beads are most often used as chokes to reduce current in a series circuit! **Fig 5.54A** and **Fig 5.54B** are both useful representations of the voltage divider formed by

a ferrite choke and a small bypass capacitor across the device input. Which we use will depend on what we know about our ferrite.

If we know R_P , L_P and C_P and they are constant over the frequency range of interest, **Fig 5.54A** may be more useful, because we can insert values in a circuit model and perhaps tweak the circuit. But if we have a graph of R_S and X_S vs frequency, **Fig 5.54B**

Fig 5.56 — At A, the impedance of multi-turn chokes on a Type #43 2.4-in. OD toroidal core. At B, the equivalent series resistance of the chokes of A. (Measured data).

will give us a good answer faster. Because we will most often be dealing with R_S and X_S data, the series circuit equivalents are used most often. Another reason for using R_S and X_S is that the impedance of two or more ferrite chokes in series can be computed simply by adding their R_S and X_S components, just as with any other series impedances! When you look at the data sheet plots of R_S , X_L and Z for

a standard ferrite part, you are looking at the series equivalent parameters of their dominant resonance. For most MnZn materials, it is dimensional resonance, while, for most NiZn materials, it is the circuit resonance.

Values for R_p , L_p and C_p for nearly any ferrite choke can be obtained by curve-fitting the data for its parallel-resonance curve. (Self-resonance is discussed earlier in this chapter.)

Because the C_p of many practical chokes is quite small and their impedance at resonance is often rather high, they are quite difficult to measure accurately, especially with reflection-based measurement systems. See the **Test Equipment and Measurements** chapter for a simple measurement method that can provide good results. More information on the use of ferrite cores and beads for EMI suppression is available in the chapter on **RF Interference** and in *The ARRL RFI Book*. A thorough treatment of the use of these ferrite materials for EMI suppression is continued in the online publication *A Ham's Guide to RFI, Ferrites, Baluns, and Audio Interfacing* at www.audiosystemsgroup.com/publish. The use of ferrite beads and cores for transmitting chokes is presented in the **Transmission Lines** chapter.

5.5.4 Type 31 Material

The relatively new Type #31 material made by Fair-Rite Products is extremely useful as a choke core, especially if some component of your problem occurs below 5 MHz. Measured data for the new material is displayed in **Figs 5.55A** and **5.55B**. Compare it with **Figs 5.56A** and **5.56B**, which are corresponding plots for the older Type #43 material. By comparison, Type #31 provides nearly 7 dB greater choking impedance at 2 MHz, and at least 3 dB more on 80 meters. At 10 MHz and above, the two materials are nearly equivalent, with Type #43 being about 1 dB better. If your goal is EMI suppression or a feed line choke (a so-called “current balun”), the Type #31 material is the best all round performer to cover all HF bands, and is clearly the material of choice at 5 MHz and below. Between 5 MHz and 20 MHz, Type #43 has a slight edge (about 1 dB), and above 20 MHz they're equivalent. (Baluns are discussed more in the section below on Transmission Line Transformers and in the chapters on **Transmission Lines** and **Antennas**.)

The new Type #31 material is useful because it exhibits both of the resonances in our equivalent circuit — that is, the dimensional resonance of the core and the resonance of the choke with the lossy permeability of the core material. Below 10 MHz, these two resonances combine (in much the manner of a stagger-tuned IF) to provide significantly greater suppression bandwidth (roughly one octave, or one additional harmonically related ham band). The result is that a single choke on a Type #31 core can be made to provide very good suppression over about 8:1 frequency span, as compared to 4:1 for Type #43. Type #31 also has somewhat better temperature characteristics at HF.

5.6 Impedance Matching Networks

An impedance transforming or matching network is one that accepts power from a generator with one characteristic impedance, the source, and delivers virtually all of that power to a load at a different impedance. The simple designs in this section provide matching at only one frequency. More refined methods discussed in the reference texts can encompass a wide band of frequencies.

Both source and load impedances are likely to be complex with both real and imaginary (reactive) parts. The procedures given in this section allow the reader to design the common impedance-matching networks based on the simplification that both the source and load impedance are resistive (with no reactive component). To use these procedures with a complex load or source impedance, the usual method is to place a reactance in series with the impedance that has an equal and opposite reactance to cancel the reactive component of the impedance to be matched. Then treat the

resulting purely-resistive impedance as the resistance to be transformed. For example, if a load impedance to be matched is $120 + j 40 \Omega$, add capacitive reactance of $-j 40 \Omega$ in series with the load, resulting in a load impedance of $120 + j 0 \Omega$ so that the following procedures can be used. The series reactance-canceling component may then be combined with the matching network's output component in some configurations.

A set of 14 simple resonant networks, and their equations, is presented in Fig 5.58. Note that in these diagrams R_S is the low impedance side and R_L is the high impedance side and that the X values are calculated in the top-down order given.

The formulas for the various networks use and produce values of reactance. To convert the reactances to L and C values, use the formulas

$$C = \frac{1}{2\pi f X_c} \text{ and } L = \frac{X_L}{2\pi f}$$

The program *MATCH.EXE* on the CD-ROM accompanying this *Handbook* can perform the calculations.

You may wish to review the section on series-parallel impedance transformations in the **Electrical Fundamentals** chapter as those techniques form the basis of impedance-matching network design. There is additional discussion of L networks in the chapters on **Transmission Lines** and of Pi networks in the **RF Power Amplifiers** chapter. These discussions apply to more specific applications of the networks.

5.6.1 L Networks

Perhaps the most common LC impedance transforming network is the L network, so named because it uses two elements — one series element and one parallel — resembling the capital L on its side. There are eight different types of L networks as shown in Fig 5.57.

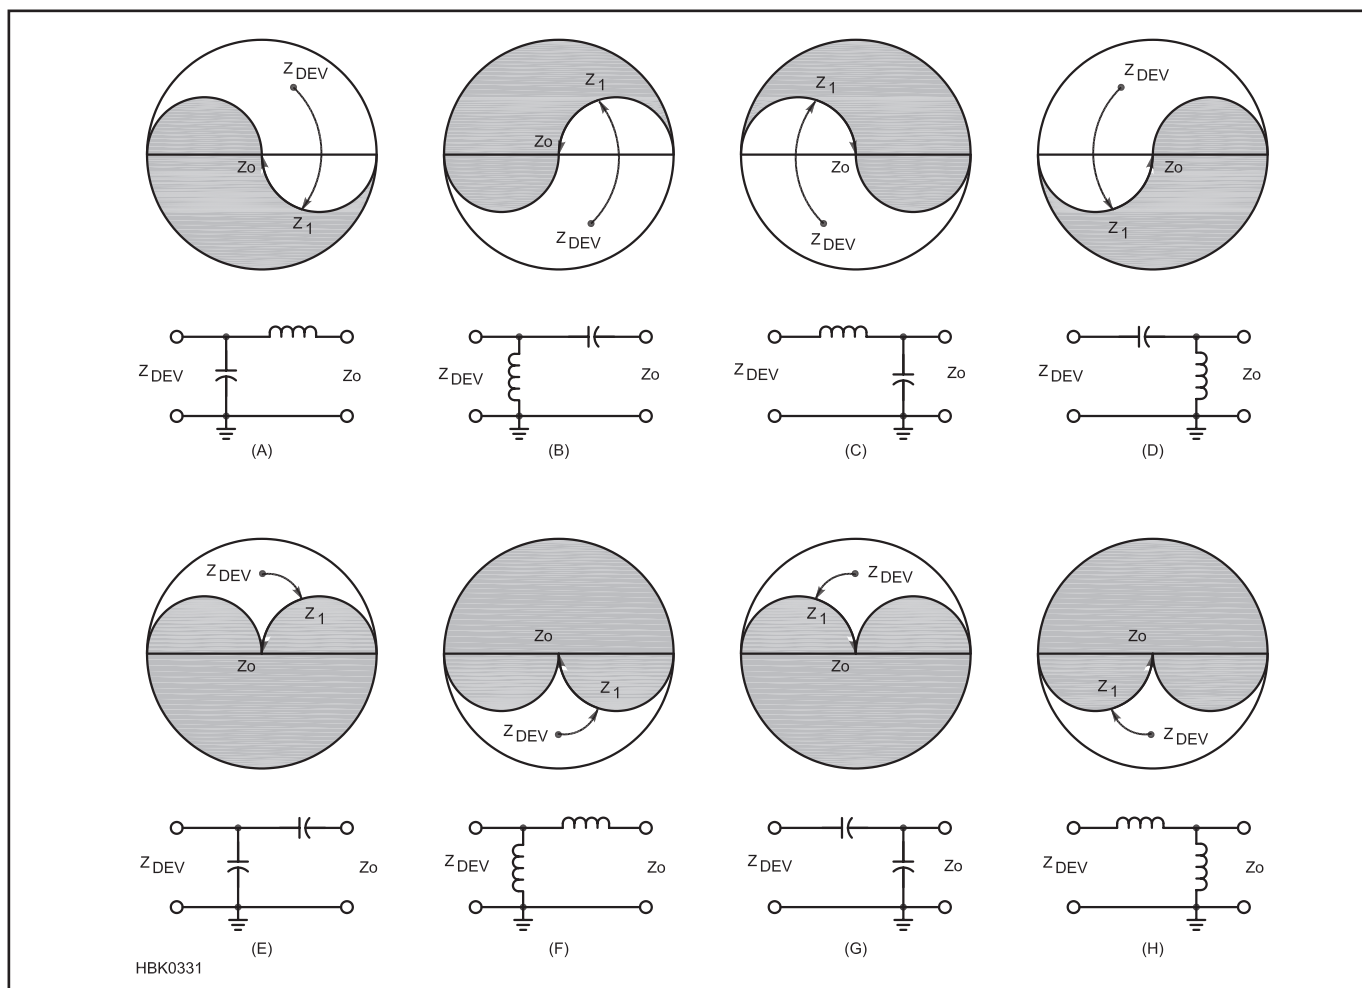

Fig 5.57 — L-networks which will match a complex impedance (shown here as Z_{DEV} , the output impedance of a device) to Z_0 , a resistive source or load. Impedances within the shaded portion of the simplified Smith Chart cannot be matched by the network. Z_1 represents the impedance that is transformed from Z_{DEV} by the series element.

HBK0674

Fig 5.58 — Fourteen impedance transforming networks with their design equations (for lossless components).

(Types G and H are not as widely used and not covered here.) The simplified Smith Chart sketches show what range of impedance values can be transformed to the required impedance Z_0 and the path on the chart by which the transformation is achieved by the two reactances. (An introductory discussion of the Smith Chart is provided on this book's CD-ROM and a detailed treatment is available in *The ARRL Antenna Book*.) Z_{DEV} represents the output impedance of a device, such as a transistor amplifier or any piece of equipment.

The process of transformation works the same in both "directions." That is, a network designed to transform Z_{DEV} to Z_0 will also transform Z_0 to Z_{DEV} if reversed. The L network (and the Pi and T networks discussed below) is *bilateral*, as are all lossless networks.

Purely from the standpoint of impedance matching, the L-network can be constructed with inductive or capacitive reactance in the series arm and the performance will be exactly the same in either case. However, the usual case in amateur circuits is to place the inductive reactance in the series arm to act as a low pass filter. Your particular circumstances may dictate otherwise, however. For example, you may find it useful that the series-C/parallel-L network places a dc short circuit across one side of the network while blocking dc current through it.

The design procedure for L network configurations A through F in Fig 5.57 is as follows:

Given the two resistance values to be matched, connect the series arm of the circuit to the smaller of the two (R_S) and the parallel arm to the larger (R_P).

Find the ratio R_P/R_S and the L network's Q:

$$Q = \sqrt{\frac{R_P}{R_S} - 1}$$

Calculate the series reactance $X_S = QR_S$

Calculate the parallel reactance $X_P = R_P/Q$.

5.6.2 Pi Networks

Another popular impedance matching network is the Pi network shown in circuits 1 and 2 of Fig 5.58. The Pi network can be thought of as two L networks "back to back." For example, the Pi network in circuit 1 can be split into the L network of circuit 13 on the right and its mirror image on the

left. The two inductors in series are combined into the single inductance of the Pi network. There are other forms of the Pi network with different configurations of inductance and capacitance, but the version shown is by far the most common in amateur circuits.

The use of two transformations allows the designer to choose Q for the Pi network, unlike the L network for which Q is determined by the ratio of the impedances to be matched. This is particularly useful for matching amplifier outputs as discussed in the **RF Power Amplifier** chapter because it allows more control of the network's frequency response and of component values. Q must be high enough that $(Q^2 + 1) > (R_1/R_2)$. If these two quantities are equal, X_{C2} becomes infinite, meaning zero capacitance, and the Pi network reduces to the L network in Fig 5.57A. The design procedure for the Pi network in Fig 5.58 is as follows:

Determine the two resistance values to be matched, $R_1 > R_2$, and select a value for Q. Follow the calculation sequence for circuit 1 or 2 in Fig 5.58.

Calculate the value of the parallel reactance $X_{C1} = R_1 / Q$.

Calculate the value of the parallel reactance X_{C2}

$$X_{C2} = R_2 \sqrt{\frac{R_1/R_2}{Q^2 + 1 - R_1/R_2}}$$

Calculate the value of the series reactance X_L

$$X_L = \frac{QR_1 + R_1R_2 / X_{C2}}{Q^2 + 1}$$

5.6.3 T Networks

Many amateur transmission line impedance matching units ("antenna tuners") use the version of the T network in circuit 6 of Fig 5.58. The circuits are constructed using variable capacitors and a tapped inductor. This is easier and less expensive to construct than a fully-adjustable version of circuit 5 in which two variable inductors are required. Circuit 5 is especially useful in matching relatively low input impedances from solid-state amplifier outputs to 50-Ω loads with low Q and good harmonic suppression due to the series inductances. Circuit 7 is also useful in solid-state amplifier design as described in the

reference texts listed at the end of this chapter.

The T network shown in circuit 5 of Fig 5.58 is especially useful for matching to relatively low impedance from 50-Ω sources with practical components and low Q. Like the Pi network, Q must be high enough that $(Q^2 + 1) > (R_1/R_2)$. Designing the component values for this network requires the calculation of a pair of intermediate values, A and B, to make the equations more manageable.

Determine the two resistance values to be matched, $R_1 > R_2$, and select a value for Q.

Calculate the intermediate variables A and B

$$A = R_1(Q^2 + 1) \text{ and } B = \sqrt{\left(\frac{A}{R_2} - 1\right)}$$

Calculate the value of the input series reactance $X_{L1} = R_1 Q$.

Calculate the value of the output series reactance $X_{L2} = R_2 B$.

Calculate the value of the parallel reactance $X_C = A / (Q + B)$

Convert the reactances to component values:

$$C = \frac{1}{2\pi f X_C} \text{ and } L = \frac{X_L}{2\pi f}$$

5.6.4 Impedance Inversion

Symmetrical Pi and T networks have the useful property of *impedance inversion* when the reactances of all elements are the same at the design frequency: $X_C = X_L = |X|$, resulting in a Q of 1. For either type of network, the impedance looking into the network, Z_{IN} , will be the load impedance, Z_{OUT} , inverted about X:

$$Z_{IN} = \frac{X^2}{Z_{OUT}}$$

This is the same effect as if the network were replaced with a $1/4$ -wavelength transmission line with $Z_0 = |X|$. Since the network is symmetrical, the inversion occurs in either direction through the network. The result is true only at the frequency for which all reactances are equal.

For example, to invert all impedances about 50 Ω, set $X = 50 \Omega$ at the design frequency. The input impedance will then be $50^2/Z_{OUT}$. If $Z = 10 + j10 \Omega$ is connected to one end of the network, the impedance looking into the other end of the network will be $2500 / (10 + j10) = 125 - j125 \Omega$.

5.7 RF Transformers

5.7.1 Air-Core Nonresonant RF Transformers

Air-core transformers often function as mutually coupled inductors for RF applications. They consist of a primary winding and a secondary winding in close proximity. Leakage reactances are ordinarily high, however, and the coefficient of coupling between the primary and secondary windings is low. Consequently, unlike transformers having a magnetic core, the turns ratio does not have as much significance. Instead, the voltage induced in the secondary depends on the mutual inductance.

In a very basic transformer circuit operating at radio frequencies, such as in Fig 5.59, the source voltage is applied to L1. R_S is the series resistance inherent in the source. By virtue of the mutual inductance, M , a voltage is induced in L2. A current flows in the secondary circuit through the reactance of L2 and the load resistance of R_L . Let X_{L2} be the reactance of L2 independent of L1, that is, independent of the effects of mutual inductance. The impedance of the secondary circuit is then:

$$Z_S = \sqrt{R_L^2 + X_{L2}^2} \tag{12}$$

where

- Z_S = the impedance of the secondary circuit in ohms,
- R_L = the load resistance in ohms, and
- X_{L2} = the reactance of the secondary inductance in ohms.

The effect of Z_S upon the primary circuit is the same as a coupled impedance in series with L1. Fig 5.60 displays the coupled impedance (Z_P) in a dashed enclosure to indicate that it is not a new physical component. It has the same absolute value of phase angle as in the secondary impedance, but the sign of the reactance is reversed; it appears as a capacitive reactance. The value of Z_P is:

$$Z_P = \frac{(2 \pi f M)^2}{Z_S} \tag{13}$$

where

- Z_P = the impedance introduced into the primary,
- Z_S = the impedance of the secondary circuit in ohms, and
- $2 \pi f M$ = the mutual reactance between the reactances of the primary and secondary coils (also designated as X_M).

5.7.2 Air-Core Resonant RF Transformers

The use of at least one resonant circuit in place of a pair of simple reactances elimi-

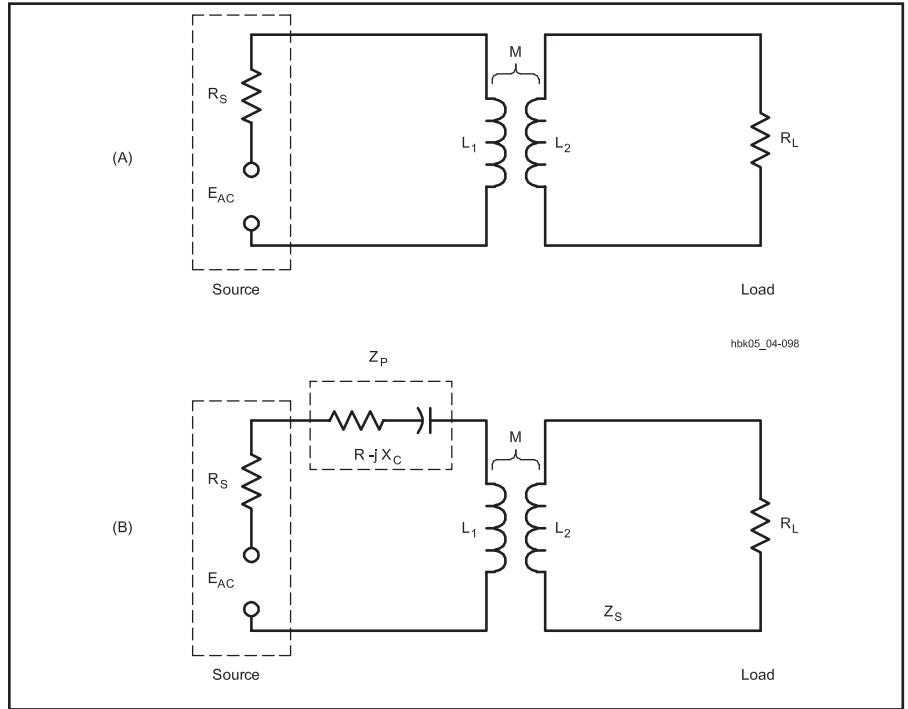

Fig 5.59 — The coupling of a complex impedance back into the primary circuit of a transformer composed of nonresonant air-core inductors.

Fig 5.60 — An air-core transformer circuit consisting of a resonant primary circuit and an untuned secondary. R_S and C_S are functions of the source, while R_L and C_L are functions of the load circuit.

nates the reactance from the transformed impedance in the primary. For loaded or operating Q of at least 10, the resistances of individual components is negligible. Fig 5.60 represents just one of many configurations in which at least one of the inductors is in a resonant circuit. The reactance coupled into the primary circuit is cancelled if the circuit is tuned to resonance while the load is connected. If the reactance of the load capacitance, C_L is at least 10 times any stray capacitance in the circuit, as is the case for low impedance loads, the value of resistance coupled to the primary is

$$R1 = \frac{X_M^2 R_L}{X_2^2 + R_L^2} \tag{14}$$

where:

- $R1$ = series resistance coupled into the primary circuit,
- X_M = mutual reactance,
- R_L = load resistance, and
- X_2 = reactance of the secondary inductance.

The parallel impedance of the resonant circuit is just $R1$ transformed from a series to a parallel value by the usual formula, $R_p = X_2 / R1$.

The higher the loaded or operating Q of the circuit, the smaller the mutual inductance required for the same power transfer. If both the primary and secondary circuits consist of resonant circuits, they can be more loosely coupled than with a single tuned circuit for the same power transfer. At the usual loaded Q of 10 or greater, these circuits are quite selective, and consequently narrowband.

Although coupling networks have to a large measure replaced RF transformer coupling that uses air-core transformers, these circuits are still useful in antenna tuning units and other circuits. For RF work, powdered-iron toroidal cores have generally replaced air-core inductors for almost all applications except where the circuit handles very high power or the coil must be very temperature stable. Slug-tuned solenoid coils for low-power circuits offer the ability to tune the circuit precisely to resonance. For either type of core, reasonably accurate calculation of impedance transformation is possible. It is often easier to experiment to find the correct values for maximum power transfer, however.

5.7.3 Broadband Ferrite RF Transformers

The design concepts and general theory of ideal transformers presented in the **Electrical Fundamentals** chapter apply also to transformers wound on ferromagnetic-core materials (ferrite and powdered iron). As is the case with stacked cores made of laminations in the classic I and E shapes, the core material has a specific permeability factor that determines the inductance of the windings versus the number of wire turns used. (See the earlier discussion on Ferrite Materials in this chapter.)

Toroidal cores are useful from a few hundred hertz well into the UHF spectrum. The principal advantage of this type of core is the self-shielding characteristic. Another feature is the compactness of a transformer or inductor. Therefore, toroidal-core transformers are excellent for use not only in dc-to-dc converters, where tape-wound steel cores are employed, but at frequencies up to at least 1000 MHz with the selection of the proper core material for the range of operating frequencies. Toroidal cores are available from micro-miniature sizes up to several inches in diameter that can handle multi-kW military and commercial powers.

One of the most common ferromagnetic transformers used in amateur circuits is the conventional broadband transformer. Broadband transformers with losses of less than 1 dB are employed in circuits that must have a uniform response over a substantial frequency range, such as a 2- to 30-MHz broadband amplifier. In applications of this sort, the reactance of the windings should be at least

four times the impedance that the winding is designed to look into at the lowest design frequency.

Example: What should be the winding reactances of a transformer that has a 300- Ω primary and a 50- Ω secondary load? Relative to the 50- Ω secondary load:

$$X_S = 4 Z_S = 4 \times 50 \Omega = 200 \Omega$$

and the primary winding reactance (X_P) is:

$$X_P = 4 Z_P = 4 \times 300 \Omega = 1200 \Omega$$

The core-material permeability plays a vital role in designing a good broadband transformer. The effective permeability of the core must be high enough to provide ample winding reactance at the low end of the operating range. As the operating frequency is increased, the effects of the core tend to disappear until there are scarcely any core effects at the upper limit of the operating range. The limiting factors for high frequency response are distributed capacity and leakage inductance due to uncoupled flux. A high-permeability core minimizes the number of turns needed for a given reactance and therefore also minimizes the distributed capacitance at high frequencies.

Ferrite cores with a permeability of 850 are common choices for transformers used between 2 and 30 MHz. Lower frequency ranges, for example, 1 kHz to 1 MHz, may require cores with permeabilities up to 2000. Permeabilities from 40 to 125 are useful for VHF transformers. Conventional broadband transformers require resistive loads. Loads with reactive components should use appropriate networks to cancel the reactance.

The equivalent circuit in Fig 5.33 applies to any coil wound on a ferrite core, including transformer windings. (See the section on Ferrite Materials.) However, in the series-equivalent circuit, $\mu'S$ is not constant with frequency as shown in Fig 5.34A and 5.34B. Using the low-frequency value of $\mu'S$ is a useful approximation, but the effects of the parallel R and C should be included. In high-power transmitting and amplifier applications, the resistance R may dissipate some heat, leading to temperature rise in the core. Regarding C, there are at least two forms of stray capacitance between windings of a transformer; from wire-to-wire through air and from wire-to-wire through the ferrite, which acts as a dielectric material. (Ferrites with low iron content have a relative dielectric constant of approximately 10-12.)

Conventional transformers are wound in the same manner as a power transformer. Each winding is made from a separate length of wire, with one winding placed over the previous one with suitable insulation between. Unlike some transmission-line transformer

designs, conventional broadband transformers provide dc isolation between the primary and secondary circuits. The high voltages encountered in high-impedance-ratio step-up transformers may require that the core be wrapped with glass electrical tape before adding the windings (as an additional protection from arcing and voltage breakdown), especially with ferrite cores that tend to have rougher edges. In addition, high voltage applications should also use wire with high-voltage insulation and a high temperature rating.

Fig 5.61 illustrates one method of transformer construction using a single toroid as the core. The primary of a step-down impedance transformer is wound to occupy the entire core, with the secondary wound over the primary. The first step in planning the winding is to select a core of the desired permeability. Convert the required reactances determined earlier into inductance values for the lowest frequency of use. To find the number of turns for each winding, use the A_L value for the selected core and the equation for determining the number of turns:

$$L = \frac{A_L \times N^2}{1000000} \quad (15)$$

where

L = the inductance in mH

A_L = the inductance index in mH per 1000 turns, and

N = the number of turns.

Be certain the core can handle the power by calculating the maximum flux and comparing the result with the manufacturer's guidelines.

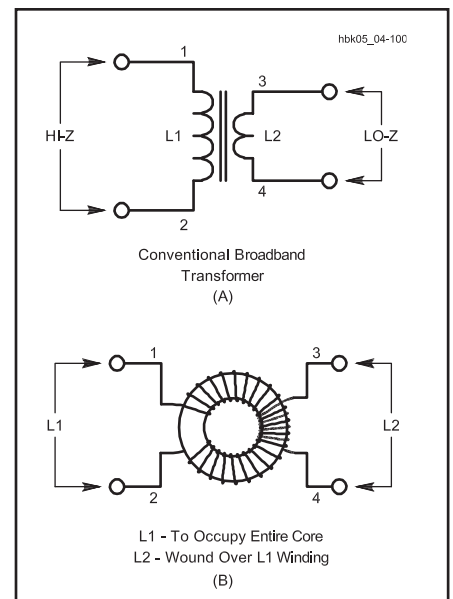

Fig 5.61 — Schematic and pictorial representation of a conventional broadband transformer wound on a toroid core. The secondary winding (L2) is wound over the primary winding (L1).

$$B_{\max} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f} \quad (16)$$

where

B_{\max} = the maximum flux density in gauss

E_{RMS} = the voltage across the inductor

A_e = the cross-sectional area of the core in square centimeters

N = the number of turns in the inductor, and

f = the operating frequency in Hz.

(Both equations are from the section on ferrite toroidal inductors in the **Electrical Fundamentals** chapter and are repeated here for convenience.)

Example: Design a small broadband transformer having an impedance ratio of 16:1 for a frequency range of 2.0 to 20.0 MHz to match the output of a small-signal stage (impedance $\approx 500 \Omega$) to the input (impedance $\approx 32 \Omega$) of an amplifier.

Since the impedance of the smaller winding should be at least 4 times the lower impedance to be matched at the lowest frequency,

$$X_S = 4 \times 32 \Omega = 128 \Omega$$

The inductance of the secondary winding should be

$$L_S = \frac{X_S}{2 \pi f} = \frac{128}{6.2832 \times 2.0 \times 10^6 \text{ Hz}}$$

$$= 0.0101 \text{ mH}$$

Select a suitable core. For this low-power application, a $\frac{3}{8}$ inch. ferrite core with permeability of 850 is suitable. The core has an A_L value of 420. Calculate the number of turns for the secondary.

$$N_S = 1000 \sqrt{\frac{L}{A_L}} = 1000 \sqrt{\frac{0.010}{420}}$$

$$= 4.88 \text{ turns}$$

Fig 5.62 — Schematic and pictorial representation of a “binocular” style of conventional broadband transformer. This style is used frequently at the input and output ports of transistor RF amplifiers. It consists of two rows of high-permeability toroidal cores, with the winding passed through the center holes of the resulting stacks.

A 5-turn secondary winding should suffice. The primary winding derives from the impedance ratio:

$$N_P = N_S \sqrt{\frac{Z_P}{Z_S}} = 5 \sqrt{\frac{16}{1}}$$

$$= 5 \times 4 = 20 \text{ turns}$$

This low-power application will not approach the maximum flux density limits for

the core, and #28 AWG enamel wire should both fit the core and handle the currents involved.

A second style of broadband transformer construction appears in **Fig 5.62**. The key elements in this transformer are the stacks of ferrite cores aligned with tubes soldered to pc-board end plates. This style of transformer is suited to high power applications, for example, at the input and output ports of transistor RF power amplifiers. Low-power versions of this transformer can be wound on “binocular” cores having pairs of parallel holes through them.

For further information on conventional transformer matching using ferromagnetic materials, see the **RF Power Amplifiers** chapter. Refer to the **Component Data and References** chapter for more detailed information on available ferrite cores. A standard reference on conventional broadband transformers using ferromagnetic materials is *Ferromagnetic Core Design and Applications Handbook* by Doug DeMaw, W1FB, published by MFJ Enterprises.

NOTES ON TOROID WINDINGS

Toroids do have a small amount of leakage flux. Toroid coils are wound in the form of a helix (screw thread) around the circular length of the core. This means that there is a small component of the flux from each turn that is perpendicular to the circle of the toroid (parallel to the axis through the hole) and is therefore not adequately linked to all the other turns. This effect is responsible for a small leakage flux and the effect is called the “one-turn” effect, since the result is equivalent to one turn that is wound around the outer edge of the core and not through the hole. Also, the inductance of a toroid can be adjusted. If the turns can be pressed closer together or separated a little, inductance variations of a few percent are possible. A grounded aluminum shield between adjacent toroidal coils can eliminate any significant capacitive or inductive (at high frequencies) coupling.

5.8 Noise

The following material was contributed by Paul Wade, W1GHZ. The section on background noise by Joe Taylor, K1JT, is reproduced from his discussion of Earth-Moon-Earth (EME) communications on the CD-ROM accompanying this book. Additional discussion of noise measurement is available in the **Test Instruments and Measurements** chapter and in the Noise Instrumentation document provided on the CD-ROM.

As anyone who has listened to a receiver suspects, everything in the universe generates noise. In communications, the goal is to maximize the desired signal in relation to the undesired noise we hear. In order to accomplish this goal, it would be helpful to understand where noise originates, how much our own receiver adds to the noise we hear, and how to minimize it.

It is difficult to improve something unless we are able to measure it. Measurement of noise in receivers does not seem to be clearly understood by many amateurs, so this section attempts to explain the concepts and clarify the techniques, and to describe the standard “measure of merit” for receiver noise performance: “noise figure.” In addition, the Noise Instrumentation document on the CD-ROM describes how to build your own noise generator for noise figure measurements.

A number of equations are included, but only a few need be used to perform noise figure measurements. The rest are included to as an aid to understanding supported by explanatory text.

5.8.1. Noise Power

The most pervasive source of noise is *thermal noise* (also called *Johnson* or *Johnson-Nyquist noise*), due to the motion of thermally agitated free electrons in a conductor. Since everything in the universe is at some temperature above absolute zero, every conductor must generate noise.

Every resistor (and all conductors have resistance) generates an RMS noise voltage:

$$e = \sqrt{4kTRB}$$

where R is the resistance, T is the absolute temperature in kelvins (K), B is the bandwidth in hertz, and k is Stefan-Boltzmann’s constant, 1.38×10^{-23} joules /K (or J K⁻¹).

Converting to power, e^2/R , and adjusting for the Gaussian distribution of noise voltage, the noise power generated by the resistor is:

$$P_n = kTB \text{ (watts)}$$

which is independent of the resistance. Thus, all resistors at the same temperature generate

the same noise power.

Thermal noise is *white noise*, meaning that the power density does not vary with frequency, but always has a *power density* or *spectral density* of kT watts/Hz. (The corresponding noise voltage distribution is a *spectral voltage density*, measured in volts / $\sqrt{\text{Hz}}$, spoken as “volts per root hertz”.) More important is that the noise power is directly proportional to absolute temperature T, since k is a constant. At the nominal ambient temperature of 290 K, we can calculate this power; converted to dBm, we get the familiar -174 dBm/Hz. Multiply by the bandwidth in hertz to get the available noise power at ambient temperature. The choice of 290 K for ambient might seem a bit cool, since the equivalent 17° C or 62° F would be a rather cool room temperature, but the value 290 makes for an easier-to-remember numeric calculation of $P_n = (1.38 \times 10^{-23} \times 290) B = 400 \times 10^{-23} B$.

The *instantaneous* noise voltage has a *Gaussian distribution* around the RMS value. The Gaussian distribution has no limit on the peak amplitude so at any instant the noise voltage may have any value from $-\infty$ to $+\infty$. For design purposes we can use a value that will not be exceeded more than 0.01% of the time. This voltage is 4 times the RMS value, or 12 dB higher, so our system must be able to handle peak powers 12 dB higher than the average noise power if we are to measure noise without errors. (See Pettai in the Reference section.)

5.8.2. Signal to Noise Ratio

Now that we know the noise power in a given bandwidth, we can easily calculate how much signal is required to achieve a desired *signal to noise ratio*, *S/N* or *SNR*. For SSB, perhaps 10 dB SNR is required for good communications; since ambient thermal noise in a 2.5 kHz bandwidth is -140 dBm, calculated as follows:

$$P_n = kTB = 400 \times 10^{-23} \times 2500 \\ = 1.0 \times 10^{-17} \text{ W}$$

$$\text{dBm} = 10 \log (P_n \times 1000) \text{ [multiplying} \\ \text{watts by 1000 converts to milliwatts]}$$

The signal power must be 10 dB larger, so minimum signal level of -130 dBm is required for a 10 dB S/N. This represents the noise and signal power levels at the antenna. We are then faced with the task of amplifying the signal without degrading SNR.

5.8.3. Noise Temperature

There are many types of noise, but most have similar characteristics to thermal noise

and are often added together, creating a single equivalent noise source whose output power per unit of bandwidth is P_N . The *noise temperature* of the source is defined as the temperature $T = P_N / k$ at which a resistor would generate the same noise power per unit of bandwidth as the source. This is a useful way to characterize the various sources of noise in a communications system.

All amplifiers add additional noise to the noise present at their input. The input noise per unit of bandwidth is $N_i = kT_g$, where T_g is the noise temperature at the amplifier’s input. Amplified by power gain G, the output noise is $kT_g G$. The additional noise contributed by the amplifier can also be represented as a noise temperature, T_n . The noise power added by the amplifier, kT_n , is then added to the amplified input noise to produce a total output noise:

$$N_o = kT_g G + kT_n$$

We can treat the amplifier as ideal and noise-free but with an additional noise-generating resistor of temperature $T_e = T_n / G$ at the input so that all sources of noise can be treated as inputs to the amplifier as illustrated by **Fig 5.63**. The output noise is then:

$$N_o = kG (T_g + T_e)$$

The noise added by an amplifier can then be represented as kGT_e , which is amplifier’s noise temperature amplified by the amplifier gain. T_e is sometimes referred to as *excess temperature*.

Note that while the noise temperature of a resistor is the same as its physical temperature, the noise temperature of a device such as a diode or transistor can be many times the physical temperature.

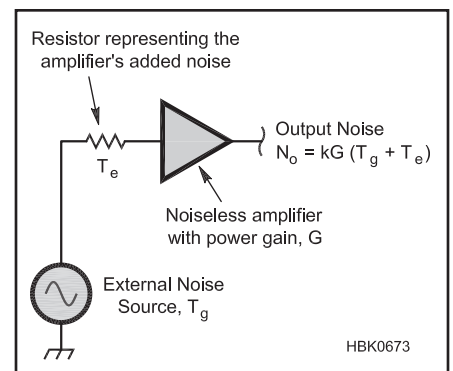

Fig 5.63 — The noise generated by an amplifier can be represented as an external resistor with a noise temperature of T_e connected at the input of a noiseless amplifier.

5.8.4. Noise Factor and Noise Figure

The *noise factor*, F , of an amplifier is the ratio of the total noise output of an amplifier with an input T_g of 290 K to the noise output of an equivalent noise-free amplifier. A more useful definition is to calculate it from the excess temperature T_e :

$$F = 1 + T_e / T_g, \text{ where } T_g = 290 \text{ K}$$

It is often more convenient to work with *noise figure*, NF , the logarithm of noise factor expressed in dB:

$$NF = 10 \log (1 + T_e / T_g) = 10 \log F$$

$$F = \log^{-1} (NF/10)$$

Expressed in terms of signal, S , and noise power, N , at the input and output of a device:

$$F = (S_{in}/N_{in}) / (S_{out}/N_{out}) \text{ and}$$

$$F = G_{noise} / G_{signal}$$

where G_{signal} is the device's power gain and G_{noise} is the device's *noise gain*. If SNR in dB is known at the input and output:

$$NF = SNR_{in} - SNR_{out}$$

If NF or F is known, then T_e may be calculated as:

$$T_e = (F - 1) T_g$$

Typically, T_e is specified for very low noise amplifiers where the NF would be fraction of a dB. NF is used when it seems a more manageable number than thousands of K.

Noise figure is sometimes stated as *input noise figure* to emphasize that all noise sources and noise contributions are converted to an equivalent set of noise sources at the input of a noiseless device. In this way, noise performance can be compared on equal terms across a wide variety of devices.

Noise figure is particularly important at VHF and UHF where atmospheric and other artificial noise is quite low. Typical noise figures of amateur amplifiers range from 1 to 10 dB. Mixers are generally toward the high end of that range. Modern GaAsFET and HEMT preamplifiers are capable of attaining an NF of 0.1 to 0.2 dB at UHF with NF under 1 dB even at 10 GHz.

5.8.5. Losses

We know that any loss or attenuation in a system reduces the signal level. If attenuation also reduced the noise level then we could suppress thermal noise by adding attenua-

tion. We know intuitively that this can't be true — the attenuator or any lossy element has a noise temperature, T_x , which contributes noise to the system while the input noise is being attenuated.

The output noise after a loss L (expressed as ratio) expressed as an equivalent input noise temperature is:

$$T_g' = T_g / L + [(L - 1)/L] T_x$$

If the original source temperature, T_g , is higher than the attenuator temperature, T_x , then the noise contribution is found by adding the loss in dB to the NF . However, for low source temperatures the degradation can be much more dramatic. If we do a calculation for the effect of 1 dB of loss ($L = 1.26$) on a T_g of 25 K:

$$T_g' = 25/1.26 + (0.26/1.26) \times 290 = 80 \text{ K}$$

The resulting T_g' is 80 K, a 5 dB increase in noise power (or 5 dB degradation of signal to noise ratio). Since noise power = kT and k is a constant, the increase is the ratio of the two temperatures, $80/25$, or in dB, $10 \log (80/25) = 5 \text{ dB}$.

It is also useful to note that for linear, passive devices, such as resistors or resistive attenuators, noise figure is the same as loss in dB. A resistive attenuator with 6 dB loss has a noise figure of 6 dB which is equal to a noise factor of 4.

5.8.6. Cascaded Amplifiers

If several amplifiers are cascaded, the output noise N_o of each becomes the input noise T_g to the next stage. We can create a single equation for the total system of amplifiers. After removing the original input noise term, we are left with the added noise:

$$N_{added} = (k T_{e1} G_1 G_2 \dots G_N) + (k T_{e2} G_2 \dots G_N) + \dots + (k T_{eN} G_N)$$

where N is the number of stages cascaded.

Substituting in the total gain $G_T = (G_1 G_2 \dots G_N)$ results in the total excess noise:

$$T_{eT} = T_{e1} + \frac{T_{e2}}{G_1} + \frac{T_{e2}}{G_1 G_2} + \dots + \frac{T_{eN}}{G_1 G_2 \dots G_{N-1}}$$

with the relative noise contribution of each succeeding stage reduced by the gain of all preceding stages.

The *Friis formula for noise* (a.k.a. the *Friis equation*) expresses this in terms of noise factor:

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \dots + \frac{F_N - 1}{G_1 G_2 \dots G_{N-1}}$$

Clearly, if the gain of the first stage, G_1 , is large, then the noise contributions of the succeeding stages become too small to be significant. In addition, the noise temperature of the first stage is the largest contributor to the overall system noise because it is amplified by all remaining stages. The effect on overall noise figure of adding a low-noise preamplifier ahead of a noisy receiver are illustrated in **Fig 5.64**, in which the system's noise figure changes from 20 dB for the receiver alone to 7.1 dB with the preamplifier added.

Any lossy component of an antenna system, such as the feed line, increases the noise figure at its input by an amount equal to the loss. As a result, it is important to concentrate noise-reduction efforts on the first amplifier or preamplifier in a system. Because noise performance is so important in early stages of cascaded systems such as receivers, low-noise VHF+ preamplifiers are usually mounted at the antenna so that their gain occurs ahead of the feed line loss. **Fig 5.65** compares the results of adding a preamplifier before and after 1.5 dB of feed line loss. Moving the preamplifier to the antenna improves the system's noise figure from 2.57 to 1.13 dB.

5.8.7. Antenna Temperature

Antenna temperature, T_A , is a way of describing how much noise an antenna produces. It is not the physical temperature of the an-

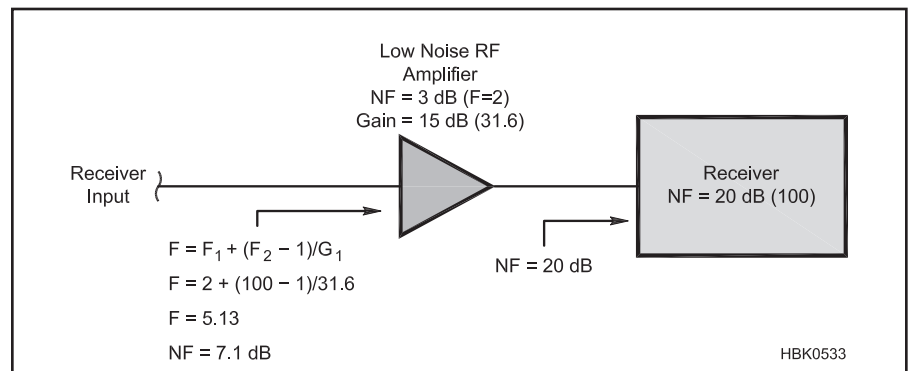

Fig 5.64 — The effect of adding a low-noise preamplifier in front of a noisy receiver system.

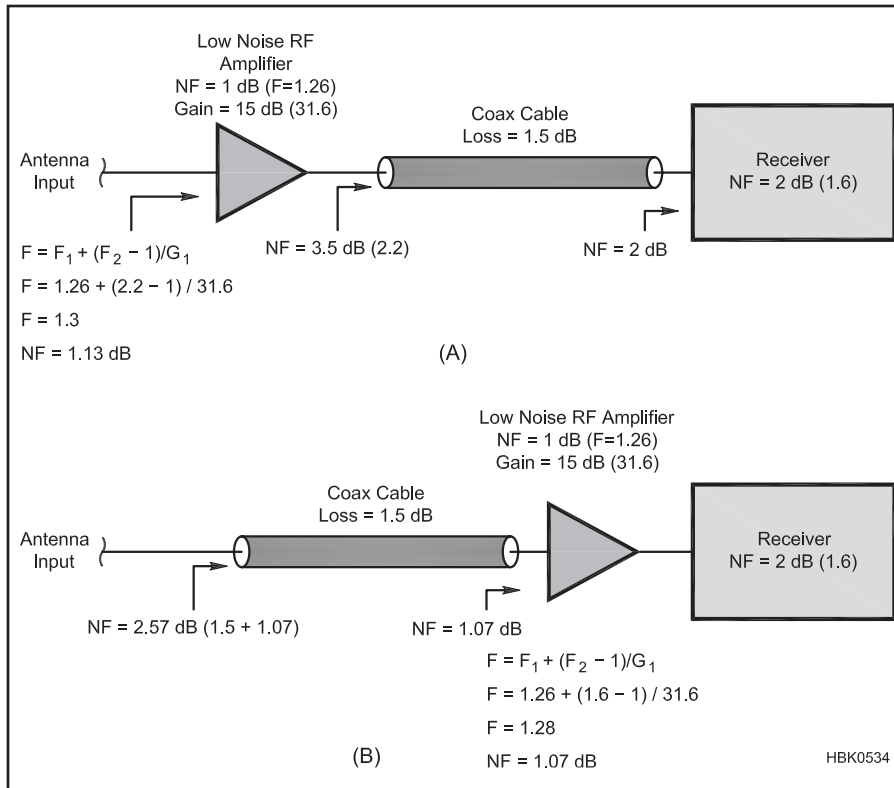

Fig 5.65 — The effect of adding a low-noise preamplifier at the antenna (A) compared to adding it at the receiver input (B).

tenna because the antenna gathers noise from the environment according to its radiation pattern. If the antenna is directional and looks at a warm environment, T_A will be higher than if the antenna is looking at something cooler.

For example, if a lossless dish antenna is receiving signals from space rather than the warm Earth then the background noise is much lower than the warmer ambient temperature of 290 K or so. The background temperature of the universe has been measured as about 3.2 K. An empirical temperature for a 10 GHz antenna pointing into clear sky is about 6 K, since the antenna must always look through attenuation and temperature of the atmosphere. (See Graves in the Reference section.)

If the antenna's radiation pattern has any *spillover* (reception of signals from directions away from where the dish is pointed), that must be accounted for in the total noise received by the antenna. This raises the noise temperature. If a warm body, such as the sun, moves into the antenna's view, the additional *sun noise* will raise T_A as well. If the antenna is looking directly at the Earth, T_A will be close to ambient temperature. As an example, T_A will vary with frequency, but a good EME antenna might have a T_A of around 20 K at UHF and higher frequencies.

5.8.8. Image Response

Most receiving systems use at least one frequency converting mixer which has two responses: the desired frequency and an image frequency above and below the frequency of the local oscillator. If the image response is not filtered out, it will add additional noise to the mixer output. Since most preamps are sufficiently broadband to have significant gain (and thus, noise output) at both the desired frequency, G_{desired} , and at the image frequency, G_{image} , an image filter must be placed between the preamplifier and the mixer. The total NF including image response is:

$$NF = 10 \log \left[\left(\frac{1 + T_e}{T_0} \right) \left(1 + \frac{G_{\text{image}}}{G_{\text{desired}}} \right) \right]$$

Fig 5.66 —Top: All-sky contour map of sky background temperature at 144 MHz. The dashed curve indicates the plane of our Galaxy, the Milky Way; the solid sinusoidal curve is the plane of the ecliptic. The sun follows a path along the ecliptic in one year; the moon moves approximately along the ecliptic ($\pm 5^\circ$) each month. Map contours are at noise temperatures 200, 500, 1000, 2000 and 5000 K. Bottom: One-dimensional plot of sky background temperature at 144 MHz along the ecliptic, smoothed to an effective beamwidth of 15° .

Fig 5.67 — Typical contributions to system noise temperature T_s as function of frequency. See text for definitions and descriptions of the various sources of noise.

assuming equal noise bandwidth for the desired and image responses.

Without any filtering, $G_{\text{image}} = G_{\text{desired}}$ so $G_{\text{image}}/G_{\text{desired}} = 1$, doubling the noise figure, which is the same as adding 3 dB. Thus, without any image rejection, the overall noise figure is at least 3 dB regardless of the NF of the preamplifier. For the image to add less than 0.1 dB to the overall NF, gain at the image frequency must be at least 16 dB lower than at the operating frequency.

5.8.9. Background Noise

A received signal at VHF and higher frequencies necessarily competes with noise generated in the receiver as well as that picked up by the antenna, including contributions from the warm Earth, the atmosphere, the lunar surface, the diffuse galactic and cosmic background and possibly the sun and other sources, filling the entire sky. If P_n is the total noise power collected from all such noise sources expressed in dBW (dB with respect to 1 W), we can write the expected signal-to-noise ratio of the EME link as:

$$\text{SNR} = P_r - P_n = P_t + G_t + L + G_r - P_n$$

where P_r is received power, P_n is noise power, P_t is transmitted power, G_t is gain of the transmitting antennas in dBi, L is *isotropic path loss*, and G_r is gain of the receiving antennas. All powers are expressed in dBW and gain in dBi. (Isotropic path loss is explored further in the material on Earth-Moon-Earth (EME) communications on the CD-ROM accompanying this book.)

Since isotropic path loss, L , is essentially fixed by choice of a frequency band, optimizing the signal-to-noise ratio generally involves trade-offs designed to maximize P_r and minimize P_n — subject, of course, to such practical considerations as cost, size, maintainability and licensing constraints.

It is convenient to express P_n (in dBW) in terms of an equivalent system noise temperature, T_s , in kelvins (K), the receiver bandwidth, B , in Hz and Stefan-Boltzmann's constant $k = 1.38 \times 10^{-23} \text{ J K}^{-1}$:

$$P_n = 10 \log (kT_s B)$$

Fig 5.68 — Percentage contributions to system noise temperature as a function of frequency.

Table 5.2
Typical Contributions to System Noise Temperature

Freq (MHz)	CMB (K)	Atm (K)	Moon (K)	Gal (K)	Side (K)	T_a (K)	T_r (K)	T_s (K)
50	3	0	0	2400	1100	3500	50	3500
144	3	0	0	160	100	260	50	310
222	3	0	0	50	50	100	50	150
432	3	0	0	9	33	45	40	85
902	3	0	1	1	30	35	35	70
1296	3	0	2	0	30	35	35	70
2304	3	0	4	0	30	37	40	77
3456	3	1	5	0	30	40	50	90
5760	3	3	13	0	30	50	60	110
10368	3	10	42	0	30	85	75	160
24048	3	70	170	0	36	260	100	360

The system noise temperature may in turn be written as

$$T_s = T_r + T_a$$

Here, T_r is receiver noise temperature, related to the commonly quoted noise figure (NF) in dB by:

$$T_r = 290 (10^{0.1 \text{ NF} - 1})$$

Antenna temperature, T_a , includes contributions from all noise sources in the field of view, weighted by the antenna pattern. Side lobes are important, even if many dB down from the main beam, because their total solid angle is large and therefore they are capable of collecting significant unwanted noise power.

At VHF the most important noise source is diffuse background radiation from our gal-

axy, the Milky Way. An all-sky map of noise temperature at 144 MHz is presented in the top panel of Fig 5.66. This noise is strongest along the plane of the galaxy and toward the galactic center. Galactic noise scales as frequency to the -2.6 power, so at 50 MHz the temperatures in Fig 5.66 should be multiplied by about 15, and at 432 divided by 17. At 1296 MHz and above galactic noise is negligible in most directions. (See the previously mentioned CD-ROM EME material for the effects of lunar noise.)

By definition the sun also appears to an observer on Earth to move along the ecliptic and during the day solar noise can add significantly to P_n if the moon is close to the sun or the antenna has pronounced side lobes. At frequencies greater than about 5 GHz the Earth's atmosphere also contributes significantly. An ultimate noise floor of 3 K, independent of frequency, is set by cosmic background radiation that fills all space. A practical summary of significant contributions to system noise temperature for the amateur bands 50 MHz through 24 GHz is presented in Table 5.2 and Fig 5.67 and Fig 5.68.

5.9 Two-Port Networks

A *two-port network* is one with four terminals. The terminals are arranged into pairs, each being called a *port*. The general network schematic is shown in Fig 5.69. The input port is characterized by input voltage and current, V_1 and I_1 , and the output is described by V_2 and I_2 . By convention, currents into the network are usually considered positive.

Many devices of interest have three terminals rather than four. Two-port methods are used with these by choosing one terminal to be common to both input and output ports. The two-port representations of the common emitter, common base and common collector connections of the bipolar transistor are shown in Fig 5.70. Similar configurations

may be used with FETs, vacuum tubes, ICs or passive networks.

The general concepts of two-port theory are applicable to devices with a larger number of terminals. The theory is expandable to any number of ports. Alternatively, the bias on some terminals can be established with attention fixed only upon two ports of a multi-element device. An example would be a dual-gate MOSFET in a common-source configuration as shown in Fig 5.71. The input port contain the source and gate 1 while the output port contains the source and drain leads. The fourth device terminal, gate 2, has

a fixed bias potential and is treated as an ac ground. Signal currents at this terminal are ignored in the analysis.

5.9.1 Two-Port Parameters

There are four variables associated with any two-port network; two voltages and two currents. These are signal components. Any two variables may be picked as independent. The remaining variables are then dependent variables. These are expressed as an algebraic linear combination of the two independent quantities. The following overview are in-

Fig 5.69 — General configuration of a two-port network. Note the voltage polarities and direction of currents.

Fig 5.70 — Two-port representations of the common emitter, common base and common collector amplifiers.

Fig 5.71 — A dual-gate MOSFET treated as a three-terminal device in a two-port network.

tended for definition purposes. A complete discussion of the use of two-port parameters can be found in the reference texts at the end of this chapter and examples of their use in RF circuit design in Hayward's *Introduction to Radio Frequency Design*.

Y AND Z PARAMETERS

Assume that the two voltages are chosen as independent variables. The two currents are then expressed as linear combinations of the voltages, $I_1 = K_a V_1 + K_b V_2$ and $I_2 = K_c V_1 + K_d V_2$. The constants of proportionality, K_a through K_d , have the dimensions of admittance. The usual representation is

$$\begin{aligned} I_1 &= y_{11} V_1 + y_{12} V_2 \\ I_2 &= y_{21} V_1 + y_{22} V_2 \end{aligned} \quad (22)$$

The independent and dependent variable sets are column vectors, leading to the equivalent matrix representation

$$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix} \quad (23)$$

The y matrix for a two-port network uniquely describes that network. The set of y_{11} through y_{22} are called the two-port network's Y parameters or *admittance parameters*. Consider the y parameters from an experimental viewpoint. The first y parameter, y_{11} , is the input admittance of the network with V_2 set to zero. Hence, it is termed the *short-circuit input admittance*. y_{21} is the *short-circuit forward transadmittance*, the reciprocal of transconductance. Similarly, if V_1 is set to zero, realized by short circuiting the input, y_{22} is the *short-circuit output admittance* and y_{12} is the *short-circuit reverse transadmittance*.

The matrix subscripts are sometimes replaced by letters. The set of y parameters can be replaced by $y_i, y_r, y_f,$ and y_o where the subscripts indicate respectively input, reverse, forward, and output. The subscripts are sometimes modified further to indicate the connection of the device. For example, the short circuit forward transfer admittance

of a common emitter amplifier would be y_{21e} or y_{fe} .

The y parameters are only one set of two-port parameters. The open-circuited Z parameters or *impedance parameters* result if the two currents are treated as independent variables

$$\begin{pmatrix} V_1 \\ V_2 \end{pmatrix} = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \end{pmatrix} \quad (24)$$

The parameter sets describe the same device; hence, they are related to each other. If equation 22 is multiplied by y_{12} and the resulting equations are subtracted, the result is the input voltage as a function of the currents

$$V_1 = \frac{I_1 y_{22} - y_{12} I_2}{y_{11} y_{22} - y_{12} y_{21}}$$

A similar procedure is used to find the output voltage as a function of the currents, leading to the general relationships

$$\begin{aligned} z_{11} &= \frac{y_{22}}{\Delta y} & z_{12} &= \frac{-y_{12}}{\Delta y} \\ z_{21} &= \frac{-y_{21}}{\Delta y} & z_{22} &= \frac{y_{11}}{\Delta y} \end{aligned} \quad (25)$$

where Δy is the determinant of the y matrix, $y_{11} y_{22} - y_{12} y_{21}$. The inverse transformations, yielding the y parameters when z parameters are known, are exactly the same as those in equation 25, except that the y_{jk} and z_{jk} values are interchanged. The similarity is useful when writing transformation programs for a programmable calculator or computer.

H PARAMETERS

The H parameters or *hybrid parameters* are defined if the input current and output voltage are selected as independent variables

$$\begin{pmatrix} V_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ V_2 \end{pmatrix} \quad (26)$$

The input term, h_{11} , is an impedance, while h_{22} represents an output admittance. The forward term, h_{21} , is the ratio of the output to the input current, beta for a bipolar transistor. The reverse parameter, h_{12} , is a voltage ratio. The mixture of dimensions accounts for the "hybrid" name of the set.

SCATTERING (S) PARAMETERS

The two-port parameters presented above deal with four simple variables; input and output voltage and current at the ports. The variables are interrelated by appropriate matrices. The choice of which matrix is used depends upon which of the four variables are chosen to be independent.

There is no reason to limit the variables to simple ones. Linear combinations of the simple variables are just as valid. The more complicated variables chosen should be lin-

early independent and, ideally, should have some physical significance.

A transformation to other variables is certainly not new. For example, logarithmic transformations such as the dB or dBm are so common that we used them interchangeably with the fundamental quantities without even mentioning that a transformation has occurred. Such a new viewpoint can be of great utility in working with transmission line when an impedance is replaced by a reflection coefficient, $\Gamma = (Z - Z_0) / (Z + Z_0)$.

Scattering parameters or S parameters are nothing more than a repeat of this viewpoint. Instead of considering voltages and currents to be the fundamental variables, we use four "voltage waves." They are interrelated through an appropriate matrix of s parameters.

Fig 5.72 shows the traditional two-port network and an alternate one with voltage waves incident on and reflected from the ports. The voltage waves are defined with the letters $a_1, b_1, a_2,$ and b_2 . The a waves are considered to be incident waves on the parts and are the independent variables. The b waves are the result of reflection or "scattering" and are the dependent variables. The waves are related to voltages and currents and defined with respect to a characteristic impedance, Z_0 .

The scattered waves are related to the incident ones with a set of linear equations just as the port currents were related to the port voltages with y parameters. The relating equations are

$$\begin{aligned} b_1 &= S_{11} a_1 + S_{12} a_2 \\ b_2 &= S_{21} a_1 + S_{22} a_2 \end{aligned} \quad (27)$$

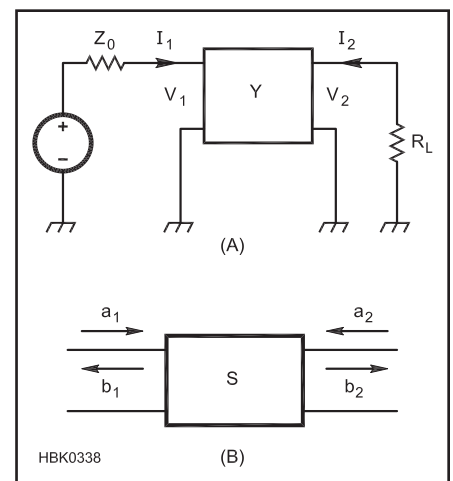

Fig 5.72 — A two-port network viewed as being driven by voltages and currents (A) or voltage waves (B). The voltages and currents are related by Y parameters while the voltage waves are related by scattering or S parameters.

or, in matrix form

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \quad (28)$$

Consider the meaning of S_{11} . If the incident wave at the output, a_2 , is set to zero, the set of equations 27 reduce to $b_1 = S_{11}a_1$ and $b_2 = S_{21}a_1$. S_{11} is the ratio of the input port reflected wave to the incident one. This reduces, using the defining equations for a_1 and b_1 to

$$S_{11} = \frac{Z - Z_0}{Z + Z_0} \quad (29)$$

This is the *input port reflection coefficient*. Similarly, S_{21} is the voltage wave emanating from the output as the result of an incident wave at the network input. In other words, S_{21} represents a forward gain. The other two S parameters have similar significance. S_{22} is the *output reflection coefficient* when looking back into the output port of the network with the input terminated in Z_0 . S_{12} is the reverse gain if the output is driven and the signal at the input port detected.

The reflection coefficient nature of S parameters makes them especially convenient for use in design and specification and even more so when displayed on a Smith Chart.

5.9.2 Return Loss

Although SWR as described in the **Trans-**

mission Lines chapter is usually used by amateurs to describe the relationship between a transmission line's characteristic impedance and a terminating impedance, the engineering community generally finds it more convenient to use *return loss, RL*, instead.

Return loss and SWR measure the same thing — how much of the incident power, P_{INC} , in the transmission line is transferred to the load and how much is reflected by it, P_{REFL} — but state the result differently.

$$\text{Return Loss (dB)} = -10 \log \left(\frac{P_{REFL}}{P_{INC}} \right) \quad (30)$$

Because P_{REFL} is never greater than P_{FWD} , RL is always positive. The more positive RL, the less the amount of power reflected from the load compared to forward power. If all the power is transferred to the load because $Z_L = Z_0$, $RL = \infty$ dB. If none of the power is transferred to the load, such as at an open- or short-circuit, $RL = 0$ dB. (You may encounter negative values for RL in literature or data sheets. Use the absolute magnitude of these values — the negative value does not indicate power gain.)

RL can also be calculated directly from power ratios, such as dBm (decibels with respect to 1 mW) or dBW (decibels with respect to 1 watt). In this case, $RL = P_{INC} - P_{REFL}$ because the logarithm has already been taken in the conversion to dBm or dBW. (Ratios in dB are computed by subtraction, not division.) For example, if $P_{INC} = 10$ dBm and $P_{REFL} =$

0.5 dBm, $RL = 10 - 0.5 = 9.5$ dB. Both power measurements must have the same units (dBm, dBW, and so on) for the subtraction to yield the correct results — for example, dBW can't be subtracted from dBm directly.

Since SWR and RL measure the same thing — reflected power as a fraction of forward power — they can be converted from one to the other. Start by converting RL back to a power ratio:

$$\frac{P_{REFL}}{P_{INC}} = \log^{-1}(-0.1 \times RL) \quad (31)$$

Now use the equation for computing SWR from forward and reflected power (see the **Transmission Lines** chapter):

$$\text{SWR} = \frac{1 + \sqrt{\frac{P_{REFL}}{P_{INC}}}}{1 - \sqrt{\frac{P_{REFL}}{P_{INC}}}} \quad (32)$$

SWR can also be converted to RL by using the equation for power ratio in terms of SWR:

$$\frac{P_{REFL}}{P_{INC}} = \left[\frac{\text{SWR} - 1}{\text{SWR} + 1} \right]^2 \quad (33)$$

Then convert to RL using equation 30.

5.10 RF Techniques Glossary

Arc — Current flow through an insulator due to breakdown from excessive voltage.

Balun — A device that transfers power between *balanced* and *unbalanced* systems, sometimes transforming the impedance level as well (see also **unun**).

Bead — Hollow cylinder of magnetic material through which a wire is threaded to form an inductor.

Bilateral — A network that operates or responds in the same manner regardless of the direction of current flow in the network.

Choke balun — see **current balun**.

Core — Magnetic material around which wire is wound or through which it is threaded to form an inductor.

Current balun — A balun that transfers power from an unbalanced to a balanced system by forcing current flow in the balanced system to be balanced as well (also called a **choke balun**).

Dielectric strength — The rated ability of an insulator to withstand voltage.

Distributed element — Electronic component whose effects are spread out over a significant distance, area or volume.

Dynamic resistance — The change in current in response to a small change in voltage.

Equivalent Series Inductance (ESL) — A capacitor's parasitic inductance.

Ferrite — A ferromagnetic ceramic.

Gain-bandwidth product — The frequency at which a device's gain drops unity. Below that frequency the product of the device's gain and frequency tends to be constant.

Hybrid- π — High-frequency model for a bipolar transistor.

Impedance inversion — Dividing a characteristic impedance by the ratio of the impedance to be inverted to the characteristic impedance. For example, 25 Ω inverted about 50 Ω is 100 Ω and 200 Ω inverted about 50 Ω is 12.5 Ω .

Insertion loss (IL) — The loss inherent in a circuit due to parasitic resistance.

Inter-electrode capacitance —

Capacitance between the internal elements of a semiconductor or vacuum tube.

Lumped element — Electronic component that exists at a single point.

Mix — The chemical composition of a ferrite or powdered-iron material (also called **type**).

Noise — Any unwanted signal, usually refers to signals of natural origins or random effects resulting from interfering signals.

Noise factor (F) — The amount by which noise at the output of a device is greater than that at the input multiplied by the gain of the device. A measure of how much noise is generated by a device.

Noise figure (NF) — $10 \log$ (noise factor).

Noise gain — Circuit output noise power divided by the available input noise power. This is not always equal to signal gain, depending on the source of the noise and the location of the noise source in the circuit.

Nonideal — Behavior that deviates from that of an ideal component (see also **parasitic**).

Nonlinear — A component that acts on a signal differently depending on the signal's amplitude.

Parasitic — Unintended characteristic related to the physical structure of a component.

Permeability — The ability of a material to support a magnetic field.

Return loss (RL) — The difference in dB between forward and reflected power at a network port.

Self-resonant — Resonance of a component due to parasitic characteristics.

Simulate — Model using numerical methods, usually on a computer.

Skin effect — The property of a conductor that restricts high-frequency ac current flow to a thin layer on its surface.

Skin depth — The depth of the layer at the surface of a conductor to which ac current flow is restricted (see **skin effect**).

Spectral Power Density — The amount of power per unit of bandwidth, usually “root-Hz” or $\sqrt{\text{Hz}}$, the square root of the

measurement bandwidth.

Stray — see **parasitic**.

Toroid (toroidal) — A ring-shaped continuous core.

Two-port network — A network with four terminals organized in two pairs, each pair called a port.

Two-port parameters — A set of four parameters that describe the relationship between signals at the network's two ports.

Unun — A device that transfers power between two unbalanced systems, usually performing an impedance transformation (see also **balun**).

Computer-Aided Circuit Design

This chapter provides an overview of computer-aided design (CAD) for electronic design and PCB layout. These tools enable the hobbyist to harness some of the circuit simulation power employed by professional electronic and RF engineers in the product and system design cycle.

Material originally contributed by David Newkirk, W9VES, addresses generic circuit simulation tools. Dr Ulrich Rohde, N1UL, surveys issues associated with linear and nonlinear RF simulation and contributes three extensive papers on the accompanying CD-ROM. Dale Grover, KD8KYZ, presents a comprehensive introduction to the use of PCB design and layout software.

The purpose of this chapter is not to provide detailed instructions for using any particular software package, but to explain the basic operations, limitations and vocabulary for CAD packages commonly used by amateurs. This chapter covers circuit simulators and PCB design tools. Software to aid design and analysis in specialized areas, for example filter design, switchmode power supplies, transmission lines, and RF power amplifiers, is covered in other chapters. Schematic capture is addressed as an element of both simulation and PCB design.

6.1 Circuit Simulation Overview

Mathematics can predict and analyze the action of electromagnetic signals and the radio-electronic circuitry we build to produce and process them. Program an electronic computer — which, at base, is a generic math machine — to do the radio/electronics math in practically applicable ways, and you're ready to do computer-aided design (CAD) of radio and electronic circuits. (Program a computer to do radio-electronics math *in real time*, and you're ready to replace radio-electronics hardware with software, as this book's **DSP and Software Radio Design** chapter describes.)

6.1.1 Hobby versus Professional Circuit Simulation Tools

Professional grade circuit simulation software exists to facilitate the construction of tightly packaged, highly integrated, no-tweaking-required modern electronics/RF products. These products work predictably well even when reproduced by automated processes in large quantities — quantities that may, with sufficient marketing success and buyer uptake, exceed millions of units.

Manufacturers of specialized *electronic design automation (EDA)* software serve the engineering needs of this industry. Through comprehensive CAD suites, one may proceed from graphical component level circuit and/or IC design (*schematic capture*), through simulation of circuit and IC behavior (often using a variant of the simulator called *SPICE*, but increasingly with non-*SPICE* simulators more fluent in issues of RF and electromagnetic design), through design of PC board and IC masks suitable for driving validation, testing and production. Comprehensive EDA CAD reduces costs and speeds time to market with the help of features that can automatically modify circuits to achieve specific performance goals (*optimization*); predict effects of component tolerances and temperature on circuit behavior across large populations of copies (*Monte Carlo analysis*); and generate bills of materials (BOMs) suitable for driving purchasing and procurement at every step of the way.

Demonstration or student versions are available for some EDA CAD products at no or low cost (see **Table 6.1**), and a subset of these are especially useful for hobby purposes. Although these *demoware* tools come to us with a large-scale-production pedigree, they are greatly (and strategically) feature-limited. Only a relatively few components, often representing only a subset of available component models, may be used per simulation. Monte Carlo analysis, optimization, BOM generation and similar enhancements are usually unavailable. The licenses for these packages often limits the use of the software to noncommercial applications. Demoware is intended to drive software purchasing decisions and serve as college level learning aids — learning aids in college study toward becoming electronics/RF professionals who will each day work with the unlimited, full versions of the demoware. *Freeware* versions of simulation and layout software with considerable power are also available and may also have some restrictions. In either case, read the licensing agreement to become aware of any obligations on your part.

The radio hobbyist's circuit simulation needs are much simpler than the professional. Most of us will build only one copy of a given design — a copy that may be lovingly tweaked and refined to our hearts' content far beyond "good enough." Many of us may build as much with the intent of learning about and exploring the behavior of circuits as achieving practical results

Table 6.1
Some Sources of Freeware/Demoware Electronic CAD Software

Source	Address	Resource
Ansoft (now Ansys)	www.ansys.com	<i>Ansoft Designer SV 2</i> (schematic, linear RF simulator, planar electromagnetic simulator, layout [PCB] design), more. No longer available but older copies of the program may be available

with them. A demoware circuit simulator can accelerate such self-driven exploration and education in electronics and RF.

6.1.2 The Design Cycle

The components we use to build real circuits always operate to the full extent of their actual properties, regardless of our relative ignorance of what those properties may be and how and why they operate the way they do. *No real-world component operates ideally.* So it is that we may set out to design, build and publish an amplifier circuit only to discover at power-up that we have instead built a persistent oscillator. Or if the prototype is an oscillator, that for 3 out of every 100 subsequent reader-builders the circuit does not oscillate at all!

The electrical and electronic components available in circuit simulators are only mathematical *models* of real world components — because every modeled behavior of a component is only an approximation relative to the behaviors of its real world counterpart. Simulated component characteristics and behaviors approach those of real world components only as closely as science may allow and only as closely as the model's description of the real world behavior.

Were this chapter a textbook, or part of a textbook, on computer-aided circuit design, we might begin exploring simulation by reviewing the basics of what electronic circuits are and do, following this with a discussion of what computerized circuit simulation is and how it works. An excursion into the arcane world of active device modeling — the construction and workings of mathematical electrical equivalents to the transistors, diodes and integrated circuits that await us at our favorite electronics suppliers and in our junk boxes — might follow. Finally, we might systematically proceed through a series of simulation examples from the basic to the more complex, progressively building our store of understood, trustworthy and applicable-to-future-work concepts as we go.

But this is a chapter in a handbook, not a

textbook, and following a sequence of abstract basics to concrete practice very likely does not reflect the process most of us have followed, and follow yet, in learning and using what we know about electronics and radio. More realistically, our approach is more like this: We find ourselves in need of a solution to a problem, identify one, and attempt to apply it. If it works, we move on, likely having learned little if we have not had to troubleshoot. If the solution does *not* work, we may merely abandon it and seek another, or — better, if we are open to learning — we may instead seek to understand why, with the happily revised aim of understanding what we need to understand to make the solution work. Even if we must ultimately abandon the solution as unworkable in favor of another, we do not consider our time wasted because we have further accelerated our deepening intuition by taking the initiative to understand why.

There is no smell of burning resistor or overheated transistor in a simulation. The placement of components on the screen has no effect on the behavior of the circuit, so a high gain stage whose input is too close to its output will never break into oscillation. The dc power sources are free of ripple and noise. These effects and many more can only be experienced (and remedies learned) by building real circuits.

Fig 6.1 shows the process by which you really learn circuit design from concept to finished project. The first step is to select a type of circuit and describe what it is supposed to do — these are the *performance requirements*. For example, an amplifier will need to achieve some level of gain over some frequency range. You may need a certain input impedance and output impedance. Armed with that information, choose a circuit and come up with a preliminary set of component values by using pencil and paper or a computer design tool. This is your *design*.

Next, *simulate* the circuit's performance. If the result satisfies your performance requirements, you can move to the next step. If not, change the circuit in some way (or change your requirements) until you are satisfied.

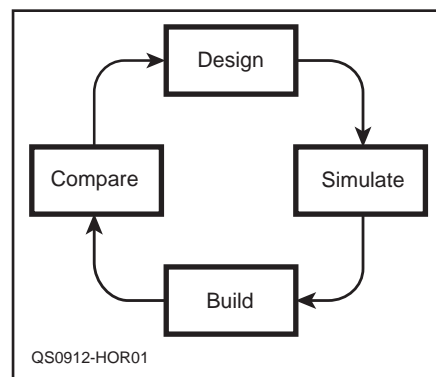

Fig 6.1 — Getting the most out of circuit simulation requires that you compare what the simulator predicts with how the actual circuit behaves.

Now *build* your design as a real world collection of components and verify that the circuit works. This is where the real fun begins as the effects of construction and actual component variation take effect. Are you done? Not yet!

To soak up every bit of design experience and know-how, go back and *compare* your actual measured performance to what the simulator predicted, particularly near the limits of the circuit's function. Look for *design sensitivities* by substituting different parts or values. If the circuit's behavior diverges from the simulator's predictions, now is the time to take a closer look. You may not be able to say exactly why differences are present, but you'll be aware they exist.

This continual *design cycle* simultaneously builds your knowledge of how real circuits and components behave, how your simulation tools work, and — most importantly — the circumstances for which the two are likely to be different.

The CD-ROM that comes with this book includes a number of design examples developed by the original author of this section, David Newkirk, W9VES. In these examples, he creates real world circuits, simulates their

behavior, compares it to actual performance, and explains why there are differences. Later in this chapter, a section by Ulrich Rohde, N1UL, discusses the differences among the different types of simulation tools used at RF — there are even differences among the different tools!

6.1.3 Schematic Capture and Simulation Tools

Almost any circuit-simulation program or electronic design automation (EDA) suite that uses schematic circuit capture can serve as a first rate schematic editor. (See Table 6.1) Although demoware component library limitations usually restrict the types of components you can use — in CAD-speak, *place* — in a design, *part count* limitations usually operate only at simulation time. Restrictions in physical size of the output drawing and layer count will likely apply to whatever layout design facilities may be available. After all, the main purpose of demoware is to let students and potential buyers taste the candy without giving away the store.

Excellent simulation-free schematic capture and layout design products exist, of course. The schematic style long standard in ARRL publications comes from the use of Autodesk *AutoCAD*, a fully professional product with a fully professional price. Long popular with radio amateurs and professionals alike is CadSoft *EAGLE*, a schematic capture and layout design product available in freeware and affordable full version forms. You can even export *EAGLE* schematics to a *SPICE* simulator and back with Beige Bag Software's *B2 Spice* (www.beigebag.com). The full function

CAD Software and Your Computer's Operating System

The *OrCAD 16.0* and *Ansoft Designer SV 2* demoware packages used in this chapter, and most other CAD products you're likely to use, are compiled to run under Microsoft *Windows*. So what if you want to run RF and electronics CAD software under *Linux* or on the Mac?

You're in luck. *EAGLE* schematic and layout software is available in native versions for *Windows*, *Linux*, and the Macintosh. The GPLed EDA application suite, *gEDA*, are primarily developed on *Linux*, but are intended to run under, or at least be portable to, *POSIX*-compliant systems in general. The GPLed schematic and layout editor *Kicad* runs natively under *Windows* and *Linux*, and has been tested under *FreeBSD* and *Solaris*. Further, the great strides made in the *Wine* translation layer (www.winehq.com/) allow many applications written for *Windows* to run well under the operating systems supported by *Wine*, including *Linux* and the Macintosh.

MicroSim DesignLab 8 (a widely distributed precursor to *OrCAD 16* that can run all of the *SPICE* examples described in this chapter) and *Ansoft Serenade SV 8.5* (a precursor to *Ansoft Designer SV 2*) can be run in *Wine* under *Linux* with few artifacts and their expected schematic capture and simulation capabilities intact. Cursor handling in *OrCAD 16* installs under *Wine* readily enough, but cursor handling artifacts in its schematic editor, at least in the computers tried, seems to preclude its use under *Wine* for now. *Ansoft Designer SV 2* installs but does not properly start.

All things considered, however, especially as *Wine* and CAD applications continue to strengthen and mature, running your favorite *Windows* based applications under *Wine* is well worth a try. You may also consider purchasing an inexpensive used computer that runs one of the later versions of *Windows*, such as XP, and dedicating it to running the simulation

freeware schematic and PCB layout application *Kicad* and the EDA suite *gEDA* come to us from the open source community.

The basic drawing utility included with your computer's operating system, such as *Paint* which comes with *Windows*, can also serve as a limited do-it-yourself schematic capture tool. The ARRL also provides a limited set of schematic symbols that can

be used with *PowerPoint* at the Hands-On Radio web page, www.arrl.org/hands-on-radio. Cutting, copying, moving and pasting components snipped from favorite graphical schematic files and adding new connections as graphical lines is enough to create a picture of the schematic but without any of the underlying tools or facilities of a true schematic capture tool.

6.2 Simulation Basics

This section is a collection of notes and illustrations that address various important circuit simulation concepts. In this section, conventional *SPICE* notation and vocabulary are used unless specifically noted differently. Not all simulation tools use exactly the same words and phrases to label and explain their features. When in doubt, refer to the software's user manual or HELP system. There are a number of excellent textbooks about using *SPICE*-based simulators. Widely used simulation tools almost always have online communities of users, all of whom were beginners once, too. Joining one of these groups is highly recommended.

Simulation tool users groups frequently develop and maintain a library of tutorials, Frequently Asked Questions (FAQ), accessory programs and utilities, even models and complex circuit models. Before you ask questions, consult the available resources, such as searchable message archives, to see if your

question has been answered before — it usually has! The other users will appreciate your diligence before asking the entire group.

6.2.1 SPICE — History

SPICE — Simulation Program with Integrated-Circuit Emphasis — originates from the Electrical Engineering and Computer Sciences Department of the University of California at Berkeley and first appeared under its current name as *SPICE1* in 1972. “*SPICE*,” write the maintainers of the official *SPICE* homepage at <http://bwrcs.eecs.berkeley.edu/Courses/IcBook/SPICE> “is a general-purpose circuit simulation program for nonlinear dc, nonlinear transient, and linear ac analyses. Circuits may contain resistors, capacitors, inductors, mutual inductors, independent voltage and current sources, four types of dependent sources, lossless and lossy transmission lines (two separate implementa-

tions), switches, uniform distributed RC lines, and the five most common semiconductor devices: diodes, BJTs, JFETs, MESFETs, and MOSFETs.”

That *SPICE* is “general-purpose” does not mean that its usefulness is unfocused, but rather that it is well established as a circuit simulation mainstay of comprehensive power. A wide, deep *SPICE* community exists as a result of decades of its daily use, maintenance and enhancement by industrial, academic and hobby users. Many excellent commercial versions of *SPICE* exist — versions that may be improved for workhorse use in particular sub-disciplines of electronics, power and RF design.

6.2.2 Conventions SCALE FACTORS

SPICE's use of unit suffixes — *scale factors* in *SPICE*-speak — differs from what we

are generally accustomed to seeing in electrical schematics, and that we have multiple options for specifying values numerically using integer and decimal floating point numbers. The scale factors available in *SPICE* include:

- F (femto) — 1E-15
- G (giga) — 1E9
- K (kilo) — 1E3
- M (milli) — 1E-3
- MEG (mega) — 1E6
- MIL (0.001 inch) — 25.4E-6 meter
- N (nano) — 1E-9
- P (pico) — 1E-12
- T (tera) — 1E12
- U (micro) — 1E-6

Specifying the value of a resistor as 1M would cause *SPICE* to assign it the value of 1 milliohm (0.001 Ω). This would probably create a wildly different result than expected! Specifying the value of R1 as 1MEG or 1000K would be correct alternatives. *SPICE* scale factors are case insensitive. Until you are thoroughly familiar with using circuit simulation, take the time to double-check component and parameter values. It will save you a lot of time tracking down errors caused by mistaken component values.

Notice that *SPICE* assumes unit *dimensions* — ohms, farads, henrys and so on — from component name context; in specifying resistance, we need not specify ohms. In parsing numbers for scale factors, *SPICE* detects only scale factors it knows and, having found one, ignores any additional letters that follow. This lets us make our schematics more readable by appending additional characters to values — as long as we don't confuse *SPICE* by running afoul of existing scale factors. We may therefore specify "100pF" or "2.2uF" for a capacitance rather than just "100p" or "2.2u" — a plus for schematic readability. (On the reduced readability side, however, *SPICE* requires that there be *no space* between a value and its scale factor — a limitation that stems from programming expediency and is present in many circuit-simulation programs.)

SOURCES

There are two basic types of sources used in simulation models — voltage sources and current sources — as discussed in the **Electrical Fundamentals** and **Analog Basics** chapters. Sources can be *independent* with an assigned value or characteristic that does not change, or *dependent* with a value or characteristic that depends on some other circuit value. An example of an independent source would be a fixed voltage power supply (dc) or a sinusoidal signal source (ac). An example of a dependent source is a bipolar transistor model's collector current source that has a value of βI_B .

COMPONENT MODELS

All *real* inductors, capacitors, and resistors — all real components of any type — are non-ideal in many ways. For starters, as **Fig 6.2** models for a capacitor, every real *L* also exhibits some *C* and some *R*; every real *C*, some *L* and *R*; every real *R*, some *L* and *C*. These unwanted qualities may be termed *parasitic*, like the parasitic oscillations that sometimes occur in circuits that we want to act only as amplifiers. The **RF Techniques** chapter discusses parasitics for various components.

For simulating many ham-buildable circuits that operate below 30 MHz, the effects of component parasitic R, L and C can usually be ignored unless guidance or experience suggests otherwise. In oscillator and filter circuits and modeled active devices, however, and as a circuit's frequency of operation generally increases, neglecting to account for parasitic L, C and R can result in surprising performance shortfalls in real world *and* simulated performance. In active device modeling realistic enough to accurately simulate oscillator phase noise and amplifier phase shift and their effects on modern, phase-error-sensitive data communication modes, device-equivalent models must even include *nonlinear* parasitic inductances and capacitances — *L_s* and *C_s* that vary as their associated voltages and currents change.

Figuring out what the circuit of an appropriate model should be is one thing; measuring and/or realistically calculating real world values for *R_s*, *L_s* and *R_p* for application in a circuit simulator is a significant challenge. How and to what degree these parasitic character-

istics may cause the electrical behavior of a component to differ from the ideal depends on its role in the circuit that includes it and the frequency at which the circuit operates.

Designers aiming for realism in simulating power circuits that include magnetic core inductors face the additional challenge that all real magnetic cores are nonlinear. Their magnetization versus magnetic field strength (*B-H*) characteristics exhibit hysteresis. They can and will saturate (that is, fail to increase their magnetic field strength commensurately with increasing magnetization) when overdriven. Short of saturation, the permeability of magnetic cores varies, hence changing the inductance of coils that include them, with the flow of dc through their windings. These effects can often be considered negligible in modeling ham-buildable low power circuits.

As active device operation moves from small signal — in which the signals handled by a circuit do not significantly shift the dc bias points of its active devices — to large signal — in which applied signals significantly shift active device dc bias and gain — the reality of *device self-heating* must be included in the device model. Examples: When amplitude stabilization occurs in an oscillator or gain reduction occurs in an amplifier as a result of voltage or current limiting or saturation.

While manufacturers often provide detailed models for their devices, avoid the temptation to assume that models will behave in a simulation just as an actual component will behave in a real circuit. *Absolutely every desired behavior exhibited by a simulated device must be explicitly built into the model*, mathematical element by mathematical element. A simulated device can reliably simulate real world behavior only to the extent that it has been programmed and configured to do so. A 1N4148 diode from your junk box "knows" exactly what to do when ac is applied to it, regardless of the polarity and level of the signal. Mathematically *modeling* the forward and reverse biased behavior of the real diode is almost like modeling two different devices. Realistically modeling the smooth transition between those modes, especially with increasing frequency, is yet another challenge.

Mathematical transistor modeling approaches the amazingly complex, especially for devices that must handle significant power at increasingly high frequencies, and especially as such devices are used in digital communication applications where phase relationships among components of the applied signal must be maintained to keep bit error rates low. The effect of nonlinear reactances — for instance, device capacitances that vary with applied signal level — must be taken into account if circuit simulation is to accurately predict oscillator phase noise and

Fig 6.2 — A capacitor model that aims for improved realism at VHF and above. *R_s* models the net series resistance of the capacitor package; *L_s*, the net equivalent inductance of the structure. *R_p*, in parallel with the capacitance, models the effect of leakage that results in self-discharge.

effects of the large signal phenomenon known as *AM-to-PM conversion*, in which changes in signal amplitude cause shifts in signal phase. In effect, different aspects of device behavior require greatly different models — for instance, a dc model, a small signal ac model, and a large signal ac model. Of *SPICE*'s bipolar-junction-transistor (BJT) model, we learn from the *SPICE* web pages that “The bipolar junction transistor model in *SPICE* is an adaptation of the integral charge control model of Gummel and Poon introduced in the **RF Techniques** chapter. This modified Gummel-Poon model extends the original model to include several effects at high bias levels. The model automatically simplifies to the simpler Ebers-Moll model when certain parameters are not specified.”

As an illustration of device model complexity, **Fig 6.3** shows as a schematic the BIP linear bipolar junction transistor model from *ARRL Radio Designer*, a linear circuit simulator published by ARRL in the late 1990s. This model worked well at audio and relatively low radio frequencies. The model must be even more complex for accurate results in the upper HF and higher frequency ranges.

Especially in the area of MOSFET and MESFET device modeling, and large signal device modeling in general (of critical importance to designers of RF integrated circuits [RFICs] for use at microwave frequencies), *SPICE* and RF-fluent non-*SPICE* simulators include active device models home experimenters are unlikely to use. Help in deciding on what version of a model is appropriate for your application is another reason to join your simulation tool's users group.

Most of us will go (and need go) no further into the arcanities of device modeling than using *SPICE*'s JFET model for FETs such as the 2N3819, J310, and MPF102, and *SPICE*'s BJT model for bipolar transistors such as the 2N3904. *OrCAD 16* includes preconfig-

Fig 6.3 — The linear BJT model, BIP, from *ARRL Radio Designer*, a now-discontinued circuit simulation product published by ARRL in the late 1990s.

ured 1N914, 1N4148, 2N2222, 2N2907A, 2N3819, 2N3904 and 2N3906 devices, among many others, and these will be sufficient for many a ham radio simulation session. Getting the hang of the limitations and quirks of these models may well provide challenge enough for years of modeling exploration.

To get parameters for other devices, especially RF devices and specialty components like transformers, we must search the Internet in general and device manufacturer websites

in particular to find the data we need. The manufacturer sites listed in **Table 6.2** will get you started. Because the use of simulation and *SPICE* models is so widespread, manufacturers routinely make those models available at no cost. The usual place to find them is via the device's online data sheet through a hyperlink or in a special model library on the manufacturer's website — enter “models” into the site's search function if you can't find the models.

Table 6.2
Device Parameter Sources

Source	Address	Resource

Fig 6.4 — A list of parameters specified for the Gummel-Poon model of a 2N2222A transistor and the condensed form usually seen in available model files.

A typical *SPICE* model is shown in **Fig 6.4**. This particular model is for the familiar 2N2222A NPN bipolar transistor. Each parameter in the vertical list (IS, BF, NF and so forth) is one element of the Gummel-Poon model for the generic transistor used by *SPICE* simulation programs. Typically, the model is provided as plain ASCII text in the compressed form at the bottom of the figure with several parameters per line. Every parameter between the opening and closing parentheses defines some element of the underlying model. (See the *SPICE* references listed at the end of this chapter for detailed information about the syntax of *SPICE* models.)

NETLISTS

A *netlist* is a specialized table that names a circuit's components, specifies their electrical characteristics, and maps in text form the electrical interconnections among them. Uniquely numbered nodes or *nets* — in effect, specifications for each of the connections in the simulated circuit — serve as interconnects between components, with each component defined by a statement comprising one or more netlist lines.

The netlist served as the original means of circuit capture for all simulators known to the

writer, including *SPICE*; *schematic capture* as we imagine it today, using graphic symbols, came later. Further reflecting *SPICE*'s pre-graphical heritage is the fact that, to this day a *SPICE* netlist may be referred to by long-time *SPICE* users as a *SPICE deck*, as in “deck of Hollerith punch cards.” In *SPICE*'s early days, circuit definitions and simulation instructions (netlist statements that begin with a period [.]) were commonly conveyed to the simulation engine in punched-paper-card form. Netlists are still the means of conveying circuit topology and simulation instructions to most simulators, although they are text files today.

In the models and netlists that you will encounter, statements that must span multiple lines include *continuation characters* (+) to tell the netlist parser to join them at line breaks. Asterisk (*) or other non-alphanumeric characters denote comments — informational-to-human lines to be ignored by the simulator.

SUBCIRCUITS

Fig 6.5 illustrates the level of detail involved in more accurate device modeling typical for devices used at VHF and UHF. The device is a California Eastern Labs NE46134, a surface mount BJT intended to serve as a broadband linear amplifier at collector currents up to

100 mA and collector voltages up to 12.5 V.

This manufacturer supplied model for the NE46134 embeds an unpackaged device chip (NE46100, shown as Q1 in the figure) within a *subcircuit*. (Note the .SUBCKT label on the first non-comment line of the model which indicates that the following information defines a subcircuit.) The subcircuit includes Q1 plus the parasitic reactances contributed by the transistor package, such as CCBpkg — a collector-to-base package capacitance. The chip leads themselves are modeled as transmission lines, TB and TE.

Following the lines that define all of the subcircuit's component values that represent the parasitic reactances, the NE46100 transistor model is provided, beginning with the line .MODEL NE46100 NPN. That information will be used to define Q1 when referenced in the subcircuit model above.

The overall model then appears to the external circuit like a regular three terminal transistor with a base, emitter and collector. In this fashion nested subcircuits can be used to create arbitrarily complex models that can be used as components by the designer.

Figs 6.6A and 6.6B show a schematic of a typical RF circuit — a 7 MHz double-tuned filter. **Fig 6.6A** is the usual depiction you would see in a magazine or book article about the circuit. It has the usual symbols and variable capacitors of a tunable filter. **Fig 6.6B** shows the circuit after schematic capture by the *OrCAD Capture CIS* tool. An ac voltage source, V1, is placed at the input with a 50 Ω series resistor, R1, to create a 50 Ω signal source impedance. The transformers TX1 and TX2 actually contain subcircuits consisting of primary and secondary inductances and a coupling element with 0.22 Ω resistors that simulate loss resistance. The paralleled fixed and variable capacitors are combined into single fixed value capacitors. A 50 Ω load, R2, has been attached to the output. Ground symbols now have a 0 nearby to indicate zero voltage.

TIME STEP

Simulators are *discrete time* devices — calculations are performed throughout the circuit and results obtained, then time is changed by a fixed amount (the *time step*) and the calculations run again. The size of the time step can be automatically chosen by the simulator (a usually reasonable value based on a default setting or some evaluation of the circuit component values) or set to specific values by the user.

While using very small time steps makes for a smooth looking output and wide frequency ranges, it makes the simulation run slower (less of an issue as computers get faster) and makes the output data files quite a bit bigger (less of an issue as hard drives get bigger). While today's computers make short

Fig 6.8 — Time domain display of an R-C oscillator startup showing voltage on the vertical axis and time on the horizontal. The display is very much like that of an oscilloscope.

narrow pulses with some finite energy), rectangular pulses, ramps, and various other selectable waveforms.

DC AND AC SWEEPS

Once a circuit is working, it is useful to characterize its performance over a range of conditions, called a *sweep*: power supply voltage, input voltage, input frequency and so on. Even temperature can be swept to see

how the circuit behaves in different environments. Note that this requires the behavior of components with changing temperature to be accounted for in the component models.

One of the most common swept simulations for ham radio circuits is a frequency sweep to determine the frequency response of an amplifier or filter. **Fig 6.10** shows the insertion loss and return loss (see the **Analog Basics** chapter) for the 7 MHz filter in Fig 6.6

across a range of 6.8 to 7.4 MHz. **Fig 6.11** shows the gain of the amplifier in Fig 6.7 with the input frequency swept across a range of 1 to 100 MHz.

6.2.4 RF-Fluent Simulators

SPICE-based simulators can do wonders in many classes of circuit simulation. For RF use, however, *SPICE* has significant draw-

Fig 6.10 — Insertion loss (A) and return loss (B) of the 7 MHz double-tuned filter in Fig 6.6.

backs. For starters, *SPICE* is not RF-fluent in that it does not realistically model *physical* distributed circuit elements — microstrip, stripline and other distributed circuit elements based on transmission lines. It cannot directly work with network parameters (*S*, *Y*, *Z* and more — see the **Analog Basics** chapter), stability factor and group delay. It cannot simulate component *Q* attributable to skin effect. It cannot simulate noise in nonlinear circuits, including oscillator phase noise. It cannot realistically simulate intermodulation

and distortion in high-dynamic-range circuits intended to operate linearly. This also means that it cannot simulate RF mixing and intermodulation with critical accuracy.

The feature-unlimited version of *Ansoft Designer* and competing RF-fluent simulation products can do these things and more excellently — but many of these features, especially those related to nonlinear simulation, are unavailable in the student/demoware versions of these packages if such versions exist.

From 2000 to 2005, the free demoware

precursor of *Ansoft Designer SV 2*, *Ansoft Serenade SV 8.5*, brought limited use of nonlinear simulation tools to students and experimenters. With *Serenade SV 8.5*, you could simulate mixers, including conversion gain and noise figure of a mixer. Amplifier two-tone IMD could be simulated as in Fig 6.9. Optimization was enabled. Realistic nonlinear libraries were included for several Siemens — now Infineon — parts. You could accurately predict whether or not a circuit you hoped would oscillate would *actually* oscillate, and assuming that it would, you could accurately predict its output power and frequency. **Figs 6.12, 6.13 and 6.14** give some examples of the power of RF-fluent simulation software, in this case, Ansoft (now ANSYS) *Serenade Designer SV 8.5*.

The harmonic balance techniques used by Ansoft's nonlinear solver — and by the nonlinear solvers at the core of competing RF-fluent CAD products, such as Agilent *Advanced Design System (ADS)* — allowed you to simulate crystal oscillators as rapidly as you can simulate lower-*Q* oscillators based on LC circuits. (In *SPICE*, getting a crystal oscillator to start may be impossible without presetting current and/or voltages in key components to nonzero values.)

Although these features are no longer available as student/demoware/freeware, if you're serious about pushing into RF CAD beyond what *SPICE* can do, see if you can find a used copy of *Serenade SV 8.5* or find a friend working with the professional tools who will let you use it occasionally for hobby applications.

Fig 6.11 — The gain in dB of the amplifier in Fig 6.6 over a range of 1 to 100 MHz.

Fig 6.12 — A two-tone nonlinear simulation of third-order IMD performed by Ansoft *Serenade Designer SV 8.5*.

Fig 6.13 — Professional RF circuit simulators can also simulate mixing and the small signal characteristics of mixers, such as port return loss, conversion gain, and port-to-port isolation. (*Serenade SV*)

Fig 6.14 — Output spectrum of a diode-doubly balanced mixer as simulated by *Serenade SV 8.5*. Note the dynamic range implicit in this graph: In a simulation that includes a local oscillator (LO) signal at 7 dBm, accurate values are calculated for IMD products nearly 140 dB weaker without encountering mathematical noise — an achievement unapproachable with *SPICE*-based simulators.

6.3 Limitations of Simulation at RF

[Experienced users of circuit simulation software are wary of using any software near or outside the boundaries of circuits and parameters for which it was intended and tested. RF simulation can present just such situations, leading to software failure and unrealistic results. Introduced and summarized in this section, several detailed papers by Dr Ulrich Rohde, N1UL, exploring simulation at RF are provided on the CD-ROM accompanying this *Handbook*. The papers are:

- “Using Simulation at RF” by Rohde, a survey of the issues of RF simulation and the techniques used in current modeling programs.

- “The Dangers of Simple Usage of Microwave Software” by Rohde and Hartnagel, a discussion of inaccuracies introduced by device parameter measurement and model characteristics.

- “Mathematical Stability Problems in Modern Non-Linear Simulations Programs” by Rohde and Lakhe, presenting various approaches to dealing with nonlinear circuit simulation.

In addition, there are many online resources to help you obtain trustworthy simulation results with a simulator designed for RF. For the interested reader with some technical background, the online paper “Introduction to RF Simulation and its Application” by Ken Kundert (<http://icslwebs.ee.ucla.edu/dejan/researchwiki/images/3/30/Rf-sim.pdf>) provides an introduction to RF simulation methods and how they account for the characteristics of RF circuits when generating common RF measurements. The website The Designer’s Guide (www.designers-guide.org) also provides many tutorials, technical guides, models, and other resources for analog and RF simulation users.

While the precise lower bound of “RF” is ill-defined, RF effects start already at about 100 kHz. This was first noticed as self-resonance of high-Q inductors for receivers. In response, Litz wire was invented in which braided copper wires were covered with cotton and then braided again to reduce self-resonance effects.

As frequencies get higher, passive elements will show the effects of parasitic elements such as lead inductance and stray capacitance. At very high frequencies, the physical dimensions of components and their interconnections reach an appreciable fraction of the signal wavelength and their RF performance can change drastically.

RF simulators fall in the categories of SPICE, harmonic balance (HB) programs

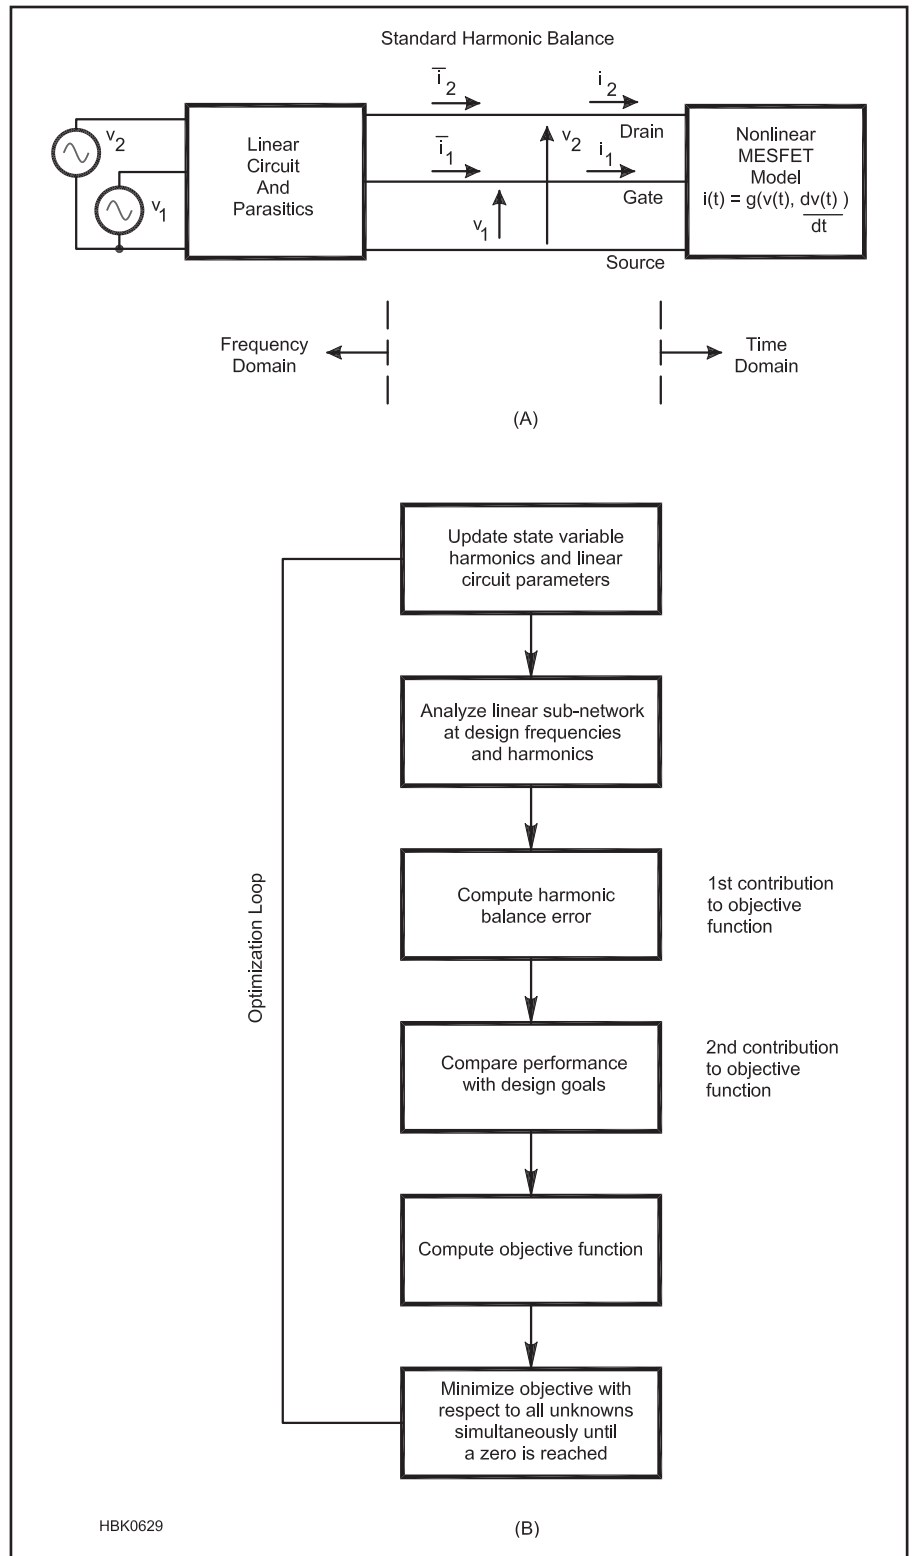

Fig 6.15 — (A) MESFET circuit partitioned into linear and nonlinear sub-circuits for harmonic balance analysis. Applied gate and drain voltages, and relevant terminal voltages and currents, are indicated. (B) Flowchart of a general purpose harmonic balance design algorithm that includes optimization.

and EM (electromagnetic) programs. The EM simulators are more exotic programs. Two types are common, the 2D (2.5) or 2-dimensional and the full 3-dimensional versions. They are used to analyze planar circuits, including vias (connections between layers) and wraparounds (top-to-ground plane connections), and solid-shapes at RF. They go far beyond the *SPICE* concept.

6.3.1 *SPICE*-based Simulators

SPICE was originally developed for low frequency and dc analysis. (Modern *SPICE* programs are based on *SPICE3* from University of California — Berkeley.) While doing dc, frequency, and time domain simulations very well, *SPICE*-based simulation has some problems. The time domain calculation uses the very complex mathematics of the Newton-Raphson solution to nonlinear equations. These methods are not always stable. All kind of adjustments to the program settings may be necessary for the calculations to converge properly. Knowledge of the specifics of different types of electronic circuits can assist the user in finding an accurate solution by specifying appropriate analysis modes, options, tolerances, and suitable model parameters. For example, oscillators require certain initializations not necessary for amplifiers and bipolar transistors may need different convergence tolerances than do MOS circuits. Generally, *SPICE* finds a solution to most circuit problems. However, because of the nonlinearity of the circuit equations and a few imperfections in the analytical device models, a solution is not always guaranteed when the circuit and its specification are otherwise correct.

The next problem at RF is that the basic *SPICE* simulator uses ideal elements and some transmission line models. As we approach higher frequencies where the lumped elements turn into distributed elements and special connecting elements become necessary, the use of the standard elements ends. To complicate matters, active elements such as diodes and transistors force the designer to more complex simulators. Adding the missing component elements leads to highly complex models and problems of convergence in which the simulator gives an error advising of a numerical problem or more likely by failing to generate a solution.

SPICE also has problems with very high-*Q* circuits and noise analysis. Questions of the noise figure of amplifiers or phase noise of an oscillator cannot be answered by a *SPICE*-based program accurately. Noise analysis, if not based on the noise correlation matrix approach, will not be correct if the feedback capacitance ($\text{Im}(Y_{12})$, the imaginary component of *Y*-parameter Y_{12}) is significant at the frequencies involved. Analysis of oscillators

in *SPICE* does not give a reliable output frequency and some of the latest *SPICE* programs resort to some approximation calculations.

6.3.2 Harmonic Balance Simulators

Harmonic balance (HB) analysis is performed using a spectrum of harmonically related frequencies, similar to what you would see by measuring signals on a spectrum analyzer. The fundamental frequencies are the

frequencies whose integral combinations form the spectrum of harmonic frequency components used in the analysis. On a spectrum analyzer you may see a large number of signals, even if the input to your circuit is only one or two tones. The harmonic balance analysis must truncate the number of harmonically related signals so it can be analyzed on a computer.

The modern HB programs have found better solutions for handling very large numbers of transistors (>1 million transistors) and their math solutions are much more efficient, lead-

Fig 6.16 — (A) is the initial simulation of a *SPICE*-based simulator. (B) is the correct response of a pulsed microwave oscillator obtained by harmonic balance simulation using the Krylov-subspace solution. (C) is the *SPICE*-based simulation after 80 pulses of the drain voltage.

ing to major speed improvements. Memory management through the use of matrix formulations reduces the number of internal nodes and solving nonlinear equations for transient analysis are some of the key factors to this success.

HB analysis performs steady-state analysis of periodically excited circuits. The circuit to be analyzed is split into linear and nonlinear sub-circuits. The linear sub-circuit is analyzed in the frequency domain by using distributed models. In particular, this enables straightforward intermodulation calculations and mixer analysis. The nonlinear sub-circuit is calculated in the time domain by using nonlinear models derived directly from device physics. This allows a more intuitive and logical circuit representation.

Fig 6.15A diagrams the harmonic balance approach for a MESFET amplifier. **Fig 6.15B** charts a general purpose nonlinear design algorithm that includes optimization. Modern analysis tools that must provide accurate phase noise calculation should be based on

the principle of harmonic balance.

Analysis parameters such as Number of Harmonics specify the truncation and the set of fundamental frequencies used in the analysis. The fundamental frequencies are typically not the lowest frequencies (except in the single-tone case) nor must they be the frequencies of the excitation sources. They simply define the base frequencies upon which the complete analysis spectrum is built.

6.3.3 Contrasts in Results

The following time domain analysis is a good example of differences between *SPICE* and harmonic balance simulation. A microwave oscillator is keyed on and off and a transient analysis is performed. When using the standard *SPICE* based on *SPICE3*, the initial calculation shows an incorrect response after one iteration as seen in **Fig 6.16A**. It takes about 80 pulses (80th period of the pulsed drain voltage) until the simulation attains the correct answer (**Fig 6.16C**) of the Krylov-subspace-

based harmonic balance in **Fig 6.16B**.

The frequencies involved need not be in the GHz range. Oscillators, in particular, can be very difficult to analyze at any frequency as shown by simulations of a low-MHz phase shift oscillator and a 10 MHz Colpitts oscillator in the referenced papers.

Validating the harmonic balance approach, **Fig 6.17** shows a BJT microwave oscillator entered into the schematic capture module of a commercially available HB simulator (*Ansoft Serenade 8.0*); **Fig 6.18** compares this oscillator's simulated phase noise to measured data. HB analysis gives similarly accurate results for mixers.

6.3.4 RF Simulation Tools

PSPICE: This popular version of *SPICE*, available from OrCAD (now Cadence Design Systems, www.cadence.com) runs under the PC and Macintosh platforms. An evaluation version, which can handle small circuits with up to 10 transistors, is freely

Fig 6.17 — Colpitts oscillator for 800 MHz with lumped elements modeled by their real values.

Fig 6.18 — Comparison between predicted and measured phase noise for the oscillator shown in Fig 6.17.

6.4 CAD for PCB Design

[With numerous PCB design software packages available and low quantity, low cost PCB manufacturing services accepting orders electronically, the development of PCBs has never been easier for the amateur. As with any assembly or manufacturing process, it is important to understand the vocabulary and technology in order to achieve the desired result. Thus, this section provides a detailed description of the entire process of PCB design. — *Ed.*]

The primary goal of using software for printed circuit board (PCB) design is the production of so-called PCB artwork — the graphic design used to create the patterns of traces that establish connectivity on the PCB. Historically, PCB artwork was created by hand on clear film using black tape and special decals which were then photographically reduced. However, free and low cost programs specifically for the PCB design process are now widely available. These programs not only allow the creation of artwork efficiently and accurately, but produce the required ancillary files for commercial production, exchange information with schematic capture software, produce Bills of Materials (parts lists), and even include such features as three dimensional visualization of the finished board. While artwork files can be shared with other people for PCB production, the “source” files used by the CAD program can

typically only be used by other people who share the same program.

The decision to produce a PCB must take into account the nature of the circuit itself (for example, high frequency, low noise and high current circuits require additional care). Other considerations are time available, expense, available alternatives, quantity required, ability to share and replicate the design, and non-electrical characteristics such as thermal and mechanical, as well as desired robustness.

6.4.1 Overview of the PCB Design Process

The PCB design process begins with establishing the list of components in the circuit, the connections between the components, the physical outline/size of the board, and any other physical, thermal and electrical constraints or design goals. Much of the connectivity and component information is reflected in the schematic for a circuit, so in many cases the PCB layout process begins by entering the schematic in a schematic capture program which may be integrated with the PCB CAD program or standalone. (Schematic capture is not required for PCB layout.) Once the schematic is entered, there may be other options possible such as simulating the circuit as described in the preceding sections. A clean, well organized schematic that is easily modi-

available, such as from www.electronic-lab.com. Contact Cadence for a full version or for more information. *AIM-spice* (www.aimspice.com) is a PC version of *SPICE* with a revised user interface, simulation control, and with extra models. A student version can be downloaded. Table 6.1 earlier in this chapter shows other free *SPICE* offerings.

There are a number of PC based *SPICE* programs in the \$1000 range but they are designed more for switching power supplies and logic circuits optimization than RF. *ICAP4* (www.intusoft.com/demos.htm) and *MICROCAP9* (www.spectrum-soft.com/index.shtml) both have demonstration/evaluation versions available for download.

Agilent, AWR, Ansys, and Synopsis offer very modern mixed-mode CAD tools and they combine the concept of *SPICE* with the advanced technologies. These are professional quality tools, but if one can arrange to make use of them through a friend or associate, the results are worth investing the time to learn their use.

fied is an asset regardless of the circuit production and construction methods.

With input from the schematic and other information, the board outline is created, mounting and other holes placed, the components positioned, and the pattern of traces created. Once the layout is complete, in many cases it is possible to run a design rules check — the equivalent of a “spell checker.” Design rules include component connections and other information to check for problems related to connectivity and manufacturability. This step can save a great deal of time and expense by catching errors that could be fixed by hand, but would otherwise negate some of the benefits of a PCB.

The final step in the PCB layout program is to produce the collection of up to a dozen or so different files required for PCB production. In brief, the list includes the artwork for the pattern of traces, files for producing the board outline, solder masks, silk screens and holes.

The user then uploads the set of files to a PCB manufacturer. As quickly as two to three days later an envelope will be delivered with the freshly minted boards ready for assembly! Alternatively, the user may create the board “in house” using photomechanical or other processes based on the output files from the software, as is discussed in the **Construction Techniques** chapter along with PCB assembly techniques.

6.4.2 Types of PCB Design Software

PCB software varies in features, function and cost, but for the radio amateur, the most interesting software for introductory use fall into the following categories:

1) Open Source: PCB design software such as *GNU PCB* (<http://pcb.gpleda.org>, for *Linux*, *Mac OS X*) and *KiCad* (http://kicad.sourceforge.net/wiki/index.php/Main_Page, for *Linux*, *Mac OS X*, and *Windows*, includes schematic capture) are free to use and have no artificial restrictions. Support is through user forums. Source code is available for the user to modify. *gschem* is a schematic capture sister program to *GNU PCB*.

2) Free, restricted use/restricted feature commercial: At least one company makes a version of their PCB and schematic software that is free to use for noncommercial purposes. Though it is restricted in number of layers (two) and maximum board size (4×3.2 inches), *Eagle PCB "Light Edition"* (www.cadsoftusa.com, for *Linux*, *Mac OS X*, *Windows*) is very popular among hobbyists. Files can be shared with others; the resulting industry standard files can be sent to nearly any PCB manufacturer. *Eagle* also contains a schematic entry program.

3) Free, restricted output commercial: Several PCB manufacturers offer schematic and PCB software with a proprietary output format tied to their PCB manufacturing service. *PCB123* from Sunstone Circuits (www.sunstone.com, for *Windows*) is one such offering, including schematic capture and layout software with up to four layers and board sizes up to 12×18 inches (double sided). For an additional fee (per design), industry standard files can be exported. Schematic entry is included. *Express PCB* (www.expresspcb.com, for *Windows*) also provides schematic capture and PCB layout capability, tied to the Express PCB board fabrication services, including the fixed size (3.8×2.5 inches) Miniboard service. Advanced Circuit's proprietary *PCB Artist* software (www.4pcb.com, for *Windows*) includes the ability to import netlists.

4. Low cost commercial: Eagle and many other companies offer PCB and schematic software at a range of prices from \$50 to many thousands of dollars. Several versions are typically offered from each company, usually based on limitations on board size, schematic size/complexity and features such as autorouting. Schematic entry may be included in some packages, or be a separate purchase.

PCB design software manuals and tutorials discuss the basic operation but also special keystrokes and other shortcuts that make operations such as routing traces much more efficient.

The first time designing and ordering a PCB

can be daunting, so keep the initial job simple and pay attention to details (and read the instructions). When starting to use a specific software package, join a user's support group or forum if one is available. Request sample designs from other users and experiment with them to see how they are constructed and what files are required in the output data set. Once you are comfortable with the tools, you can begin on a design of your own.

6.4.3 Schematic Capture

The first step in PCB design is to create a schematic. It is possible to design a layout directly from a paper schematic, but it is much easier if the schematic is entered (or "captured") in electronic form. Schematic capture software has two outputs — the visual schematic and the component and connectivity data for subsequent PCB layout. These two separate requirements can make some operations during schematic entry more complicated than what would seem at first glance necessary. Bear in mind however, that the user is creating not only a clear graphic representation of the circuit, but of the underlying electrical connectivity.

Schematics are generally entered on a (virtual) page usually corresponding to common paper sizes — for example, 11×17 inches. More complicated schematics can span multiple pages, using special labels or components to indicate both visual and electrical connectivity. Often one can group logically related elements into a module that can then be referenced as a "black box" on a higher level schematic. For complex circuits, these features are extremely useful and make the difference between a jumbled diagram that is difficult to use and an organized, compact diagram that efficiently communicates the function and operation of the circuit.

COMPONENTS

The components (resistors, capacitors, etc) on a schematic are either selected from an existing library or created by the user and stored in a custom library. It is also possible to find components and/or additional libraries on the Internet, although each program has its own specific format.

Each component includes a great deal more than shape and pin numbers. A typical component library entry includes:

Symbol — This is the graphic representation shown on the schematic. Many components may have the same symbol (eg, the op amp symbol may be shared by many different types of op amps)

Pins — For each pin or point of electrical connection, the component model may specify the pin number, label (eg, " V_{DD} "), pin type (inverting, noninverting) or pin functions (common).

PCB footprint — A given component may be available in a number of different packages (eg, DIP or surface mount). Many components may have the same physical footprint (eg, op amps, comparators and optoisolators could all map to the same eight-pin DIP footprint). Footprints include the electrical connections (pins) as well as mechanical mounting holes and pad sizes, and the component outline.

Value — Many components such as resistors and capacitors will have identical information except for a difference in value. All $\frac{1}{4}$ W resistors may be instances of the same component, differing only in value and designator.

Designator — The unique reference to the component, such as R1, C7, D3. This is assigned when the component is used (often automatically and in sequence).

Source information — Part number, vendor, cost, etc. This information is for the Bill of Materials.

Components are typically placed on the schematic by opening a library and searching for the desired component. It may be tempting for the beginner to select a component that looks "about right" when faced by a long list of components in some libraries. However, even at this early stage, the physical PCB often must be taken into account. For example, either "1/8W Resistor, Axial" or "1W Resistor, Upright" will result in the same neatly drawn resistor symbol on the schematic but in the subsequent step of using the component data to create a PCB, the footprints will be dramatically different.

It is not at all uncommon to add new components to the library in the course of creating a schematic. Since many components are closely related to existing devices, the process often consists of selecting an existing schematic symbol, editing the shape and/or component data, creating a new label, and associating the part with an existing footprint. Adding a specific type of op amp is an example. This usually only needs to be done once since symbols can be saved in a personal library (and shared with others). It is usually easier to modify a part that is close to what is desired than to "build" a new part from scratch.

Component symbols can generally be rotated and flipped when placing the component instance on the schematic. Designators (R1, T34, etc) can be assigned and modified by the user although the default designators are usually selected sequentially.

CONNECTIONS

The schematic software will have a mode for making electrical connections, called "nets." For example, one might click on the "draw net" symbol then draw a line using the mouse from one pin to another pin, us-

ing intermediate mouse clicks to route the line neatly with 90° turns on a uniform grid. Internally, the software must not only draw the visual line, but recognize what electrical connectivity that connection represents. So one must click (exactly) on a component pin to start or end a line or when making a connection between two lines that intersect, explicitly indicate a net-to-net connection (often with a special “dot” component). The connections on a schematic can often be assigned additional information, such as the desired width of the trace for this connection on the PCB or a name assigned by the user, such as “input signal.”

Not all connections on a schematic are drawn. To make any schematic — electronic or hand drawn — more readable, conventions are often employed such as ground or power symbols or grouping similar connections into busses. Schematic capture software often supports these conventions. In some cases, components may be created with implicit power connections; in these cases the connections may not even be noted on the schematic but will be exported to the PCB software. However, as a general rule, software aimed at beginning PCB designers will not require the use of these advanced features.

Since it is often possible for component pins to be assigned attributes such as “power input”, “output,” “input,” and so on, some schematic entry programs allow one to do an early design check. The program can then flag connections between two outputs, inputs that are missing connections, and so on. This is not nearly as helpful or complete as the Design Rule Check discussed below.

Free text can be placed on the schematic and there will be a text block in a corner for

date, designer, version, title and the other information that identifies the schematic.

NETLISTS

Once the components are placed and connections made, the schematic may be printed and any output files for the PCB layout software produced. The connectivity and component information needed for PCB layout is captured in a *netlist* file. The flow from schematic entry to PCB may be tightly integrated, in which case the user may switch between schematic and PCB like two views of the same design (which they are). However, most schematic software will generate a separate netlist to be used by PCB layout software, whether integrated or a separate program. The netlist can also be exported to an external circuit simulation program or be used by an integrated simulator program. (See the first part of this chapter for more information on circuit simulation.)

Netlists are often human readable text files and in most cases it is possible to create a netlist file manually. In the absence of a schematic entry program, this allows the user to take a hand drawn schematic, extract the connectivity information, and create the netlist for the PCB program to perform design rule checks. However, a netlist is generally not required for the PCB layout software; the user will also have the option to create a PCB on-the-fly, adding components and connections as they wish.

ANNOTATION AND BILL OF MATERIALS

The important features of *forward* and *backward annotation* enter at the interface between schematic entry and PCB layout. It is

not uncommon during the PCB layout process to either come across some design deficiency or realize that a change to the schematic could produce a design that would be easier to lay out. Likewise, a review of the schematic part-way through the PCB layout process could reveal some needed design change. In the case of changes to the PCB (perhaps changing some pins on a connector to make routing easier), back annotation can propagate the changes “backward” to the schematic. The connectivity data will be updated; however the user may need to manually route the connection lines to neaten up the schematic. Likewise, changes to the schematic when the PCB is already (partially) routed are known as forward annotations and like the schematic, while the connectivity is updated the user will likely need to manually route the traces. Neither forward nor back annotation is necessary, but is useful in keeping the schematic and PCB consistent. In their absence, the user is strongly urged to keep the schematic and PCB up to date manually to avoid time consuming problems later on.

Finally, the underlying data in the schematic can be used to produce a *Bill of Materials* (BOM). A BOM lists all the components of the schematic, typically ordered by reference designator(s), and may even be exportable for online ordering.

6.4.4 PCB Characteristics PCB CONSTRUCTION

It is useful to know a little bit about PCB construction in order to make sense of the PCB design process. **Fig 6.19** shows the basic structure of a PCB and some of its design elements (discussed in later sections). The lami-

Fig 6.19 — The various elements of PCB construction and specification.

Fig 6.20 — Via refers to a plated-through hole that connects one board layer to another. Vias are used for signal, power, or ground connections and even for ventilation. Different via types include through-hole (1); blind (2), and buried (3).

nate material provides a stable, insulating substrate with other known characteristics (thermal, dielectric, etc). Copper is bonded to one or both sides and selectively removed (usually chemically) to leave traces and pads. The pads provide points of connection for components. Though electrical connectivity is crucial, it is important to remember that the solder and pads provide mechanical and thermal connectivity as well. Pads may be drilled for mounting *through-hole* components or left undrilled for *surface-mount* components.

A separate electrochemical process plates the inside surface of *plated-through holes* to provide connectivity between upper and lower pads. Plated-through holes whose sole purpose is to provide electrical connectivity between layers of a PCB are known as *vias*, shown in **Fig 6.20**. Since they do not need to accommodate a component lead, their hole and pad size are smaller.

While two layer boards can mount components on either side, most PCBs will have a primary side called the *component side* upon which most of the components will be placed, and a *solder side* dominated by soldered pins and traces. Where high density is required, surface mount (and sometimes through-hole) devices are mounted on both sides, but this is considerably more complex.

Multi-layer boards are essentially a stack of two or more two-layer boards, with an insulating layer between each board. Plated-through holes make connections possible on every layer, and the laminate material is proportionally thinner so the entire multi-layer board is roughly the same thickness as a regular two-layer board. Vias that join selected, adjacent copper layers without connecting the entire stack of layers are called “buried” or “blind” vias and are typically only needed for very dense designs. Multi-layer boards provide much more flexibility in routing signals and some other benefits such as dedicated layers for power distribu-

tion and grounding, but at often substantial additional cost.

PCB MANUFACTURING SPECIFICATIONS

Unless the board is manufactured by the hobbyist, the PCB files are sent out to be manufactured by a *board house*. The most important issue for the amateur may be the pricing policies of the board house. Board size, quantity, delivery time, number of layers, number and/or density of holes, presence of solder masks and silk screens, minimum trace/separation width, type of board material, and thickness of copper will all influence pricing. One cost saving option of the past, a single-layer board, may not be offered with low-cost, low-volume services — two layers may be the simplest option and it results in a more robust board. [Note that most ordering specifications use English units of inches and ounces. Offshore board houses may use both English and metric units, or be metric-only. English units are used here because they are the most common encountered by hobbyists. — *Ed.*]

The second issue to consider is manufacturing capabilities and ordering options. These will vary with pricing and delivery times, but include the following:

Board material and thickness — FR-4 is the most popular board material for low volume PCBs; it consists of flame-resistant woven fiberglass with epoxy binder. Typical thickness is 0.062 inch ($\frac{1}{16}$ inch), but thinner material is sometimes available. Flexible laminates are also available at greater cost and longer delivery time. Special board laminates for microwave use or high-temperature applications are also available.

Copper thickness — Expressed in ounces per square foot, typical values are 1-2 oz (1 oz corresponds to 0.0014 inch of thickness.) Other values may not be available inexpensively for small volumes. Inner layers on multi-layer boards may be thinner — check if this is important. Most board designs can assume at least 1 oz copper for double-sided boards; trace width is then varied to accommodate any high current requirements.

Layers — Two-layer boards are the most common. Because of the way PCBs are manufactured, the number of copper layers will be multiples of two. For quick-turn board houses, usually only two or four layer boards are available. PCBs with more than two layers will always be more expensive and often take longer to manufacture.

Minimum hole size, number, and density of holes — Minimum hole size will rarely be an issue, but unusual board designs with high hole density or many different hole sizes may incur additional costs. Be sure to include vias when specifying minimum hole size. Some board houses may have a specific list of drill sizes they support. Note that you can often

just edit the drill file to reduce the number of different drill sizes.

Minimum trace width and clearance — Often these two numbers are close in value. Most board houses are comfortable with traces at least 0.010 inch in width, but 0.008 and 0.006 inch are often available, sometimes at a higher cost.

Minimum annular ring — A minimum amount of copper is required around each plated-through hole, since the PCB manufacturing process has variations. This may be expressed as the ratio of the pad size to hole size, but more commonly as the width of the ring.

Edge clearances — Holes, pads, and traces may not be too close to the edge of the board.

Board outline and copies — There may be options to route the outline of the board in other shapes than a rectangle, perhaps to accommodate a specific enclosure or optimize space. If multiple copies of a board are ordered, some board houses can *panelize* a PCB, duplicating it multiple times on a single larger PCB (with a reduction in cost per board). These copies may be cut apart at the board house or small tabs left to connect the boards so assembly of multiple boards can be done as a single unit.

Tin plating — Once the traces and pads have been etched and drilled, tin plating is usually applied to the exposed copper surfaces for good soldering.

Solder mask — This is a solder-resistant coating applied after tin plating to both sides of the board covering everything except the component mounting pads. It prevents molten solder from bridging the gaps between pads and traces. Solder mask is offered except by the quickest turn services. Green is the most common color, but other colors may be available.

Silkscreen — This is the ink layer, usually white, on top of the solder mask that lays out component shapes and designators and other symbols or text. A minimum line width may be specified — if not specified, try to avoid thin lines. All but the quickest turn services typically offer silk screening on one or both sides of the PCB.

6.4.5 PCB Design Elements

The schematic may not note the specific package of a part, nor the width or length of a connection. The PCB, being a physical object, is composed of specific instances of components (not just “a resistor,” but a “ $\frac{1}{4}$ W, axial-lead resistor mounted horizontally,” for example) plus traces — connections between pins of components with a specific width and separation from other conductors. Before discussing the process of layout, we briefly discuss the nature of components and connections in a PCB.

COMPONENTS

A component in a PCB design is very similar to its counterpart on the schematic. **Fig 6.21** shows the PCB footprint of an opto-interrupter, including graphics and connectivity information. The footprint of a component needs to specify what the footprint is like on all applicable copper layers, any necessary holes including non-electrical mounting holes or slots, and any additional graphics such as a silkscreen layer.

Take a common $\frac{1}{4}$ W axial-lead resistor as an example. This footprint will have two pins, each associated with a pad, corresponding to the resistor's two leads. This pad will appear on both the top and bottom layers of the board, but will also have a smaller pad associated with inner layers, should there be any. The hole's size will be based on the nominal lead diameter, plus some allowance (typically 0.006 inch). The pad size will be big enough to provide a reasonable annular ring, but is usually much larger so as to allow good quality soldering. The pins will be labeled in a way that corresponds to the pin numbering on the schematic symbol (even though for this component, there is no polarity). A silkscreen layer will be defined, usually a box within which the value or designator will appear. The silkscreen layer is particularly useful for indicating orientation of parts with polarity.

More complicated parts may require additional holes which will not be associated with a schematic pin (mounting hole, for example). These are usually added to the part differently than adding a hole with a pad — in this case, the hole is desired without any annular ring or plating. The silkscreen layer may be used to outline the part above and beyond what is obvious from the pads, for example, a TO-220 power transistor laying on its back, or the plastic packaging around the opto-interrupter in Fig 6.21.

As with schematic entry, it is not uncommon to have to modify or create a new PCB footprint. Good technical drawings are often available for electronic parts; when possible the user should verify these dimensions against a real part with an inexpensive dial caliper. It is also useful to print out the finished circuit board artwork at actual size and do a quick check against any new or unusual parts.

TRACES

Traces are the other main element of PCB construction — the copper pathways that connect components electrically. PCB traces are merely planar, flat wires — they have no magical properties when compared to an equivalent thickness of copper wire. At VHF/UHF/microwave frequencies and for high-speed digital signals, PCB traces act as transmission lines and these properties need to be accounted for, and can be used

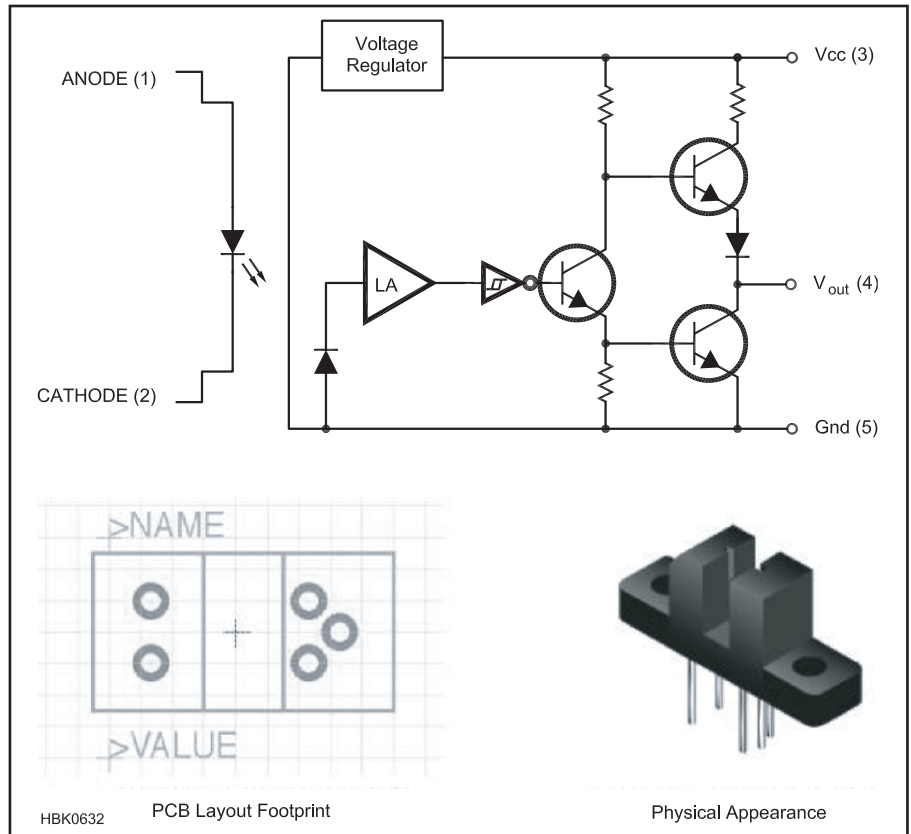

Fig 6.21 — The PCB footprint for a component, such as the opto-interrupter shown here, combines electrical connectivity as defined in the part's schematic and the part's physical attributes.

to advantage, in the design.

There are few constraints on traces apart from those such as minimum width and clearance imposed by the board house. They are created by chemical etching and can take arbitrary shapes. In fact, text and symbols may be created on copper layers which may be handy if a silkscreen is not included. Traces may be of any length, vary in width, incorporate turns or curves, and so on. However, most traces will be a uniform width their entire length (a width they will likely share with other traces carrying similar signals), make neat 45° or 90° corners, and on two-layer boards have a general preference for either horizontal travel on the component side or vertical travel on the solder side.

The same considerations when building a circuit in other methods applies to PCB design, including current capacity (width of trace, thickness of copper), voltage (clearance to other signals), noise (shielding, guarding, proximity to other signals), impedance of ground and power supplies, and so on.

6.4.6 PCB Layout

With a schematic and netlist ready and all of the PCB characteristics defined, the actual layout of the PCB can begin.

BOARD SIZE AND LAYERS

The first step in PCB layout is to create the board outline to contain not only the circuit itself and any additional features such as mounting holes. For prototype or one-off designs, the board is often best made a bit larger to allow more space between components for ease in testing and debugging. (Some low cost or freeware commercial PCB software imposes limits on board size and number of components.) The board outline may be provided in a default size that the user can modify, or the user may need to enter the outline from scratch.

As discussed above, rectangular board shapes are generally acceptable, but many board houses can accommodate more complex outlines, including curves. These outlines will be routed with reasonable accuracy and may save an assembly step if the PCB needs a cutout or odd shape to fit in a specific location.

While the software may not require deciding at the start how many layers the PCB will use, this is a decision the user should make as early as possible, since the jump from two to four or more will have a big impact on routing the traces as well as cost!

For your initial design, start with a two

layer board for a simple circuit that you have already built and tested. This will reduce the number of decisions you have to make and remove some of the unknowns from the design process.

COMPONENT PLACEMENT

Good component placement is more than half the battle of PCB layout. Poor placement will require complicated routing of traces and make assembly difficult, while good placement can lead to clean, easy-to-assemble designs.

The first elements placed should be mounting holes or other fixed location features. These are often placed using a special option selected from a palette of tools in the software rather than as parts from a library. Holes sufficient for a #4 or #6 screw are usually fine; be sure to leave room around them for the heads of the screws and nut driver or standoff below. These will be non-plated-through holes with no pad (though the board house may plate all the holes in a board, regardless).

Depending on the software and whether schematic capture was performed, the board outline may already contain the footprints of all the circuit components (sometimes stacked in a heap in one corner of the board) and the netlist will already be loaded. In this case, components may be placed by clicking and dragging the components to the desired location on the board. Most PCB programs have a “rat’s nest” option that draws a straight line for each netlist connection of a component, and this is a great aid in placement as the connections between components are apparent as the components are moved around. (See Fig 6.22) However, connections are shown to the nearest pin sharing that electrical connection; thus, components such as decoupling capacitors (which are often meant to be near a specific component) will show rats nest connections to the nearest power and ground pins and not the pins the designer may have intended. These will have to be manually edited.

The PCB layout software may offer *auto-placement* in which the components are initially arranged automatically. The beginner should certainly feel free to experiment and see how well this tool performs, but it is likely not useful for the majority of designs.

PCBs need not be arranged to precisely mimic the schematic, but it is appropriate to place components in a logical flow when possible so as to minimize the length of traces in the signal path. Sensitive components may need to be isolated or shielded from other components, and grounding and decoupling attended to, just as one would do with a point-to-point soldered version.

If the PCB is being designed “on-the-fly” or using an imported netlist, components may need to be selected and placed on the

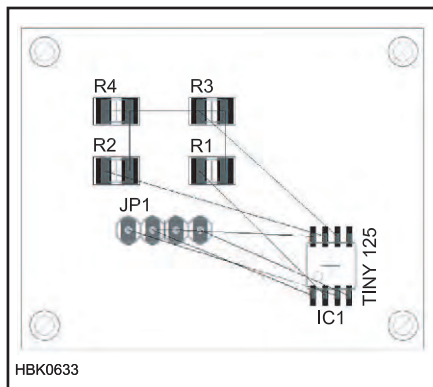

Fig 6.22 — The rat’s nest view during PCB layout shows the direct connections between component pins. This helps the designer with component placement and orientation for the most convenient routing.

board manually using the libraries of parts in the PCB software. Not all design software makes this task simple or fast — in particular, the description of component footprints may be confusing. The use of highly condensed industry standard or non-uniform naming conventions often means the user needs to browse through the component library to see the different types of components. Resistors, diodes and capacitors seem particularly prone to a propagation of perplexing options. One solution is to open an example PCB layout and see what library element that designer used for resistors, LEDs and so on. Here, the PCB layout software directed at hobbyists may be superior in that there are fewer options than in professional programs.

During placement the user will find that different orientations of components simplify routing (for example, minimizing the number of traces that have to cross over each other or reducing the trace lengths). Components are generally rotated in increments of 90°, although free rotation may be an option. The user is strongly urged to maintain the same orientation on like devices as much as possible. Mixing the position of pin 1 on IC packages, or placing capacitors, diodes, and LEDs with random orientation invites time consuming problems during assembly and testing that can be minimized by consistent, logical layout.

Placement and orientation of components can also affect how easily the final PCB can be assembled. Allow plenty of space for sockets, for example, and for ICs to be inserted and removed. Components with a mechanical interface such as potentiometers and switches should be positioned to allow access for adjustment. Any components such as connectors, switches, or indicators (eg, LEDs) should be positioned carefully, especially if they are

to protrude through a panel. Often this will involve having the component overhang the edge of the PCB. (Beware of the required clearance between copper traces and pads to the edge of the PCB.)

Components should include a silkscreen outline that shows the size of the whole component — for example, a transistor in a TO-220 package mounted flat against the PCB should have an outline that shows the mounting hole and the extent of the mounting tab. The user should also consider the clearance required by any additional hardware for mounting a component, such as nuts and bolts or heatsinks — including clearance for nut drivers or other assembly tools.

Take care to minimize the mechanical stress on the PCB, since this can result in cracked traces, separated pads, or other problems. Utilize mounting holes or tabs when possible for components such as connectors, switches, pots. Use two-layer boards with plated-through holes even if the design can be single-layer. Component leads soldered to plated-through holes produce much stronger mechanical connections than single-layer boards in which the soldered pad is held only by the bond between copper and laminate and is easily lifted if too much heat or stress is imposed.

When prototyping a new design, add a few unconnected pads on the circuit board for extra components (eg, a 16 pin DIP, 0.4 inch spaced pads for resistors and other discrete components). Include test points and ground connections. These can be simply pads to which cut off leads can be soldered to provide convenient test points for ground clips or to monitor signals.

Wires or cables can be directly soldered to the PCB, but this is inconvenient when swapping out boards, and is not very robust. Connectors are much preferred when possible

PCB Design and EMC

While amateur projects are rarely subject to electromagnetic compatibility (EMC) standards, using good engineering practices when designing the board still reduces unwanted RF emissions and susceptibility to RF interference. For example, proper layout of a microprocessor circuit’s power and ground traces can reduce RF emissions substantially. Proper application of ground planes, bypass capacitors and especially shield connections can have a dramatic effect on RFI performance. (See the **RF Interference** chapter for more on RFI.) A good reference on RFI and PCB design is *Electromagnetic Compatibility Engineering*, by Henry Ott, WA2IRQ.

and often provide strain relief for the wire or cable. However, if a wire is directly soldered to the PCB, the user should consider adding an unplated hole nearby just large enough to pass the wire including insulation. The wire can then be passed from the solder side through the unplated hole, then soldered into the regular plated-through hole. This provides some measure of strain relief which can be augmented with a dollop of glue if desired.

ROUTING TRACES

After placing components, mounting holes and other fixed location features that limit component or trace placement, traces can be *routed*. That is, to complete all the connections between pins without producing short circuits.

Most PCB design programs allow components and traces to be placed on a regular grid, similarly to drawing programs. There may be two grids — a visible coarse pitch grid, and a “snap” fine pitch grid, to which components and other objects will be aligned when placed. It is good practice to use a 0.1 or 0.050 inch grid for component placement and to route traces on a 0.025 inch grid. While the “snap to grid” feature can usually be turned off to allow fine adjustment of placement, a board routed on a grid is likely to look cleaner and be easier to route.

The trace starts at a component pin and wends its way to any other pins to which it should be connected. Traces should start and end at the center of pads, not at the edge of a pad, so that the connection is properly recorded in the program’s database. If a netlist has been loaded, most PCB software will display a rat’s nest line showing a direct connection between pads. Once the route is completed, the rat’s nest line for that connection disappears. The rat’s nest line is rarely the desired path for the trace and often not the correct destination. For example, when routing power traces, the user should use good design sense rather than blindly constructing a Byzantine route linking pins together in random order. For this reason, routing the power and ground early is a good practice.

High speed, high frequency, and low noise circuits will require additional care in routing. In general, traces connecting digital circuits such as microprocessors and memories should not cross or be in close proximity to traces carrying analog or RF signals. Please refer to the **RF Techniques and Construction Techniques** chapters of this *Handbook*, and the references listed at the end of this section.

Manual routing is a core skill of PCB design, whether or not auto-routing is used. The process is generally made as simple as possible in the software, since routing will take up most of the PCB design time. A trace will be routed on the copper layer currently selected. For a single-sided board, there is only

Fig 6.23 — This example shows traces on the side of the PCB for horizontal routing. Traces are routed between pins of ICs. The smaller pads are for vias to a different layer of the PCB.

one layer for routing; for a two-layer board the component side and solder side can have traces; and for multi-layer boards additional inner layers can have traces. Often a single keystroke can change the active copper layer (sometimes automatically inserting a via if a route is in progress). The trace is drawn in straight segments and ends at the destination pin. When routing, 90° corners are normally avoided — a pair of 45° angles is the norm. **Fig 6.23** shows some sample traces.

It is good practice on a double-sided board to have one side of the board laid out with mostly horizontal traces, and the other side laid out with mostly vertical traces. A trace that needs to travel primarily vertically can do so on the side with vertical traces and use a via to move to the other side to complete the horizontal part of the route.

It is easiest during testing and debugging to route most traces on the bottom (solder) side of the board — traces on the component side often run under ICs or other components, making them hard to access or follow. It is often much clearer to connect adjacent IC or connector pins by routing a trace that leaves one pad, moves away from the IC or connector, then heads back in to the adjacent pad to connect. This makes it clear the connection on the assembled board is not a solder bridge, which a direct connection between the two pads would resemble.

It may be the case that no amount of vias or winding paths can complete a route. The one remaining tool for the PCB designer is a jumper — a wire added as a component during assembly just for the purpose of making a connection between two points on the board. Jumpers are most often required for single-sided boards; when the “jump” is rather small, uninsulated wire can be used. Jumpers are usually straight lines, and can be horizontal or vertical. Professional production PCBs use machine-insertable zero-ohm resistors as jumpers. Jumpers on double-sided boards are usually not viewed very favorably, but this is an aesthetic and efficiency issue, not a functional one.

Multi-layer boards clearly offer additional routing options, but again having some dominant routing direction (vertical or horizontal) on each layer is recommended, since mixing directions tends to cause routing problems. However, it is not uncommon to devote one or two inner layers to power and ground, rather than merely be additional layers for routing signals. This allows power and ground to be routed with minimal resistance and exposes the traces carrying interesting signals on the component and solder sides where they are available to be probed or modified. It is very difficult to modify traces on inner layers, needless to say!

Before routing too many traces, it is help-

ful to run the *Design Rule Check (DRC)* on the board. (See the section on Design Rule Checking below.) Applied early and often, DRC can identify areas of concern when it is easiest to correct. For example, a given trace width may provide insufficient clearance when passing between two IC pads.

Some PCB design packages offer *auto-router* capability in which the software uses the component and connectivity data of the netlist and attempts to route the traces automatically. There are some circumstances when they save time, but view these tools with some caution. Auto-routers are good at solving the routing puzzle for a given board, but merely connecting all the pins correctly does not produce a good PCB design. Traces carrying critical signals may take “noisy” routes; components that should have short, low resistance connections to each other may have lengthy traces instead, and so on. More sophisticated auto-routers can be provided with extensive lists of “hints” to minimize these problems. For the beginner, the time spent conveying this design information to the auto-router is likely better spent manually routing the traces.

If an auto-router is used, at a minimum, critical connections should be first routed manually. These include sensitive signals, connections whose length should be minimized, and often power and ground (for both RFI and trace width reasons). Better still is to develop a sense of what a good layout looks like (which will come with practice and analyzing well designed boards), and learn at what stage the auto-router can be “turned loose” to finish the routing puzzle.

TRACE WIDTH AND SPACING

All traces will have some width — the width may be the default width, the last width selected, or a width provided from data in the netlist. It may be tempting to route all but the power traces using the smallest trace width available from the board house (0.008 inch or smaller), since this allows the highest density of traces and eases routing. A better design practice is to use wider traces to avoid hard-to-detect trace cracking and improve board reliability. The more common traces 0.012 inch wide can be run in parallel on a 0.025 inch grid and can pass between many pads on 0.1 inch centers. Even wider traces will make the board easier to produce “in house,” though the exact process used (CNC routing, chemical etching, etc) will limit the resolution. Note that it is possible to “neck down” traces where they pass between IC or connector pads — that is, the regular, thick trace is run up close to the narrow gap between the pads, passes between the pads with a narrow width, then expands back to the original width. There is little reason to use traces wider

Table 6.3

Maximum Current for 10 °C Rise, 1 oz/ft² Copper

Based on IPC-2221 standards (not an official IPC table)

Trace Width (inches)	Max. Current (External Trace) (A)	Max. Current (Internal Trace) (A)	Resistance (ohms/inch)
0.004	0.46	0.23	0.13
0.008	0.75	0.38	0.063
0.012	1.0	0.51	0.042
0.020	1.5	0.73	0.025
0.040	2.4	1.2	0.013
0.050	2.8	1.4	0.010
0.100	4.7	2.4	0.0051
0.200	7.8	3.9	0.0025
0.400	13	6.4	0.0013

IPC-2221 Generic Standard on Printed Circuit Design, Institute for Interconnecting and Packaging Electronic Circuits, www.ipc.org

than 0.030 inch or so for most signals (see **Table 6.3**) but power and ground trace widths should be appropriate for the current.

All traces have resistance, and this resistance is a function of the cross section of the trace (width times thickness) and the length. This resistance will convert electrical power to heat. If the heat exceeds a relatively high threshold, the trace becomes a fairly expensive and difficult-to-replace fuse. The trace width should be selected such that for the worst case expected current, heat rise is limited to some threshold, often 10 °C. In practice, power traces (especially grounds) are often made as wide as practical to reduce resistance, and they greatly exceed the width required by heat rise limits alone.

Table 6.3 summarizes maximum currents for external (component and solder side) and internal traces for some common trace widths. Internal traces (on inner layers of multi-layer boards) can carry only about half the current of external traces for the same width since the internal layers do not dissipate heat to the ambient air like external traces can. (Note that trace widths are also sometimes expressed in “mils.” 1 mil = 0.001 inch; it is shorthand for “milli-inch”, not millimeter!)

There is no upper bound on the effective trace width. It is common to have large areas of the board left as solid copper. These *copper fill* areas can serve as grounds, heat sinks, or may just simplify board production (especially homemade boards). It is not a good idea to place a component hole in the middle of a copper fill — the copper is a very efficient heat sink when soldering. Instead, a “wagon wheel” pattern known as a thermal relief is placed (sometimes automatically) around the solder pad, providing good electrical connectivity but reducing the heat sinking. Often, copper fill areas can be specified using a polygon and the fill will automatically flow around pads and traces in that area, but can lead to isolated pads of copper.

In practice, most boards will have only two or perhaps three different trace widths; narrow widths for signals, and a thicker width for power (usually with a healthy margin).

One final note on trace width — vias are typically one size (ie, small), but multiple vias can be used to create low resistance connections between layers. Spacing the vias so their pads do not touch works well; the pads are then shorted on both top and bottom layers.

Voltage also figures into the routing equation, but instead of trace width, higher voltages should be met with an increased clearance between the trace and other copper. The IPC-2221 standard calls for a clearance of 0.024 inch for traces carrying 31-150 V (peak) and 0.050 inch for traces carrying 151-300 V (peak); these are external traces with no coating. (With the appropriate polymer solder mask coating, the clearances are 0.006 inch for 31-100 V and 0.016 inch for 101-300 V. Internal traces also have reduced clearance requirements.) Fully addressing the safety (and regulatory) issues around high voltage wiring is outside the scope of this brief review, however, and the reader is urged to consult UL or IPC standards.

SILKSCREEN AND SOLDER MASK

The silkscreen (or “silk”) layer contains the text and graphics that will be silkscreened on the top of the board, shown in **Fig 6.24**. Components will generally have elements on the silkscreen layer that will automatically appear, such as designators and values, but other elements must be created and placed manually. Common silkscreen elements include: Circuit name, date, version, designer (and call sign), company name, power requirements (voltage, current, and fusing), labels for connections (eg, “Mic input”), warnings and cautions, labels for adjustments and switches. A solid white rectangle on the silkscreen layer can provide a good space to write a serial number or test information.

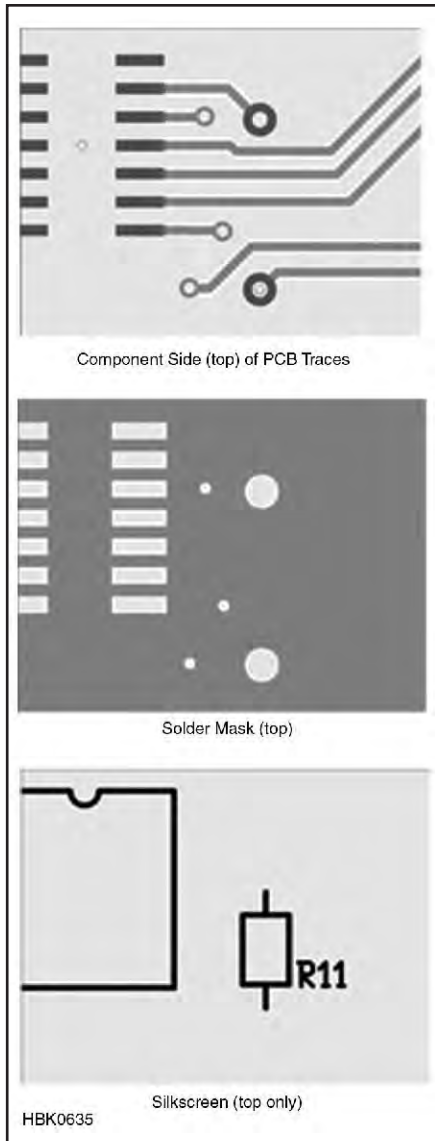

Fig 6.24 — The relationship between the layout's top copper layer with traces and pads, the solder mask that covers the copper (a separate solder mask is required for the top and bottom layers of the PCB) and the silkscreen information that shows component outlines and designators.

The board house will specify the minimum width for silkscreen lines, including the width of text. Text and graphics can be placed anywhere on the solder mask, but not on solder pads and holes.

Many quick-turn board houses omit the silkscreen for prototype boards. As noted earlier, many of the text elements above can be placed on the external copper layers. Component outlines are not possible since the resulting copper would short out traces, but component polarization can be noted with symbols such as a hand-made "+" made from two short traces, or a "1" from a single short trace. (Note that some component footprints

HBK0243

Fig 6.25 — A completed microprocessor board as it is seen in a typical PCB layout editor (*Eagle*). Solder mask layers are omitted for visibility. Traces that appear to cross each other are on different sides of the board and are in different colors in the layout software. The silkscreen layer is shown in white.

follow a practice of marking the pad for pin 1 with a square pad while others are round or oval.)

The solder mask is a polymer coating that is screened onto the board before the silkscreen graphics. As shown in Fig 6.24, it covers the entire surface of the board except for pads and vias. Solder masking prevents solder bridges between pads and from pads to traces during assembly and is particularly important for production processes that use wave soldering or reflow soldering. There is one solder mask layer for the top layer and another for the bottom layer. Internal layers do not need a solder mask. Solder masking may be omitted for a prototype board, but care must be taken to keep solder from creating unwanted bridges or short circuits.

During the PCB layout process, solder mask layers are generally not shown because they do not affect connectivity. Fig 6.25 shows a typical PCB as it appears when the PCB layout process is complete.

DESIGN RULE CHECK

If a netlist has been provided from the schematic capture program, a *design rule check (DRC)* can be made of the board's layout. The PCB software will apply a list of rules to the PCB, verifying that all the connections in the netlist are made, that there is sufficient clearance between all the traces, and so on. These rules can be modified based on the specific board house requirements. As stated above, it is useful to run the DRC even before all the traces have been routed — this can identify clearance or other issues that might require substantial re-routing or a different approach.

If the user has waited until all the routing is done before running the DRC, the list of violations can be daunting. However, it is

often the case that many if not all of the violations represent issues that may prevent the board from operating as wished. Whenever possible, all DRC violations should be rectified before fabrication.

6.4.7 Preparation for Fabrication

LAYOUT REVIEW

Once the board has passed DRC, the electrical connectivity and basic requirements for manufacturability have likely been satisfied. However, the design may benefit from an additional review pass. Turn off all the layers but one copper layer and examine the traces — often simplifications in routing will be apparent without the distractions of the other copper layers. For example, a trace can be moved to avoid going between two closely spaced pins. Densely spaced traces could be spaced farther apart. There may be opportunities to reduce vias by routing traces primarily on one layer even if that now means both vertical and horizontal travel. Repeat the exercise for all the copper layers.

Review the mechanical aspects of the board as well, including the proximity of traces to hardware. If your prototype PCB does not have a solder mask, traces that run underneath components such as crystals in a conductive case or too close to mounting hardware can form a short circuit. An insulator must be provided or the trace can be re-routed.

GENERATING OUTPUT FILES

Once the PCB design is complete, the complete set of design description files can be generated for producing the PCB. These are:

Copper layers — One file per copper layer. These are known as *Gerber files* and were

text files of commands originally intended to drive a *photoplotter*. Gerber was the primary manufacturer of photoplotters, machines that moved a light source of variable width (apertures) from one location to another to draw patterns on photographic film. While photoplotters have been replaced by digital technology, the format used by Gerber has been standardized as RS-274X and is universally used except by PCB software tied to a specific manufacturer. RS-274X is related to RS-274D (“G-Code”) used by machinists to program CNC machinery but is an *additive* description (essentially saying “put copper here”), rather than describing the movements of a tool to remove material. A program is thus required to translate between Gerber and G-Code if a CNC machine is used to make a PCB by mechanically removing copper.

Drill file — The file containing the coordinates and drill sizes for all the holes, plated or not. Also called the *NC* or *Excellon* file, some

board houses may require a specific format for the coordinates, but these are usually available to be set as options in the PCB program. There is only one drill file for a PCB, since the holes are drilled from one side. (Exotic options such as buried vias will require more information.) Like RS-274X apertures, the drill file will generally contain a drill table.

Silkscreen — Also in RS-274 format. Some board houses can provide silkscreen on both sides of the board, which will require two files.

Solder mask — The solder mask file is used by the board house to create the solder mask. One file per side is required.

A Gerber preview program such as *Gerby* (gerbv.gpleda.org, open source, *Linux*, Mac OS X) or *GC-Prevue* (www.graphicode.com, *Windows*) can be used to review the trace layout Gerber files. This is a good test — the board house will make the boards from the Gerber files, not the PCB design file. Gerber

previewers can import the copper layers, silkscreen and drill files to verify they correspond and make sense.

Any of the layers can usually be printed out within the PCB program (and/or Gerber preview program) for reference and further inspection.

In addition to files for PCB production, PCB layout programs can also generate assembly diagrams, and in some cases can provide 3D views of what the assembled board will look like. These can be useful for documentation as well as verification of mechanical issues such as height clearance.

Sending the files to the PCB manufacturer or board house and ordering PCBs is explained on the manufacturing website or a customer service representative can walk you through the process. Some firms accept sets of files on CD-ROM and may also offer a design review service for first-time customers or on a fee basis.

Power Sources

Our transceivers, amplifiers, accessories, computers and test equipment all require power to operate. This chapter illustrates the various techniques, components and systems used to provide power at the voltage and current levels our equipment needs. Topics range from basic transformers, rectifiers and filters to linear voltage regulation, switch-mode power conversion, high voltage techniques and batteries. Material on switchmode conversion was contributed by Rudy Severns, N6LF and Chuck Mullett, KR6R. A new section on batteries was contributed by Isidor Buchmann from his book *Batteries in a Portable World*. Alan Applegate, KØBG contributed the section on selecting batteries for mobile use.

Acknowledging the changing nature of amateur power requirements, the title of this chapter has updated from the traditional *Power Supplies* to *Power Sources*. More mobile and portable operation relies on power from batteries, for example. Hybrids of ac and dc power sources are becoming more common, blurring what has traditionally been known as a “power supply.” In response, the scope of this chapter now includes more of the changing power environment in the amateur station. (Generators are covered in the Portable Installations section of the chapter on **Building a Station**.)

7.1 Power Processing

Fig 7.1 illustrates the concept of a power processing unit inserted between the energy source and the electronic equipment or load. The *power processor* is often referred to as the *power supply*. That’s a bit misleading in that the energy “supply” actually comes from some external source (battery, utility power and so forth), which is then converted to useful forms by the power processor. Be that as it may, in practice the terms “power supply” and “power processor” are used interchangeably.

The real world is even more arbitrary. Power processors are frequently referred to as *power converters* or simply as *converters*, and we will see other terms used later in this chapter. It is usually obvious from the context of the discussion what is meant and the

glossary at the end of this chapter gives some additional information.

Power conversion schemes can take the form of: ac-to-ac (usually written ac-ac), ac-dc, dc-ac and dc-dc. Examples of these schemes are given in **Fig 7.2**. Specific names may be given to each scheme: ac-dc => rectifier, dc-dc => converter and dc-ac => inverter.

These are the generally recognized terms but you will see exceptions.

Power conversion normally includes voltage and current regulation functions. For example, the voltage of a vehicle battery may vary from 14 V when being charged down to 10 V or less when discharged. A converter and regulator are required to maintain adequate

voltage to mobile equipment at both over- and under-voltage conditions. Commercial utility power may vary from 90 to 270 V ac depending on where you are in the world. AC power converters are frequently required to handle that entire voltage range while still providing tightly regulated dc power.

7.2 AC-AC Power Conversion

In most US residences, three wires are brought in from the outside electrical-service mains to the house distribution panel. In this three-wire system, one wire is neutral and should be at earth ground potential. (See the **Safety** chapter for information on electrical safety.) The neutral connection to a ground rod or electrode is usually made at the distribution panel. The voltage between the other two wires is 60-Hz ac with a potential difference of approximately 240 V RMS. Half of this voltage appears between each of these wires and the neutral, as indicated in **Fig 7.3A**. In systems of this type, the 120 V household loads are divided at the breaker panel as evenly as possible between the two sides of the power mains. Heavy appliances such as electric stoves, water heaters, central air conditioners and so forth, are designed for 240 V operation and are connected across the two ungrounded wires.

Both hot wires for 240 V circuits and the single hot wire for 120 V circuits should be protected by either a fuse or breaker. A fuse or breaker or any kind of switch should *never* be used in the neutral wire. Opening the neutral wire does not disconnect the equipment from an active or “hot” line, possibly creating a potential shock hazard between that line and earth ground.

Another word of caution should be given at this point. Since one side of the ac line is grounded (through the green or bare wire — the standard household wiring color code) to earth, all communications equipment should be reliably connected to the ac-line ground through a heavy ground braid or bus wire of #14 or heavier-gauge wire. This wire must be a separate conductor. You must not use the power-wiring neutral conductor for this safety ground. (A properly-wired 120 V outlet with a ground terminal uses one wire for the ac hot connection, one wire for the ac neutral connection and a third wire for the safety ground connection.) This provides a measure of safety for the operator in the event of accidental short or leakage of one side of the ac line to the chassis.

Remember that the antenna system is frequently bypassed to the chassis via an RF choke or tuned circuit, which could make the antenna electrically “live” with respect

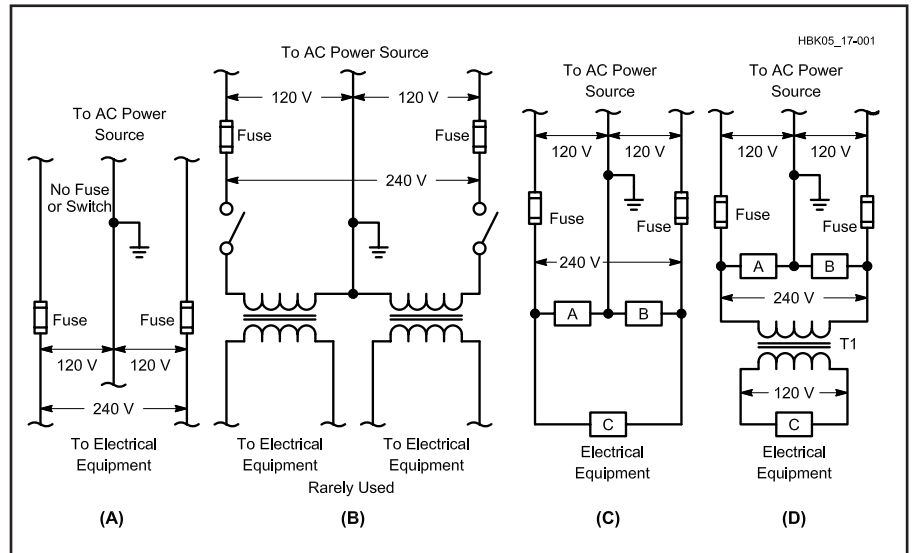

Fig 7.3 — Three-wire power-line circuits. At A, normal three-wire-line termination. No fuse should be used in the grounded (neutral) line. The ground symbol is the power company’s ground, not yours! Do not connect anything other than power return wiring, including the equipment chassis, to the power neutral wire. At B, the “hot” lines each have a switch, but a switch in the neutral line would not remove voltage from either side of the line and should never be used. At C, connections for both 120 and 240 V transformers. At D, operating a 120 V plate transformer from the 240 V line to avoid light blinking. T1 is a 2:1 step-down transformer.

to the earth ground and create a potentially lethal shock hazard. A *ground fault circuit interrupter* (GFCI or GFI) is also desirable for safety reasons, and should be a part of the shack’s electrical power wiring.

7.2.1 Fuses and Circuit Breakers

All transformer primary circuits should be fused properly and multiple secondary outputs should also be individually fused. To determine the approximate current rating of the fuse or circuit breaker on the line side of a power supply it is necessary to determine the total load power. This can be done by multiplying each current (in amperes) being drawn by the load or appliance, by the voltage at which the current is being drawn. In the case of linear regulated power supplies, this voltage has to be the voltage appearing at the output of the rectifiers before being applied to the regulator stage. Include the current drawn by bleeder

resistors and voltage dividers. Also include filament power if the transformer is supplying vacuum tube filaments. The National Electrical Code (NEC) also specifies maximum fuse ratings based on the wire sizes used in the transformer and connections.

After multiplying the various voltages and currents, add the individual products. This is the total power drawn from the line by the supply. Then divide this power by the line voltage and add 10 to 30% to account for the inefficiency of the power supply itself. Use a fuse or circuit breaker with the nearest larger current rating. Remember that the charging of filter capacitors can create large surges of current when the supply is turned on. If fuse blowing or breaker tripping at turn on is a problem, use slow-blow fuses, which allow for high initial surge currents.

For low-power semiconductor circuits, use fast-blow fuses. As the name implies, such fuses open very quickly once the current exceeds the fuse rating by more than 10%.

7.3 Power Transformers

Numerous factors are considered to match a transformer to its intended use. Some of these parameters are:

1. Output voltage and current (volt-ampere rating).
2. Power source voltage and frequency.
3. Ambient temperature.
4. Duty cycle and temperature rise of the transformer at rated load.
5. Mechanical considerations like weight, shape and mounting.

7.3.1 Volt-Ampere Rating

In alternating-current equipment, the term *volt-ampere (VA)* is often used rather than the term watt. This is because ac components must handle reactive power as well as real power. If this is confusing, consider a capacitor connected directly across the secondary of a transformer. The capacitor appears as a reactance that permits current to flow, just as if the load were a resistor. The current is at a 90° phase angle, however. If we assume a perfect capacitor, there will be no heating of the capacitor, so no real power (watts) will be delivered by the transformer. The transformer must still be capable of supplying the voltage, and be able to handle the current required by the reactive load. The current in the transformer windings will heat the windings as a result of the I^2R losses in the winding resistances. The product of the voltage and current in the winding is referred to as “volt-amperes,” since “watts” is reserved for the real, or dissipated, power in the load. The volt-ampere rating will always be equal to, or greater than, the power actually being drawn by the load.

The number of volt-amperes delivered by a transformer depends not only upon the dc load requirements, but also upon the type of dc output filter used (capacitor or choke input), and the type of rectifier used (full-wave center tap or full-wave bridge). With a capacitive-input filter, the heating effect in the secondary is higher because of the high peak-to-average current ratio. The volt-amperes handled by the transformer may be several times the power delivered to the load. The primary winding volt-amperes will be somewhat higher because of transformer losses. This point is treated in more detail in the section on ac-dc conversion. (See the **Electrical Fundamentals** chapter for more information on transformers and reactive power.)

7.3.2 Source Voltage and Frequency

A transformer operates by producing a magnetic field in its core and windings. The intensity of this field varies directly with the instantaneous voltage applied to the

transformer primary winding. These variations, coupled to the secondary windings, produce the desired output voltage. Since the transformer appears to the source as an inductance in parallel with the (equivalent) load, the primary will appear as a short circuit if dc is applied to it. The unloaded inductance of the primary (also known as the *magnetizing inductance*) must be high enough so as not to draw an excess amount of input current at the design line frequency (normally 60 Hz in the US). This is achieved by providing a combination of sufficient turns on the primary and enough magnetic core material so that the core does not saturate during each half-cycle.

The voltage across a winding is directly related to the time rate of change of magnetic flux in the core. This relationship is expressed mathematically by $V = N d\Phi/dt$ as described in the section on Inductance in the **Electrical Fundamentals** chapter. The total flux in turn is expressed by $\Phi = A_c B$, where A_c is the cross-sectional area of the core and B is the flux density.

The maximum value for *flux density* (the magnetic field strength produced in the core) is limited to some percentage (< 80% for example) of the maximum flux density that the core material can stand without saturating, since in saturation the core becomes ineffective and causes the inductance of the primary to plummet to a very low level and input current to rise rapidly. Saturation causes high primary currents and extreme heating in the primary windings.

At a given voltage, 50 Hz ac creates more flux in an inductor or transformer core because the longer time period per half-cycle results in more flux and higher magnetizing current than the same transformer when excited by same 60-Hz voltage. For this reason, transformers and other electromagnetic equipment designed for 60-Hz systems must not be used on 50-Hz power systems unless specifically designed to handle the lower line frequency.

7.3.3 How to Evaluate an Unmarked Power Transformer

Hams who regularly visit hamfests frequently develop a junk box filled with used and unmarked transformers. Over time, transformer labels or markings on the coil wrappings may come off or be obscured. There is a good possibility that the transformer is still useable, but the problem is to determine what voltages and currents the transformer can supply. First consider the possibility that you may have an audio transformer or other impedance-matching device rather than a power transformer. If you aren't sure, don't connect it to ac power!

If the transformer has color-coded leads, you are in luck. There is a standard for transformer lead color-coding, as is given in the **Component Data and References** chapter. Where two colors are listed, the first one is the main color of the insulation; the second is the color of the stripe.

Fig 7.4 — Use a test fixture like this to test unknown transformers. Don't omit the isolation transformer, and be sure to insulate all connections before you plug into the ac mains.

Check the transformer windings with an ohmmeter to determine that there are no shorted (or open) windings. In particular, check for continuity between any winding and the core. If you find that a winding has been shorted to the core, do not use the transformer! The primary winding usually has a resistance higher than a filament winding and lower than a high-voltage winding.

Fig 7.4 shows that a convenient way to test the transformer is to rig a pair of test leads to an electrical plug with a 25 W household light bulb in series to limit current to safe (for the transformer) levels. For safety reasons use an isolation transformer and be sure to insulate all connections before you plug into the ac mains. Switch off the power while making or changing any connections. You can be electrocuted if the voltmeter leads or meter insulation are not rated for the transformer output voltage! If in doubt, connect the meter with the circuit turned off, then apply power while you are not in contact with the circuit. *Be careful! You are dealing with hazardous voltages!*

Connect the test leads to each winding separately. The filament/heater windings will cause the bulb to light to full brilliance because a filament winding has a very low impedance and almost all the input voltage will be across the series bulb. The high-voltage winding will cause the bulb to be extremely dim or to show no light at all because it will have a very high impedance, and the primary winding will probably cause a small glow. The bulb glows even with the secondary windings open-circuited because of the small magnetizing current in the transformer primary.

When the isolation transformer output is connected to what you think is the primary winding, measure the voltages at the low-voltage windings with an ac voltmeter. If you find voltages close to 6 V ac or 5 V ac, you know that you have identified the primary and the filament windings. Label the primary and low voltage windings.

Even with the light bulb, a transformer can be damaged by connecting ac mains power to a low-voltage or filament winding. In such a case the insulation could break down in a

primary or high-voltage winding because of the high turns ratio stepping up the voltage well beyond the transformer ratings.

Connect the voltmeter to the high-voltage windings. Remember that the old TV transformers will typically supply as much as 800 V_{pk} or so across the winding, so make sure that your meter can withstand these potentials without damage and that you use the voltmeter safely.

Divide 6.3 (or 5) by the voltage you measured across the 6.3 V (or 5 V) winding in this test setup. This gives a multiplier that you can use to determine the actual no-load voltage rating of the high-voltage secondary. Simply multiply the ac voltage measured across the high-voltage winding by the multiplier.

The current rating of the windings can be determined by loading each winding with the primary connected directly (no bulb) to the ac line. Using power resistors, increase loading on each winding until its voltage drops by about 10% from the no-load figure. The current drawn by the resistors is the approximate winding load-current rating.

7.4 AC-DC Power Conversion

One of the most common power supply functions is the conversion of ac power to dc, or *rectification*. The output from the rectifier will be a combination of dc, which is the desired component, and ac *ripple* superimposed on the dc. This is an undesired but inescapable component. Since most loads cannot tolerate more than a small amount of ripple on the dc voltage, some form of filter is required. The result is that ac-dc power conversion is performed with a rectifier-filter combination as shown in **Fig 7.5**.

As we will see in the rectifier circuit examples given in the next sections, sometimes the rectifier and filter functions will be separated into two distinct parts but very often the two will be integrated. This is particularly true for voltage and current multipliers as described in the sections on multipliers later in the chapter. Even when it appears that the rectifier and filter are separate elements, there will still be a strong interaction where the design and behavior of each part depends heavily on the other. For example the current waveforms in the rectifiers and the input source are functions of the load and filter characteristics. In turn the voltage waveform applied to the filter depends on the rectifier circuit and the input source voltages. To simplify the discussion

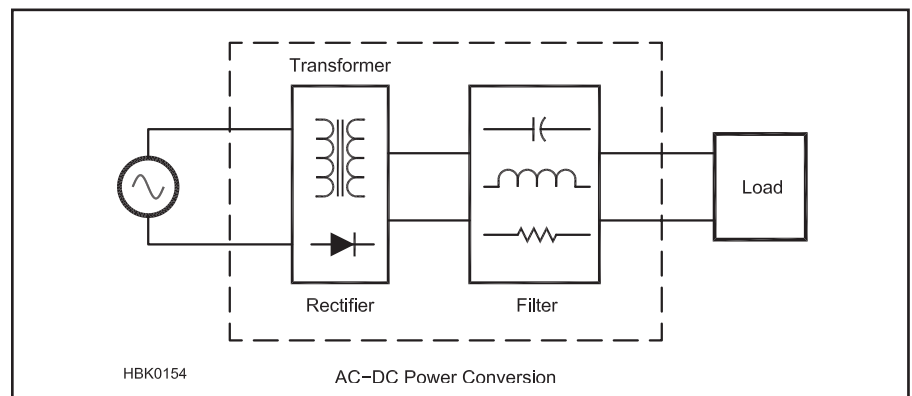

Fig 7.5 — Ac-dc power conversion with a rectifier and a filter.

we will treat the rectifier connections and the filters separately but always keeping in mind their interdependence.

The following rectifier-filter examples assume a conventional 60 Hz ac sine wave source, but these circuits are frequently used in switching converters at much higher frequencies and with square wave or quasi-square wave voltage and current waveforms. The component values may be different but

the basic behavior will be very similar.

There are many different rectifier circuits or “connections” that may be used depending on the application. The following discussion provides an overview of some of the more common ones. The circuit diagrams use the symbol for a semiconductor diode, but the same circuits can be used with the older types of rectifiers that may be encountered in older equipment.

For each circuit we will show the voltage and current waveforms in the circuit for resistive, capacitive and inductive loads. The inductive and capacitive loads represent commonly used filters. We will be interested in the peak and average voltages as well as the RMS currents.

7.4.1 Half-Wave Rectifier

Fig 7.6 shows several examples of the half-wave rectifier circuit. It begins with a simple transformer with a resistive load (Fig 7.6A)

and goes on to show how the output voltage and transformer current varies when a diode and filter elements are added.

Without the diode (Fig 7.6A) the output voltage (V_R) and current are just sine waves, and the RMS current in the transformer windings will be the same as the load (R) current.

Next, add a rectifier diode in series with the load (Fig 7.6B). During one half of the ac cycle, the rectifier conducts and there is current through the rectifier to the load. During the other half cycle, the rectifier is reverse-biased and there is no current (indicated by the

broken line in Fig 7.6B) in R. The output voltage is pulsating dc, which is a combination of two components: an average dc value of $0.45 E_{RMS}$ (the voltage read by a dc voltmeter) and line-frequency ac ripple. The transformer secondary winding current is also pulsating dc. The power delivered to R is now $\frac{1}{2}$ that for Fig 7.6A but the secondary RMS winding current in Fig 7.6B is still 0.707 times what it was in Fig 7.6A. For the same winding resistance, the winding loss, in proportion to the output power, is twice what it was in Fig 7.6A. This is an intrinsic limitation of the half-wave rectifier circuit — the RMS winding current is larger in proportion to the load power. In addition, the dc component of the secondary winding current may bias the transformer core toward saturation and increased core loss.

A filter can be used to smooth out these variations and provide a higher average dc voltage from the circuit. Because the frequency of the pulses (the ripple frequency) is low (one pulse per cycle), considerable filtering is required to provide adequately smooth dc output. For this reason the circuit is usually limited to applications where the required current is small. Parts C, D and E in Fig 7.6 show some possible capacitive and inductive filters.

As shown in Fig 7.6C and D, when a capacitor is used for filtering the output dc voltage will approach

$$V_{pk} = \sqrt{2} \times E_{RMS} \quad (1)$$

and the larger we make the filter capacitance, the smaller the ripple will be.

Unfortunately, as we make the filter capacitance larger, the diode, capacitor and transformer winding currents all become high-amplitude narrow pulses which will have a very high RMS value in proportion to the power level. These current pulses are also transmitted to the input line and inject currents at harmonics of the line frequency into the power source, which may result in interference to other equipment. Narrow high-amplitude current pulses are characteristic of capacitive-input filters in all rectifier connections when driven from voltage sources.

As shown in Fig 7.6E, it is possible to use an inductive filter instead, but a second diode (D_2 , sometimes called a *free-wheeling diode*) should be used. Without D_2 the output voltage will get smaller as we increase the size of L to get better filtering, and the output voltage will vary greatly with load. By adding D_2 we are free to make L large for small output ripple but still have reasonable voltage regulation. Currents in D_1 and the winding will be approximately square waves, as indicated. This will reduce the line harmonic currents injected into the source but there will still be some.

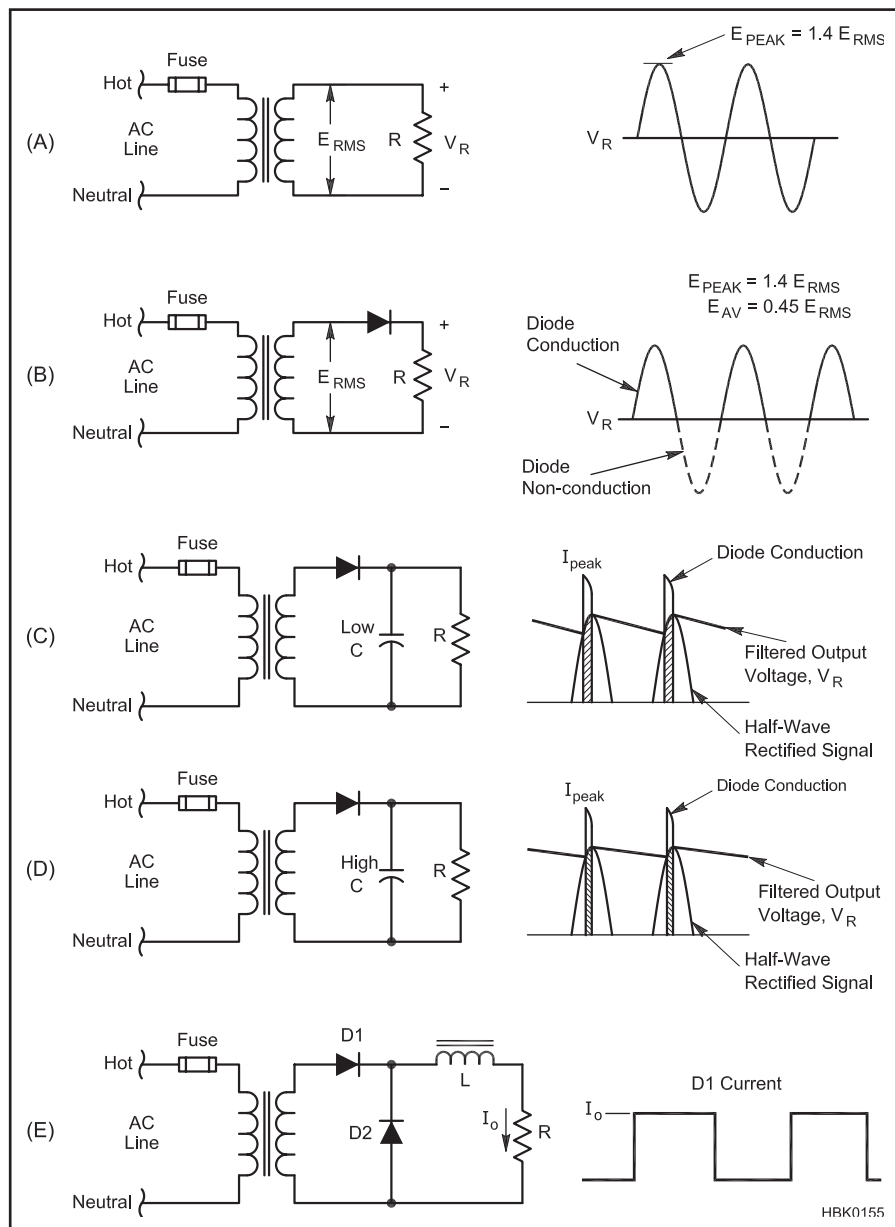

Fig 7.6 — Half-wave rectifier circuits. A illustrates the voltage waveform at the output without a rectifier. B represents the basic half-wave rectifier and the output waveform. C and D illustrate the impact of small and large filter capacitors on the output voltage and input current waveforms. E shows the effect of using an inductor filter with the half-wave rectifier. Note the addition of the shunt diode (D_2) when using inductive filters with this rectifier connection.

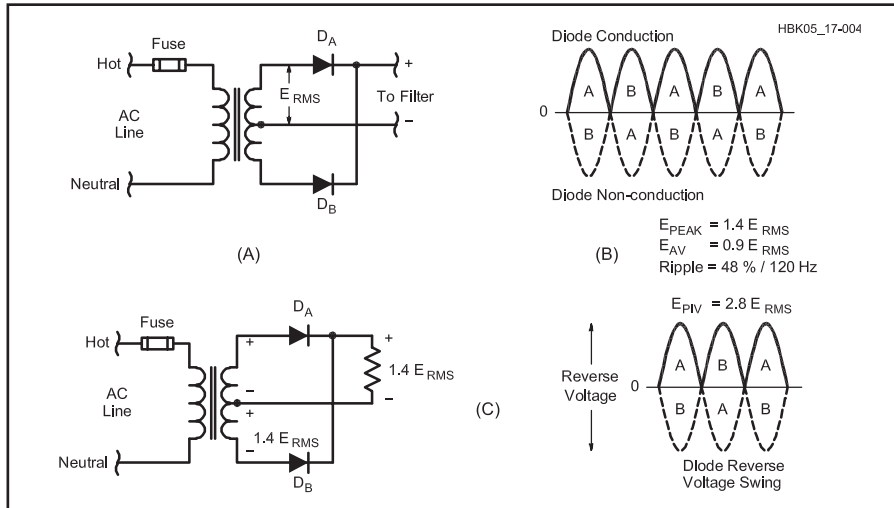

Fig 7.7 — Full-wave center-tap rectifier circuits. A illustrates the basic circuit. Diode conduction is shown at B with diodes A and B alternately conducting. The peak inverse voltage for each diode is $2.8 E_{RMS}$ as depicted at C.

Peak inverse voltage (PIV) is the maximum voltage the rectifier must withstand when it isn't conducting. This varies with the load and rectifier connection. In the half-wave rectifier, with a resistive load the PIV is the peak ac voltage ($1.4 \times E_{RMS}$); with a capacitor filter and a load drawing little or no current, the PIV can rise to $2.8 \times E_{RMS}$.

7.4.2 Full-Wave Center-Tapped Rectifier

The full-wave center-tapped rectifier circuit is shown in Fig 7.7. It is essentially an arrangement where the outputs of two half-wave rectifiers are combined so that both halves of the ac cycle are used to deliver power to the output. A transformer with a center-tapped secondary is required.

The average output voltage of this circuit is $0.9 \times E_{RMS}$ of half the transformer secondary (the center-tap to one side); this is the maximum that can be obtained with a suitable choke-input filter. The peak output voltage is $1.4 \times E_{RMS}$ of half the transformer secondary; this is the maximum voltage that can be obtained from a capacitor-input filter.

As can be seen in Fig 7.7C, the PIV impressed on each diode is independent of the type of load at the output. This is because the peak inverse voltage condition occurs when diode D_A conducts and diode D_B is not conducting. The positive and negative voltage peaks occur at precisely the same time, a condition different from that in the half-wave circuit. As the cathodes of diodes D_A and D_B reach a positive peak ($1.4 E_{RMS}$), the anode of diode D_B is at a negative peak, also $1.4 E_{RMS}$, but in the opposite direction. The total peak inverse voltage is therefore $2.8 E_{RMS}$.

RMS current in the primary winding will also be reduced.

7.4.3 Full-Wave Bridge Rectifier

Another commonly used rectifier circuit that does not require a center-tapped transformer is illustrated in Fig 7.8. In this arrangement, two rectifiers operate in series on each half of the cycle, one rectifier being in the lead supplying current to the load, the other being the current return lead. As shown in Figures 7.8A and B, when the top lead of the transformer secondary is positive with respect to the bottom lead, diodes D_A and D_C will conduct while diodes D_B and D_D are reverse-biased. On the next half cycle, when the top lead of the transformer is negative with respect to the bottom, diodes D_B and D_D will conduct while diodes D_A and D_C are reverse-biased.

The output voltage wave shape and ripple frequency are the same as for the full-wave center-tapped circuit. The average dc output voltage into a resistive load or choke-input filter is 0.9 times E_{RMS} delivered by the transformer secondary; with a capacitor filter and a light load, the maximum output voltage is 1.4 times the secondary E_{RMS} voltage.

Fig 7.8C shows the PIV to be $1.4 E_{RMS}$ for each diode which is half that of the full-wave center-tapped circuit for the same output voltage. When an alternate pair of diodes (such as D_A and D_C) is conducting, the other diodes are essentially connected in parallel

Fig 7.7C shows that the ripple frequency is twice that of the half-wave rectifier (two times the line frequency). Substantially less filtering is required because of the higher ripple frequency. Since the rectifiers work alternately, each handles half of the load current. The current rating of each rectifier need be only half the total current drawn from the supply.

The problem with dc bias in the transformer core associated with the half-wave connection is largely eliminated with this circuit and the

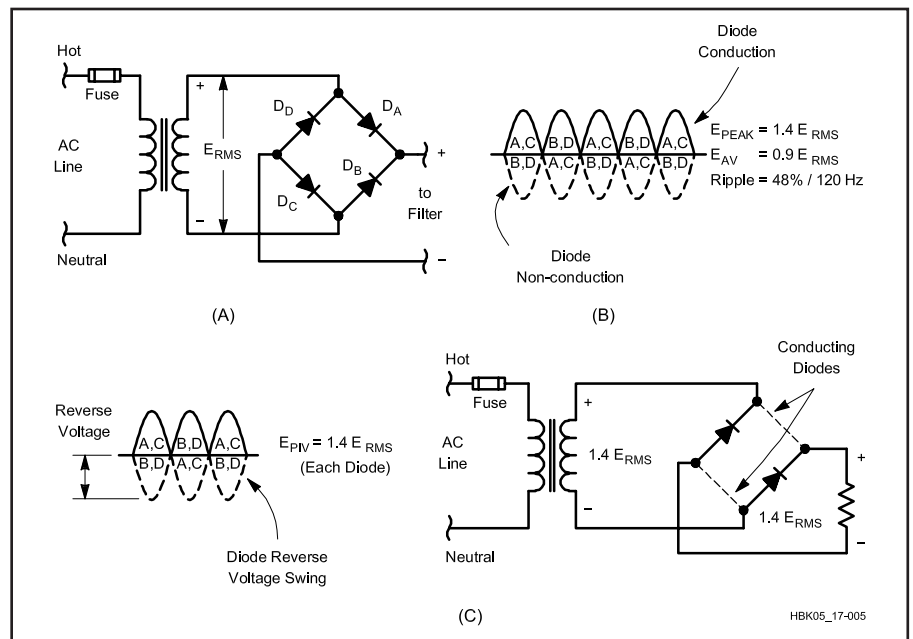

Fig 7.8 — Full-wave bridge rectifier circuits. The basic circuit is illustrated at A. Diode conduction and nonconduction times are shown at B. Diodes A and C conduct on one half of the input cycle, while diodes B and D conduct on the other. C displays the peak inverse voltage for one half cycle. Since this circuit reverse-biases two diodes essentially in parallel, $1.4 E_{RMS}$ is applied across each diode.

(the conducting diodes are essentially short circuits) in a reverse-biased direction. The reverse stress is then $1.4 E_{RMS}$. Each pair of diodes conducts on alternate half cycles, with the full load current through each diode during its conducting half cycle. Since each diode is not conducting during the other half cycle the average diode current is one-half the total load current drawn from the supply.

Compared to the half-wave and full-wave center-tapped circuit, the full-wave bridge circuit further reduces the transformer RMS winding currents. In the case of a resistive load the winding currents are the same as when the resistive load is connected directly across the secondary. The RMS winding currents will still be higher when inductive and especially capacitive filters are used because of the pulsating nature of the diode and winding currents.

7.4.4 Comparison of Rectifier Circuits

Comparing the full-wave center-tapped and the full-wave bridge circuits, we can see that the center-tapped circuit has half the number of rectifiers as the bridge but these rectifiers have twice the PIV rating requirement of the bridge diodes. The diode current ratings are identical for the two circuits. The bridge makes better use of the transformer's secondary than the center-tapped rectifier, since the transformer's full winding supplies power during both half cycles, while each half of the center-tapped circuit's secondary provides power only during its positive half-cycle.

The full-wave center-tapped rectifier is typically used in high-current, low-voltage

applications because only one diode conducts at a time. This reduces the loss associated with diode conduction. In the full-wave bridge circuit there are two diodes in series in conduction simultaneously, which leads to higher loss. The full-wave bridge circuit is typically used for higher output voltages where this is not a serious concern. The lower diode PIV and better utilization of the transformer windings makes this circuit very attractive for higher output voltages and higher powers typical of high voltage amplifier supplies.

Because of the disadvantages pointed out earlier, the half-wave circuit is rarely used in 60-Hz rectification except for bias supplies or other small loads. It does see considerable use, however, in high-frequency switchmode power supplies.

7.5 Voltage Multipliers

Other rectification circuits are sometimes useful, including *voltage multipliers*. These circuits function by the process of charging one or more capacitors in parallel on one half cycle of the ac waveform, and then connecting that capacitor or capacitors in series with the opposite polarity of the ac waveform on the alternate half cycle. In full-wave multipliers, this charging occurs during both half-cycles.

Voltage multipliers, particularly *voltage doublers*, find considerable use in high-voltage supplies. When a doubler is employed, the secondary winding of the power transformer need have only half the voltage that would be required for a bridge rectifier. This reduces voltage stress in the windings and decreases the transformer insulation requirements. This is not without cost, however, because the transformer-secondary *current* rating has to be correspondingly doubled for a given load current and charging of the capacitors leads to narrow high-RMS current waveforms in the transformer windings and the capacitors.

7.5.1 Half-Wave Voltage Doubler

Fig 7.9 shows the circuit of a half-wave voltage doubler and illustrates the circuit operation. For clarity, assume the transformer voltage polarity at the moment the circuit is activated is that shown at Fig 7.9B. During the first negative half cycle, D_A conducts (D_B is in a nonconductive state), charging $C1$ to the peak rectified voltage ($1.4 E_{RMS}$). $C1$ is charged with the polarity shown in Fig 7.9B. During the positive half cycle of the secondary voltage, D_A is cut off and D_B conducts, charging capacitor $C2$. The amount

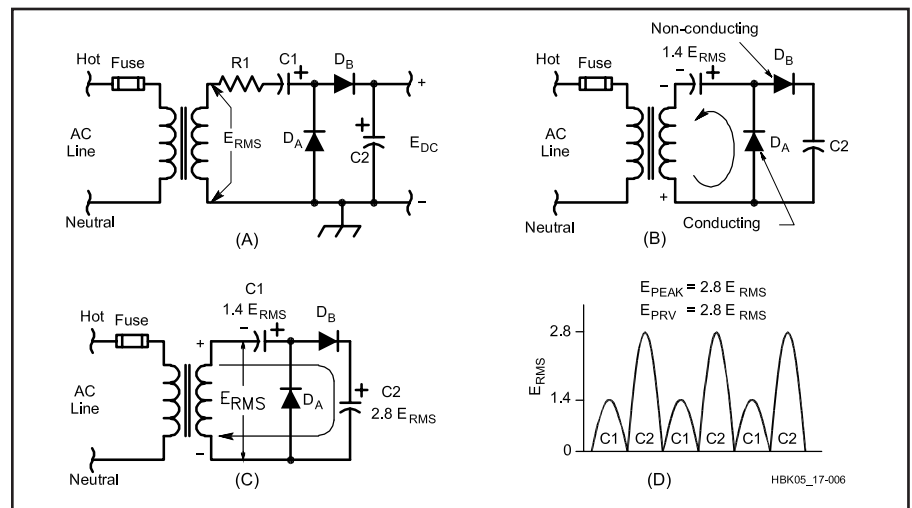

Fig 7.9 — Part A shows a half-wave voltage-doubler circuit. B displays how the first half cycle of input voltage charges $C1$. During the next half cycle (shown at C), capacitor $C2$ charges with the transformer secondary voltage plus that voltage stored in $C1$ from the previous half cycle. The arrows in parts B and C indicate the conventional current. D illustrates the levels to which each capacitor charges over several cycles.

of voltage delivered to $C2$ is the sum of the transformer peak secondary voltage plus the voltage stored in $C1$ ($1.4 E_{RMS}$). On the next negative half cycle, D_B is non-conducting and $C2$ will discharge into the load. If no load is connected across $C2$, the capacitors will remain charged — $C1$ to $1.4 E_{RMS}$ and $C2$ to $2.8 E_{RMS}$. When a load is connected to the circuit output, the voltage across $C2$ drops during the negative half cycle and is recharged up to $2.8 E_{RMS}$ during the positive half cycle.

The output waveform across $C2$ resembles that of a half-wave rectifier circuit because $C2$ is pulsed once every cycle. Fig 7.9D illustrates the levels to which the two capacitors

are charged throughout the cycle. In actual operation the capacitors will usually be large enough that they will discharge only partially, not all the way to zero as shown.

7.5.2 Full-Wave Voltage Doubler

Fig 7.10 shows the circuit of a full-wave voltage doubler and illustrates the circuit operation. During the positive half cycle of the transformer secondary voltage, as shown in Fig 7.10B, D_A conducts charging capacitor $C1$ to $1.4 E_{RMS}$. D_B is not conducting at this time.

During the negative half cycle, as shown in Fig 7.10C, D_B conducts, charging capacitor C_2 to $1.4 E_{RMS}$, while D_A is non-conducting. The output voltage is the sum of the two capacitor voltages, which will be $2.8 E_{RMS}$ under no-load conditions. Fig 7.10D illustrates that each capacitor alternately receives a charge once per cycle. The effective filter capacitance is that of C_1 and C_2 in series, which is less than the capacitance of either C_1 or C_2 alone.

Resistors R_1 and R_2 in Fig 7.10A are used to limit the surge current through the rectifiers. Their values are based on the transformer voltage and the rectifier surge-current rating, since at the instant the power supply is turned on, the filter capacitors look like a short-circuited load. Provided the limiting resistors can withstand the surge current, their current-handling capacity is based on the maximum load current from the supply. Output voltages approaching twice the peak voltage of the transformer can be obtained with the voltage doubling circuit shown in Fig 7.10.

Fig 7.11 shows how the voltage depends upon the ratio of the series resistance to the load resistance, and the load resistance times the filter capacitance. The peak inverse voltage across each diode is $2.8 E_{RMS}$. As indicated by the curves in Fig 7.11, the output voltage regulation of this doubler connection is not very good and it is not attractive for providing high voltages at high power levels.

There are better doubler connections for higher power applications, and two possibilities are shown in **Fig 7.12**. The connection in Fig 7.12A uses two bridge rectifiers in series with capacitive coupling between the ac terminals of the bridges. At the expense of more diodes, this connection will have much better output voltage regulation at higher power levels. Even better regulation can be achieved by using the connection shown in Fig 7.12B. In this example, two windings on the transformer are used. It is not essential that both windings have the same voltage, but both must be capable of providing the desired output current. In addition, the insulation of the upper winding must be adequate to accommodate the additional dc bias applied to it from the lower winding.

7.5.3 Voltage Tripler and Quadrupler

Fig 7.13A shows a voltage-tripling circuit. On one half of the ac cycle, C_1 and C_3 are charged to the source voltage through D_1 , D_2 and D_3 . On the opposite half of the cycle, D_2 conducts and C_2 is charged to twice the source voltage, because it sees the transformer plus the charge in C_1 as its source (D_1 is cut off during this half cycle). At the same time, D_3 conducts, and with the transformer and the

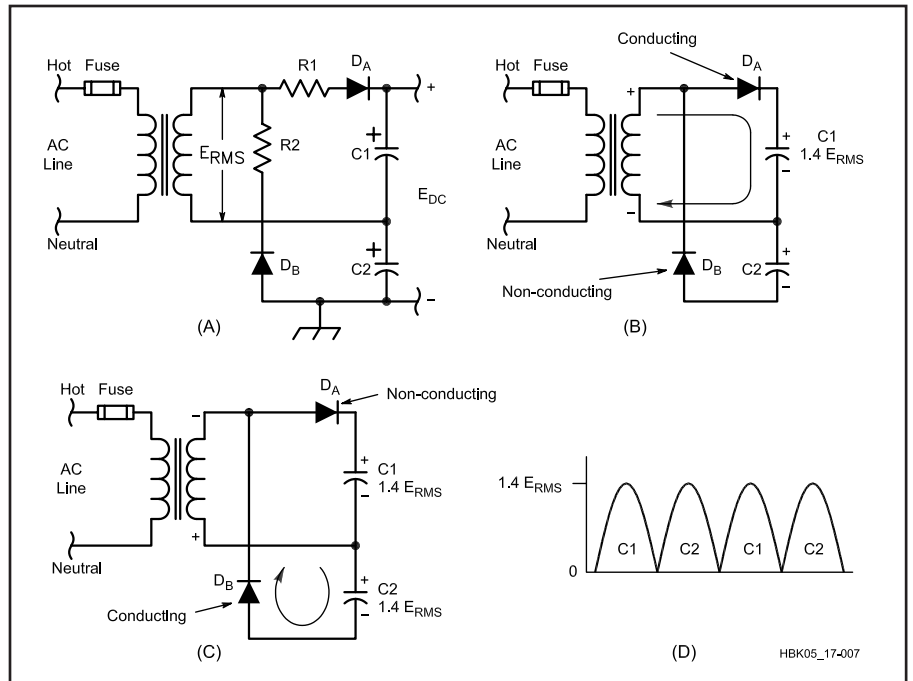

Fig 7.10 — Part A shows a full-wave voltage-doubler circuit. One-half cycle is shown at B and the next half cycle is shown at C. Each capacitor receives a charge during every input-voltage cycle. D illustrates how each capacitor is charged alternately.

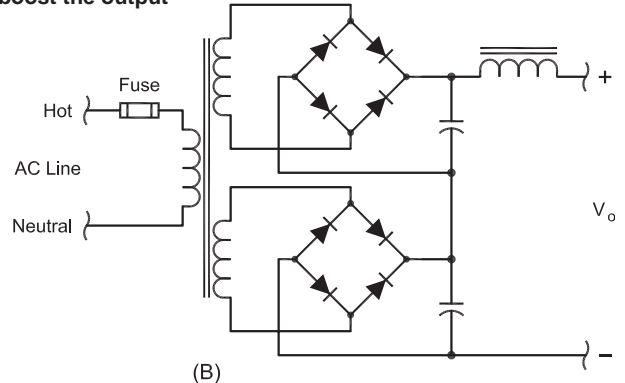

Fig 7.11 — DC output voltages from a full-wave voltage-doubler circuit as a function of the filter capacitances and load resistance. For the ratio R_1 / R_3 and for the $R_3 \times C_1$ product, resistance is in ohms and capacitance is in microfarads. Equal resistance values for R_1 and R_2 , and equal capacitance values for C_1 and C_2 are assumed. These curves are adapted from those published by Otto H. Schade in "Analysis of Rectifier Operation," *Proceedings of the I. R. E.*, July 1943.

Fig 7.12 — Voltage-doubler rectifier connections for higher power levels. A is a capacitor-coupled doubler that can be extended to more sections for a higher multiplying factor. The circuit in B uses multiple transformer windings to boost the output voltage.

HBK0156

(B)

Fig 7.13 — Voltage-multiplying circuits with one side of the transformer secondary used as a common connection. A shows a voltage tripler and B shows a voltage quadrupler. Capacitances are typically 20 to 50 μF , depending on the output current demand. Capacitor dc ratings are related to E_{PEAK} ($1.4 E_{\text{RMS}}$):

- C1 — Greater than E_{PEAK}**
- C2 — Greater than $2 E_{\text{PEAK}}$**
- C3 — Greater than $3 E_{\text{PEAK}}$**
- C4 — Greater than $2 E_{\text{PEAK}}$**

charge in C2 as the source, C3 is charged to three times the transformer voltage.

The voltage-quadrupling circuit of Fig 7.13B works in similar fashion. In either of the circuits of Fig 7.13, the output voltage will approach an exact multiple of the peak ac voltage when the output current drain is low and the capacitance values are large.

HBK05_17-009

7.6 Current Multipliers

Just as there are voltage multiplier connections for high-voltage, low-current loads, there are current multiplier connections for low-voltage, high-current loads. An example of a current-doubler is given in **Fig 7.14A**.

To make the circuit operation easier to visualize, we can represent L1 and L2 as current sources (Fig 7.14B) which is a good approximation for steady-state operation. When terminal 1 of the secondary winding is positive with respect to terminal 2, diode D_A will be reverse-biased and therefore non-conducting. The current flows within the circuit are shown in Fig 7.14B. Note that all of the output current (I_o) flows through D_B but only half of I_o flows through the winding. At the cathode of D_B the current divides with half going to L2 and the other half to the transformer secondary. The output voltage will be one-half the voltage of the average winding voltage ($0.45 E_{RMS}$). This rectifier connection divides the voltage and multiplies the current! Because of the need for two inductors, this circuit is seldom used in line-frequency applications but it is very useful in high-frequency switchmode regulators with very low output voltages ($<10\text{ V}$) because it makes the secondary winding design easier and can improve circuit efficiency. At high frequencies, the inductors can be quite small.

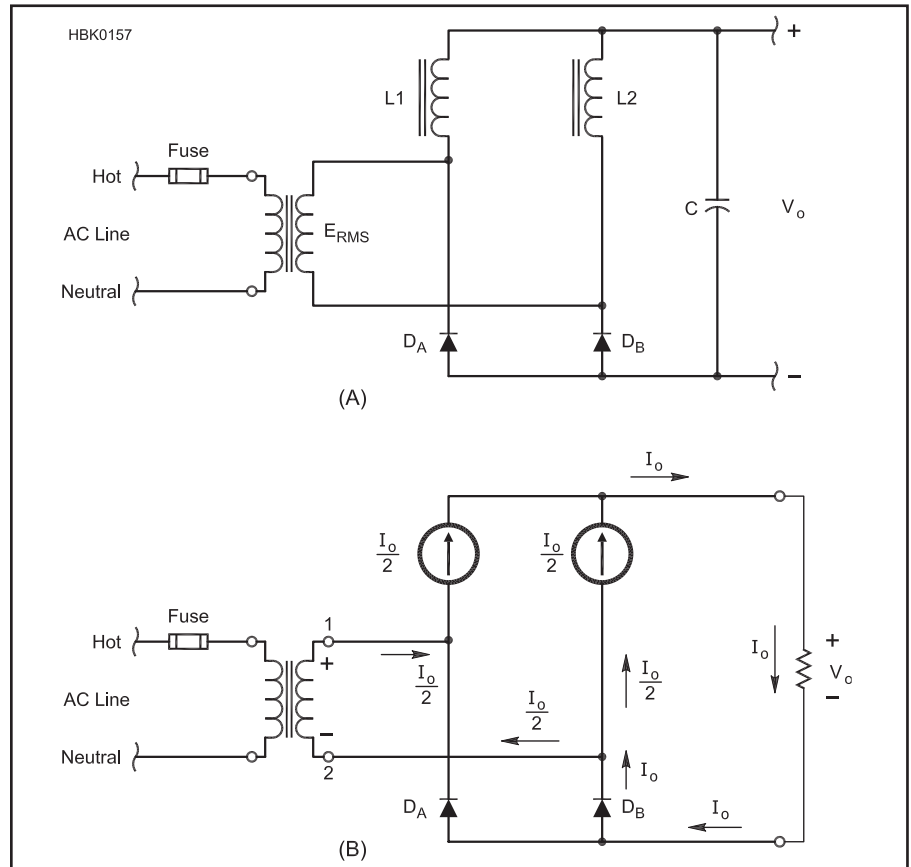

Fig 7.14 — A current doubler rectifier connection. A is the basic circuit. B illustrates current flow within the circuit.

7.7 Rectifier Types

Rectifiers have a long history beginning with mechanical rectifiers in the 1800s to today's abundant variety of semiconductor devices. While many different devices have been created for this purpose, they all have the characteristic that they block current flow in the reverse direction, withstanding substantial reverse voltage and allowing current flow in the forward direction with minimum voltage drop. The simplest rectifiers are diodes, but it is also possible to have three-terminal devices (such as a thyristor) that can be controlled to regulate the output dc in addition to providing rectification. It is also possible to use devices like MOSFETs as synchronous rectifiers with very low forward drop during conduction. This is typically done to improve efficiency for very low voltage outputs. The following is a brief description of several of the more common examples. The sections on vacuum tube and other obsolete types of rectifiers from previous editions are available as a PDF article on the CD-ROM accompanying this book.

7.7.1 Semiconductor Diodes

Rectifier diodes can be made from a number of different semiconductor materials such as germanium, silicon, silicon-carbide or gallium-arsenide, and no doubt other materials will appear in the future. The choice will depend on the application and as always cost is a factor.

Germanium diodes were the first of the solid-state semiconductor rectifiers. They have an extremely low forward voltage drop but are relatively temperature sensitive, having high reverse leakage currents at higher temperatures. They can be easily destroyed by overheating during soldering as well. Germanium diodes are no longer used as power rectifiers.

Today, silicon diodes are the primary choice for virtually all power rectifier applications. They are characterized by extremely high reverse resistance (low reverse leakage), forward drops of a volt or less and operation at junction temperatures up to $125\text{ }^{\circ}\text{C}$. Some

multi-junction HV diodes will have forward drops of several volts, but that is still low compared to the voltage at which they are being used.

Many different types of silicon diodes are available for different applications. Silicon rectifiers fall into two general categories: PN-junction diodes and Schottky barrier diodes (see the **Analog Basics** chapter). Schottky diodes are the usual choice for low output voltages ($<20\text{ V}$) where their low forward conduction drop is critical for efficiency. For higher voltages however, the high reverse leakage of Schottky diodes is not acceptable and PN-junction diodes are normally chosen.

For 50/60 Hz applications, diodes with reverse recovery times of a microsecond or even more are suitable and very economical. For switchmode converters and inverters that regularly operate at 25 kHz and higher frequencies, fast-recovery diodes are needed. These converters typically have waveform transitions of less than $1\text{ }\mu\text{s}$ within the circuit.

MOSFET power transistors often have transitions of less than 100 ns.

During the switching transitions, previously conducting diodes see a reversal of current direction. This change tends to reverse-bias those diodes, and thereby put them into an open-circuit condition. Unfortunately, as explained in the **Analog Basics** chapter, solid-state rectifiers cannot be made to cease conduction instantaneously. As a result, when the opposing diodes in a bridge rectifier or full-wave rectifier become conductive at the time the converter switches states, the diodes being turned off will actually conduct in the reverse direction for a brief time. That effectively short circuits the converter for a period of time depending on the reverse recovery characteristics of the rectifiers. This characteristic can create high current transients that stress the switching transistors and lead to increased loss and electromagnetic interference. As the switching frequency increases, more of these transitions happen each second, and more power is lost because of diode cross-conduction.

These current transients and associated losses are reduced by using *fast recovery* diodes, which are specially doped diodes designed to minimize storage time. Diodes with recovery times of 50 ns or less are available.

7.7.2 Rectifier Strings or Stacks

DIODES IN SERIES

When the PIV rating of a single diode is not sufficient for the application, similar diodes may be used in series. (Two 500 PIV diodes in series will withstand 1000 PIV and so on.) There used to be a general recommendation to place a resistor across each diode in the string to equalize the PIV drops. With modern diodes, this practice is no longer necessary.

Modern silicon rectifier diodes are constructed to have an avalanche characteristic. Simply put, this means that the diffusion process is controlled so the diode will exhibit a Zener characteristic in the reverse-biased direction before destructive breakdown of the junction can occur. This provides a measure of safety for diodes in series. A diode will go into Zener conduction before it self-destructs. If other diodes in the chain have not reached their avalanche voltages, the current through the avalanched diode will be limited to the leakage current in the other diodes. This should normally be very low. For this reason, shunting resistors are generally not needed across diodes in series rectifier strings. In fact, shunt resistors can actually create problems because they can produce a low-impedance source of damaging current to any diode that may have reached avalanche potential.

DIODES IN PARALLEL

Diodes can be placed in parallel to increase current-handling capability. Equalizing resistors should be added as shown in **Fig 7.15**. Without the resistors, one diode may take most of the current. The resistors should be selected to have a drop of several tenths of a volt at the expected peak current. A disadvantage of this form of forced current sharing will be the increase in power loss because of the added resistors.

7.7.3 Rectifier Ratings versus Operating Stress

Power supplies designed for amateur equipment use silicon rectifiers almost exclusively. These rectifiers are available in a wide range of voltage and current ratings: PIV ratings of 600 V or more and current ratings as high as 400 A are available. At 1000 PIV, the current ratings may be several amperes. It is possible to stack several units in series for higher voltages. Stacks are available commercially that will handle peak inverse voltages up to 10 kV at a load current of 1 A or more.

7.7.4 Rectifier Protection

The discussion of rectifier circuits included the peak reverse voltage seen by the rectifiers in each circuit. You will need this information to select the voltage rating of the diodes in given application. It is normal good practice to not expose the diodes to more than 75% of their rated voltage for the worst case reverse voltage. This will probably be when operating at the highest input voltage but should also take into account transients that may occur.

The important specifications of a silicon diode are:

1. PIV — the peak inverse voltage.
2. I_0 — the average dc current rating.
3. I_{REP} — the peak repetitive forward current.
4. I_{SURGE} — a non-repetitive peak half-sine wave of 8.3 ms duration (one-half cycle of 60-Hz line frequency).
5. Switching speed or reverse recovery time.
6. Power dissipation and thermal resistance.

The first two specifications appear in most catalogs. I_{REP} and I_{SURGE} are not often specified in catalogs, but they are very important. Except in some switching regulator and capacitive filter circuits, rectifier current typically flows half the time — when it does conduct, the rectifier has to pass at least twice the average direct current. With a capacitor-input filter, the rectifier conducts much less than half the time. In this case, when it does conduct, it may pass as much as 10 to 20 times the average dc current, under certain conditions.

Fig 7.15 — Diodes can be connected in parallel to increase the current-handling capability of the circuit. Each diode should have a series current-equalizing resistor, with a value selected to have a drop of several tenths of a volt at the expected current.

CURRENT INRUSH

When the supply is first turned on, the filter capacitors are discharged and act like a dead short. The result can be a very heavy current surge through the diode for at least one half-cycle and sometimes more. This current transient is called I_{SURGE} . The maximum surge current rating for a diode is usually specified for a duration of one-half cycle (at 60 Hz), or about 8.3 ms. Some form of surge protection is usually necessary to protect the diodes until the filter capacitors are nearly charged, unless the diodes used have a very high surge-current rating (several hundred amperes). If a manufacturer's data sheet is not available, an educated guess about a diode's capability can be made by using these rules of thumb for silicon diodes commonly used in Amateur Radio power supplies:

Rule 1. The maximum I_{REP} rating can be assumed to be approximately four times the maximum I_0 rating, where I_0 is the average dc current rating.

Rule 2. The maximum I_{SURGE} rating can be assumed to be approximately 12 times the maximum I_0 rating. This figure should provide a reasonable safety factor. Silicon rectifiers with 750 mA dc ratings, for example, seldom have 1-cycle surge ratings of less than 15 A; some are rated up to 35 A or more. From this you can see that the rectifier should be selected on the basis of I_{SURGE} and not on I_0 ratings.

Although you can sometimes rely on the resistance of the transformer windings to provide surge-current limiting, this is seldom adequate in high-voltage power supplies. Series resistors are often installed between the secondary and the rectifier strings or in the transformer's primary circuit, but these can be a deterrent to good voltage regulation.

One way to have good surge current limiting at turn-on without affecting voltage regulation during normal operation is to have a resistor in series with the input, along with a relay across the resistor that shorts it out after 50 ms or so. This kind of arrangement is particularly important in HV supplies.

VOLTAGE TRANSIENTS

Vacuum-tube rectifiers had little problem with voltage transients on the incoming power lines. The possibility of an internal arc was of little consequence, since the heat produced was of very short duration and had little effect on the massive plate and cathode structures.

Unfortunately, such is not the case with silicon diodes. Because of their low forward voltage drop, silicon diodes create very little heat with high forward current and therefore have tiny junction areas. However, conduction in the reverse direction beyond the normal reverse recovery time (reverse avalanching) can cause junction temperatures to rise extremely rapidly with the resulting destruction of the semiconductor junction.

To protect semiconductor rectifiers from voltage transients, special surge-absorption devices are available for connection across the incoming ac bus or transformer secondary. These devices operate in a fashion similar to a Zener diode; they conduct heavily when a specific voltage level is reached. Unlike Zener diodes, however, they have the ability to absorb very high transient energy levels without damage. With the clamping level set well above the normal operating voltage range for the rectifiers, these devices normally appear as open circuits and have no effect on the power-supply circuits. When a voltage transient occurs, however, these protection devices clamp the transient and thereby prevent destruction of the rectifiers.

Transient protectors are available in three basic varieties:

1. *Silicon Zener diodes* — large junction Zeners specifically made for this purpose and available as single junction for dc (unipolar) and back-to-back junctions for ac (bipolar). These silicon protectors are available under the trade name of TransZorb from General

Semiconductor Corporation and are also made by other manufacturers. They have the best transient-suppressing characteristics of the three varieties mentioned here, but are expensive and have the least energy absorbing capability per dollar of the group.

2. *Varistors* — made of a composition metal-oxide material that breaks down at a certain voltage. Metal-oxide varistors, also known as MOVs, are cheap and easily obtained, but have a higher internal resistance, which allows a greater increase in clamped voltage than the Zener variety. Varistors can also degrade with successive transients within their rated power handling limits (this is not usually a problem in the ham shack where transients are few and replacement of the varistor is easily accomplished).

Varistors usually become short-circuited when they fail. Large energy dissipation can result in device explosion. Therefore, it is a good idea to include a fuse that limits the short-circuit current through the varistor, and to protect people and circuitry from debris.

3. *Gas tube* — similar in construction to the familiar neon bulb, but designed to limit conducting voltage rise under high transient currents. Gas tubes can usually withstand the highest transient energy levels of the group. Gas tubes suffer from an ionization time problem, however. A high voltage across the tube will not immediately cause conduction. The time required for the gas to ionize and clamp the transient is inversely proportional to the level of applied voltage in excess of the device ionization voltage. As a result, the gas tube will let a little of the transient through to the equipment before it activates.

In installations where reliable equipment operation is critical, the local power is poor and transients are a major problem, the usual practice is to use a combination of

protectors. Such systems consist of a varistor or Zener protector, combined with a gas-tube device. Often there is an indicator light to warn when a surge has blown out the varistor. Operationally, the solid-state device clamps the surge immediately, with the beefy gas tube firing shortly thereafter to take most of the surge from the solid-state device.

HEAT

The junction of a diode is quite small, so it must operate at a high current density. The heat-handling capability is, therefore, quite small. Normally, this is not a prime consideration in high-voltage, low-current supplies. Use of high-current rectifiers at or near their maximum ratings (usually 2 A or larger, stud-mount rectifiers) requires some form of heat sinking. Frequently, mounting the rectifier on the main chassis — directly or with thin thermal insulating washers — will suffice.

When a rectifier is directly mounted on the heatsink it is good practice to use a thin layer of thermal grease between the diode and the heat sink to assure good heat conduction. Most modern insulating thermal washers do not require the use of grease, but the older mica and other washers may benefit from a *very thin layer* of grease. Thermal grease and heat conducting insulating washers and pads are standard products available from mail-order component sellers.

Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling from a fan is sometimes used as a further aid. Safe case temperatures are usually given in the manufacturer's data sheets and should be observed if the maximum capabilities of the diode are to be realized. See the thermal design section in the chapter on **Electrical Fundamentals** for more information.

7.8 Power Filtering

Most loads will not tolerate the ripple (an ac component) of the pulsating dc from the rectifiers. Filters are required between the rectifier and the load to reduce the ripple to a low level. As pointed out earlier, some capacitances or inductances may be inherent in the rectifier connection, reducing the ripple amplitude. In most cases, however, additional filtering is required. The design of the filter depends to a large extent on the dc voltage output, the desired voltage regulation of the power supply and the maximum load current. Power-supply filters are low-pass devices using series inductors and/or shunt capacitors.

7.8.1 Load Resistance

In discussing the performance of power-supply filters, it is sometimes convenient to characterize the load connected to the output as a resistance. This *load resistance* is equal to the output voltage divided by the total load current, including the current drawn by the bleeder resistor.

7.8.2 Voltage Regulation

In an unregulated supply, the output voltage usually decreases as more current is drawn. This happens not only because of increased voltage drops in the transformer and filter

chokes, but also because the output voltage at light loads tends to soar to the peak value of the transformer voltage as a result of charging the first capacitor. Proper filter design can reduce this effect. The change in output voltage with load is called the *voltage regulation* and is expressed as a percentage.

$$\text{Percent Regulation} = \frac{(E1 - E2)}{E2} \times 100\% \quad (2)$$

where

E1 = the no-load voltage

E2 = the full-load voltage.

A steady load, such as that represented

by a receiver, speech amplifier or unkeyed stages of a transmitter, does not require good (low) regulation as long as the proper voltage is obtained under load conditions. The filter capacitors must have a voltage rating safe for the highest value to which the voltage will rise when the external load is removed.

Typically the output voltage will display a larger change with long-duration changes in load resistance than with short transient changes. The reason for this is that transient load currents are supplied from energy stored in the output capacitance. The regulation with long-term changes is often called the *static regulation*, to distinguish it from the *dynamic regulation* (transient load changes). A load that varies at a syllabic or keyed rate, as represented by some audio and RF amplifiers, usually requires good dynamic regulation (<15%) if distortion products are to be held to a low level. The dynamic regulation of a power supply can be improved by increasing the output capacitance.

When essentially constant voltage is required, regardless of current variation (for stabilizing an oscillator, for example), special voltage regulating circuits described later in this chapter are used.

7.8.3 Bleeder Resistors

A *bleeder resistor* is a resistance (R) connected across the output terminals of the power supply as shown in Fig 7.16A. Its functions are to discharge the filter capacitors as a safety measure when the power is turned off and to improve voltage regulation by providing a minimum load resistance. When voltage regulation is not of importance, the resistance may be as high as 100 Ω per volt of output voltage. The resistance value to be used for voltage-regulating purposes is discussed in later sections. From the consideration of safety, the power rating of bleeder resistors should be as conservative as possible — having a burned-out bleeder resistor is dangerous!

7.8.4 Ripple Frequency and Voltage

The ripple at the output of the rectifier is an alternating current superimposed on a steady direct current. From this viewpoint, the filter may be considered to consist of: 1) shunt capacitors that short circuit the ac component while not interfering with the flow of the dc component; and/or 2) series chokes that readily pass dc but will impede the ac component.

The effectiveness of the filter can be expressed in terms of percent ripple, which is the ratio of the RMS value of the ripple to the dc value in terms of percentage.

$$\text{Percent Ripple (RMS)} = \frac{E1}{E2} \times 100\% \quad (3)$$

Fig 7.16 — Capacitor-input filter circuits. At A is a simple capacitor filter. B and C are single- and double-section filters, respectively.

where

- E1 = the RMS value of ripple voltage
- E2 = the steady dc voltage.

Any frequency multiplier or amplifier supply in a CW transmitter should have less than 5% ripple. A linear amplifier can tolerate about 3% ripple on the plate voltage. Bias supplies for linear amplifiers should have less than 1% ripple. VFOs, speech amplifiers and receivers may require no greater than 0.01% ripple.

Ripple frequency refers to the frequency of the pulsations in the rectifier output waveform — the number of pulsations per second. The ripple frequency of half-wave rectifiers is the same as the line-supply frequency — 60 Hz with a 60-Hz supply. Since the output pulses are doubled with a full-wave rectifier, the ripple frequency is doubled — to 120 Hz with a 60-Hz supply.

The amount of filtering (values of inductance and capacitance) required to give adequate smoothing depends on the ripple frequency. More filtering is required as the ripple frequency is reduced. This is why the filters used for line-frequency rectification are much larger than those used in switchmode converters where the ripple frequency is often in the hundreds of kHz.

7.8.5 Capacitor-Input Filters

Typical capacitor-input filter systems are shown in Fig 7.16. The ripple can be reduced by making C1 larger, but that can lead to very large capacitances and high inrush currents at turn-on. Better ripple reduction will be obtained when moderate values for C1

are employed and LC sections are added as shown in Fig 7.16B and C.

INPUT VERSUS OUTPUT VOLTAGE

The average output voltage of a capacitor-input filter is generally poorly regulated with load-current variations. As shown earlier (Fig 7.6) the rectifier diodes conduct for only a small portion of the ac cycle to charge the filter capacitor to the peak value of the ac waveform. When the instantaneous voltage of the ac passes its peak, the diode ceases to conduct. This forces the capacitor to support the load current until the ac voltage on the opposing diode in the bridge or full wave rectifier is high enough to pick up the load and recharge the capacitor. For this reason, the peak diode currents are usually quite high.

Since the cyclic peak voltage of the capacitor-filter output is determined by the peak of the input ac waveform, the minimum voltage and, therefore, the ripple amplitude, is determined by the amount of voltage discharge, or “droop,” occurring in the capacitor while it is discharging and supporting the load. Obviously, the higher the load current, the proportionately greater the discharge, and therefore the lower the average output.

There is an easy way to approximate the peak-to-peak ripple for a certain capacitor and load by assuming a constant load current. We can calculate the droop in the capacitor by using the relationship:

$$C \times E = I \times t \quad (4)$$

where

C = the capacitance in microfarads

E = the voltage droop, or peak-to-peak ripple voltage
 I = the load current in milliamperes
 t = the length of time in ms per cycle during which the rectifiers are not conducting, during which the filter capacitor must support the load current. For 60-Hz, full-wave rectifiers, t is about 7.5 ms.

As an example, let's assume that we need to determine the peak-to-peak ripple voltage at the dc output of a full-wave rectifier/ filter combination that produces 13.8 V dc and supplies a transceiver drawing 2.0 A. The filter capacitor in the power supply is 5000 μF . Using the above relationship:

$$C \times E = I \times t \quad (5)$$

$$5000 \mu\text{F} \times E = 2000 \text{ mA} \times 7.5 \text{ ms}$$

$$E = \frac{2000 \text{ mA} \times 7.5 \text{ ms}}{5000 \mu\text{F}} = 3 \text{ V P-P}$$

Obviously, this is too much ripple. A capacitor value of about 20,000 μF would be better suited for this application. If a linear regulator is used after this rectifier/filter combination, then it is possible to trade off higher ripple voltage against high power dissipation in the regulator. A properly designed linear regulator can reduce the ripple amplitude to a very small value.

7.8.6 Choke-Input Filters

Choke-input filters provide the benefits of greatly improved output voltage stability over varying loads and low peak-current surges in the rectifiers. On the negative side, the output voltage will be lower than that for a capacitor-input filter.

In line-frequency power supplies, choke-input filters are less popular than they once were. This change came about in part because

Fig 7.17 — Inductive filter output voltage regulation as a function of load current. The transition from capacitive peak charging to inductive averaging occurs at the critical load current, I_c .

Fig 7.18 — The choke inductor constant, A , is used to solve equation 6.

of the high surge current capability of silicon rectifiers, but more importantly because size, weight and cost are reduced when large filter chokes are eliminated. However, choke input filters are frequently used in high-frequency switchmode converters where the chokes will be much smaller.

As long as the inductance of the choke is large enough to maintain a continuous current over the complete cycle of the input ac waveform, the filter output voltage will be the average dc value of the rectified output. The average dc value of a full-wave rectified sine wave is 0.637 times its peak voltage. Since the RMS value is 0.707 times the peak, the output of the choke input filter will be $(0.637 / 0.707)$, or 0.9 times the RMS ac voltage.

As shown in Fig 7.17, there is a minimum or "critical" load current below which the choke does not provide the necessary filtering. For light loads, there may not be enough energy stored in the choke during the input waveform crest to allow continuous current over the full cycle. When this happens, the filter output voltage will rise as the filter assumes more and more of the characteristics of a capacitor-input filter. One purpose of the bleeder resistor is to keep the minimum load current above the critical value.

The value for the critical (or minimum) inductance for a given maximum value of load resistance in a single phase, full-wave rectifier with a sine wave source voltage can be approximated from:

$$L_c = R/A \quad (6)$$

where

R = the maximum load resistance

A = a constant obtained from Fig 7.18, derived from the frequency of the input current (see Reference 1).

Low values for minimum load current (high minimum load R) can lead to large values for L_c which may not be practical. Standard filter inductors typically have a relatively constant value for L as the dc current is varied but it is possible to use a swinging choke instead. This is an inductor which has a high inductance at low currents and much lower inductance at high currents. Using a swinging choke will usually result in a much smaller filter choke and/or better output regulation.

7.9 Power Supply Regulation

The output of a rectifier/filter system may be usable for some electronic equipment, but for today's transceivers and accessories, further measures may be necessary to provide power sufficiently clean and stable for their needs. Voltage regulators are often used to provide this additional level of conditioning.

Rectifier/filter circuits by themselves are unable to protect the equipment from the problems associated with input-power-line fluctuations, load-current variations and residual ripple voltages. Regulators can eliminate these problems, but not without costs in circuit complexity and power-conversion efficiency.

7.9.1 Zener Diodes

A Zener diode (developed by Dr Clarence Zener) can be used to maintain the voltage applied to a circuit at a practically constant value, regardless of the voltage regulation of the power supply or variations in load current. The typical circuit is shown in Fig 7.19. Note that the cathode side of the diode is connected to the positive side of the supply.

Zener diodes are available in a wide variety of voltages and power ratings. The voltages range from less than 2 V to a few hundred volts, while the power ratings (power the diode can dissipate) run from less than 0.25 W to 50 W. The ability of the Zener diode to stabilize a voltage depends on the diode's conducting impedance. This can be as low as 1 Ω or less in a low-voltage, high-power diode or as high as 1000 Ω in a high-voltage, low-power diode.

The circuit in Fig 7.19 is a *shunt* regulator in that it "shunts" current through a controlling device (the Zener diode) to maintain a constant output voltage. To design a Zener shunt regulator, you must know the minimum and maximum input voltage (E_{DC}); the

Fig 7.19 — Zener-diode voltage regulation. The voltage from a negative supply may be regulated by reversing the power-supply connections and the diode polarity.

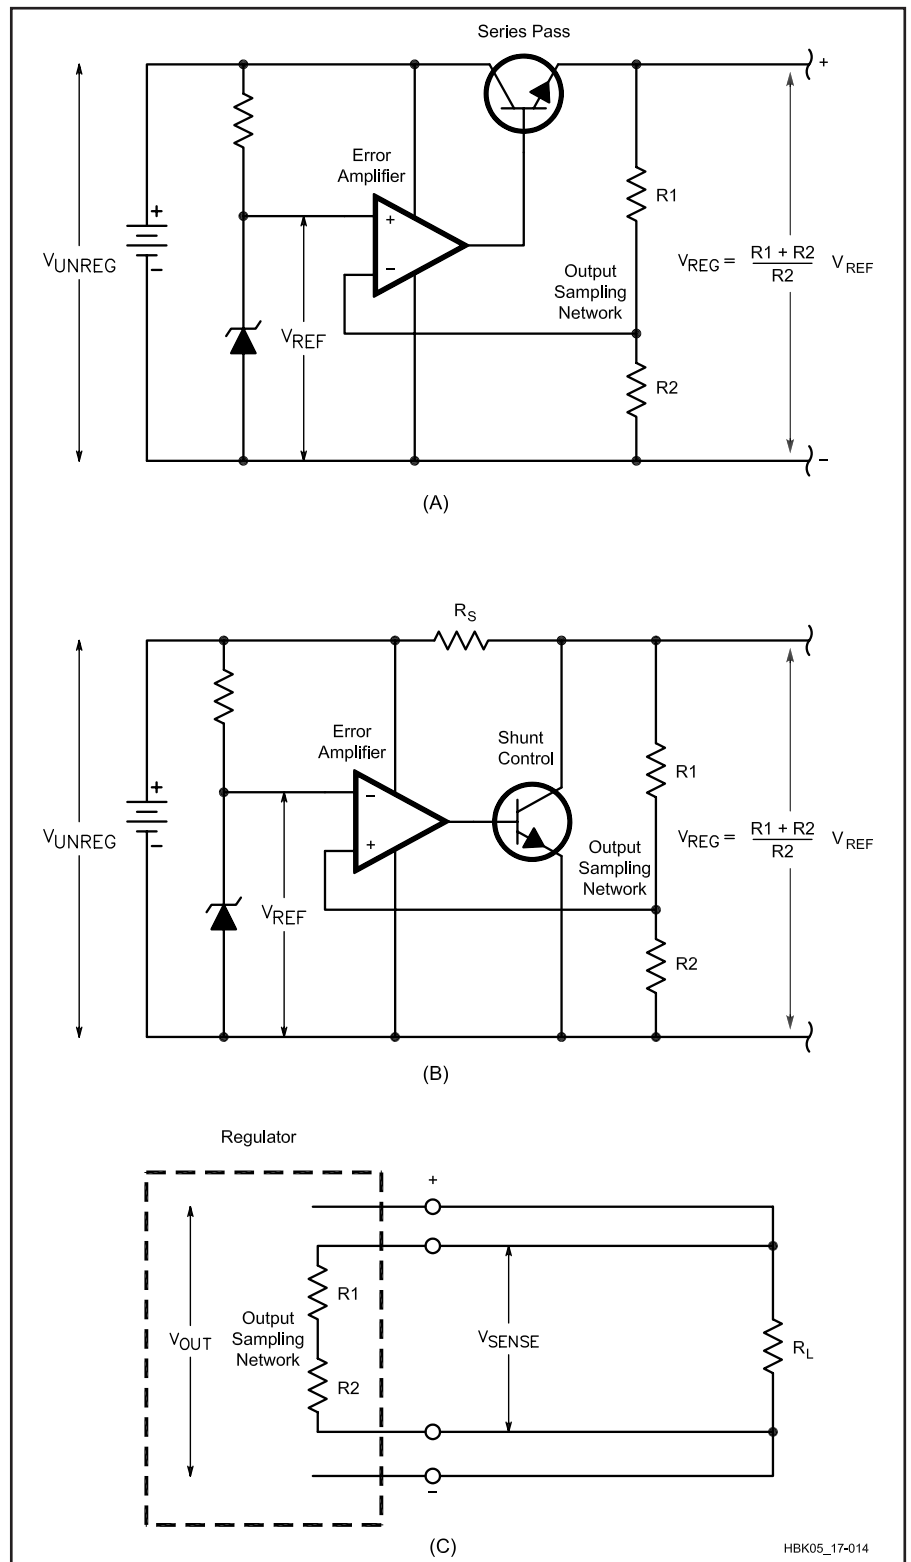

Fig 7.20 — Linear electronic voltage regulator circuits. In these diagrams, batteries represent the unregulated input-voltage source. A transformer, rectifier and filter would serve this function in most applications. Part A shows a series regulator and Part B shows a shunt regulator. Part C shows how remote sensing overcomes poor load regulation caused by the IR drop in the connecting wires by bringing them inside the feedback loop. The use of extra connections to sense voltage is called a "four wire Kelvin connection."

output voltage, which is equal to the Zener diode voltage (E_Z); and the minimum and maximum load current (I_L) through R_L . If the input voltage is variable, you must specify the maximum and minimum values for E_{DC} . As a rule of thumb, the current through the Zener should be 10% of the maximum load current for good regulation and must be greater than the $I_{Z(min)}$ at which the Zener diode maintains its constant voltage drop. Once these quantities are known the series resistance, R_S , can be determined:

$$R_S = \frac{E_{DC(min)} - E_Z}{1.1 I_{L(max)}} \quad (7)$$

The power dissipation of the Zener diode, P_{DZ} , is

$$P_{DZ} = \left[\frac{E_{DC(max)} - E_Z}{R_S} - I_{L(min)} \right] E_Z \quad (8)$$

and of the series resistor, R_S ,

$$P_{DR} = \frac{(E_{DC(max)} - E_Z)^2}{R_S} \quad (9)$$

It is good practice to provide a five times rated power dissipation safety margin for both the series resistor and the Zener diode. This avoids heating in the Zener and the resulting drift in voltage. High-power Zener diodes (10 W dissipation or more) will require heat-sinking as discussed in the section on Managing Heat in the **Electrical Fundamentals** chapter.

7.9.2 Linear Regulators

Linear regulators come in two varieties, *series* and *shunt*, as shown in **Fig 7.20**. The shunt regulator is simply an electronic (also called “active”) version of the Zener diode. For the most part, the active shunt regulator (**Fig 7.20B**) is rarely used since the series regulator is a superior choice for most applications.

The series regulator (**Fig 7.20A**) consists of a stable voltage reference, which is usually established by a Zener diode, a transistor in series between the power source and the load (called a *series pass transistor*), and an error amplifier. In critical applications a temperature-compensated reference diode would be used instead of the Zener diode.

The output voltage is sampled by the error amplifier, which compares the output (usually scaled down by a voltage divider) to the reference. If the scaled-down output voltage becomes higher than the reference voltage, the error amplifier reduces the drive current to the pass transistor, thereby allowing the output voltage to drop slightly. Conversely, if the load pulls the output voltage below the desired value, the amplifier drives the pass transistor into increased conduction.

The “stiffness” or tightness of regulation

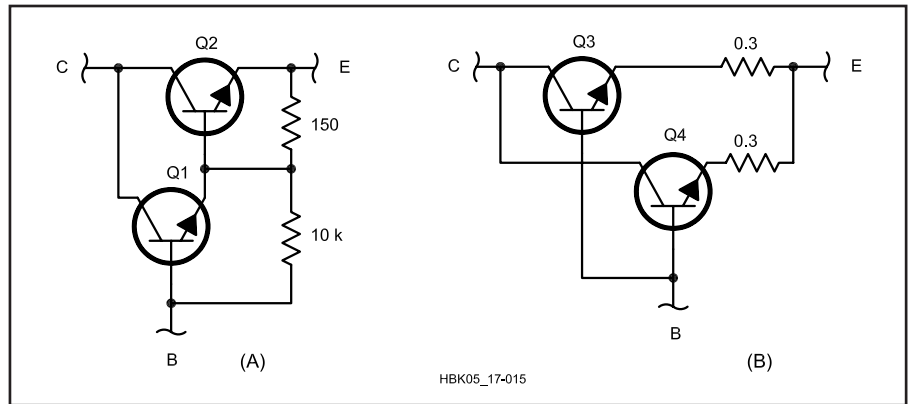

Fig 7.21 — At **A**, a Darlington-connected transistor pair for use as the pass element in a series-regulating circuit. At **B**, the method of connecting two or more transistors in parallel for high-current output. Resistances are in ohms. The circuit at **A** may be used for load currents from 100 mA to 5 A, and the one at **B** may be used for currents from 6 A to 10 A.

Q1 — NPN transistor, MJE340 or equivalent

Q2-Q4 — Power transistor such as 2N3055 or 2N3772

of a linear regulator depends on the gain of the error amplifier and the ratio of the output scaling resistors. In any regulator, the output is cleanest and regulation stiffest at the point where the sampling network or error amplifier is connected. If heavy load current is drawn through long leads, the voltage drop can degrade the regulation at the load. To combat this effect, the feedback connection to the error amplifier can be made directly to the load. This technique, called *remote sensing*, or a *four wire Kelvin connection*, moves the point of best regulation to the load by bringing the connecting loads inside the feedback loop. This is shown in **Fig 7.20C**.

INPUT VERSUS OUTPUT VOLTAGE

In a series regulator, the pass-transistor power dissipation is directly proportional to the load current and input/output voltage differential. The series pass element can be located in either leg of the supply. Either NPN or PNP devices can be used, depending on the ground polarity of the unregulated input.

The differential between the input and output voltages is a design tradeoff. If the input voltage from the rectifiers and filter is only slightly higher than the required output voltage, there will be minimal voltage drop across the series pass transistor. A small drop results in minimal thermal dissipation and high power-supply efficiency. The supply will have less capability to provide regulated power in the event of power line brownout and other reduced line voltage conditions, however. Conversely, a higher input voltage will provide operation over a wider range of input voltage, but at the expense of increased heat dissipation.

7.9.3 Linear Regulator Pass Transistors

DARLINGTON PAIRS

A simple Zener-diode reference or IC op-amp error amplifier may not be able to source enough current to a pass transistor that must conduct heavy load current. The Darlington configuration of **Fig 7.21A** multiplies the pass-transistor beta, thereby extending the control range of the error amplifier. If the Darlington arrangement is implemented with discrete transistors, resistors across the base-emitter junctions may be necessary to prevent collector-to-base leakage currents in Q1 from being amplified and turning on the transistor pair. These resistors are contained in the envelope of a monolithic Darlington device.

When a single pass transistor is not available to handle the current required from a regulator, the current-handling capability may be increased by connecting two or more pass transistors in parallel. The circuit of **Fig 7.21B** shows the method of connecting these pass transistors. The resistances in the emitter leads of each transistor are necessary to equalize the currents.

TRANSISTOR RATINGS

When bipolar (NPN, PNP) power transistors are used in applications in which they are called upon to handle power on a continuous basis, rather than switching, there are four parameters that must be examined to see if any maximum limits are being exceeded. Operation of the transistor outside these limits can easily result in device failure, and these parameters must be considered during the design process.

Fig 7.22 — Typical graph of the safe operating area (SOAR) of a transistor. See text for details. Safe operating conditions for specific devices may be quite different from those shown here.

The four limits are maximum collector current (I_C), maximum collector-emitter voltage (V_{CE0}), maximum power and *second breakdown* (I_{SB}). All four of these parameters are graphically shown on the transistor's data sheet on what is known as a *safe operating area* (SOA) graph. (see **Fig 7.22**) The first three of these limits are usually also listed prominently with the other device information, but it is often the fourth parameter — secondary breakdown — that is responsible for the “sudden death” of the power transistor after an extended operating period.

The maximum current limit of the transistor ($I_{C\ MAX}$) is usually the current limit for fusing of the bond wire connected to the emitter, rather than anything pertaining to the transistor chip itself. When this limit is exceeded, the bond wire can melt and open circuit the emitter. On the operating curve, this limit is shown as a horizontal line extending out from the Y-axis and ending at the voltage point where the constant power limit begins.

The maximum collector-emitter voltage limit of the transistor ($V_{CE\ MAX}$) is the point at which the transistor junctions can no longer withstand the voltage between collector and emitter.

With increasing collector-emitter voltage drop at maximum collector current, a point is reached where the power in the transistor will cause the junction temperature to rise to a level where the device leakage current rapidly increases and begins to dominate. In this region, the product of the voltage drop and the current would be constant and represent the maximum power (P_T) rating for the transistor; that is, as the voltage drop continues to increase, the collector current must decrease to maintain the power dissipation at a constant value.

With most transistors rated for higher voltages, a point is reached on the constant power portion of the curve whereby, with further increased voltage drop, the maximum power rating is *not* constant, but decreases as the collector to emitter voltage increases. This decrease in power handling capability continues until the maximum voltage limit is reached.

This special region is known as the *forward bias second breakdown* (FBSB) area. Reduction in the transistor's power handling capability is caused by localized heating in certain small areas of the transistor junction (“hot spots”), rather than a uniform distribution of power dissipation over the entire surface of the device.

The region of operating conditions contained within these curves is called the safe operating area, or SOA. If the transistor is always operated within these limits, it should provide reliable and continuous service for a long time.

MOSFET TRANSISTORS

The bipolar junction transistor (BJT) is rapidly being replaced by the MOSFET in new power supply designs because MOSFETs are easier to drive. The N-channel MOSFET (equivalent to the NPN bipolar) is more

popular than the P-channel for pass transistor applications.

There are some considerations that should be observed when using a MOSFET as a linear regulator series pass transistor. Several volts of gate drive are needed to start conduction of the device, as opposed to less than 1 V for the BJT. MOSFETs are inherently very-high-frequency devices and will readily oscillate with stray-circuit capacitances. To prevent oscillation in the transistor and surrounding circuits, it is common practice to insert a small resistor of about 100 Ω directly in series with the gate of the series-pass transistor to reduce the gate circuit Q.

OVERCURRENT PROTECTION

Damage to a pass transistor can occur when the load current exceeds the safe amount. **Fig 7.23A** illustrates a simple current-limiter circuit that will protect Q1. All of the load current is routed through R1. A voltage difference will exist across R1; the value will depend on the exact load current at a given time. When the load current exceeds a predetermined safe value, the voltage drop across R1 will forward-bias Q2 and cause it to conduct. Because Q2 is a silicon transistor, the voltage drop across R1 must exceed 0.6 V to

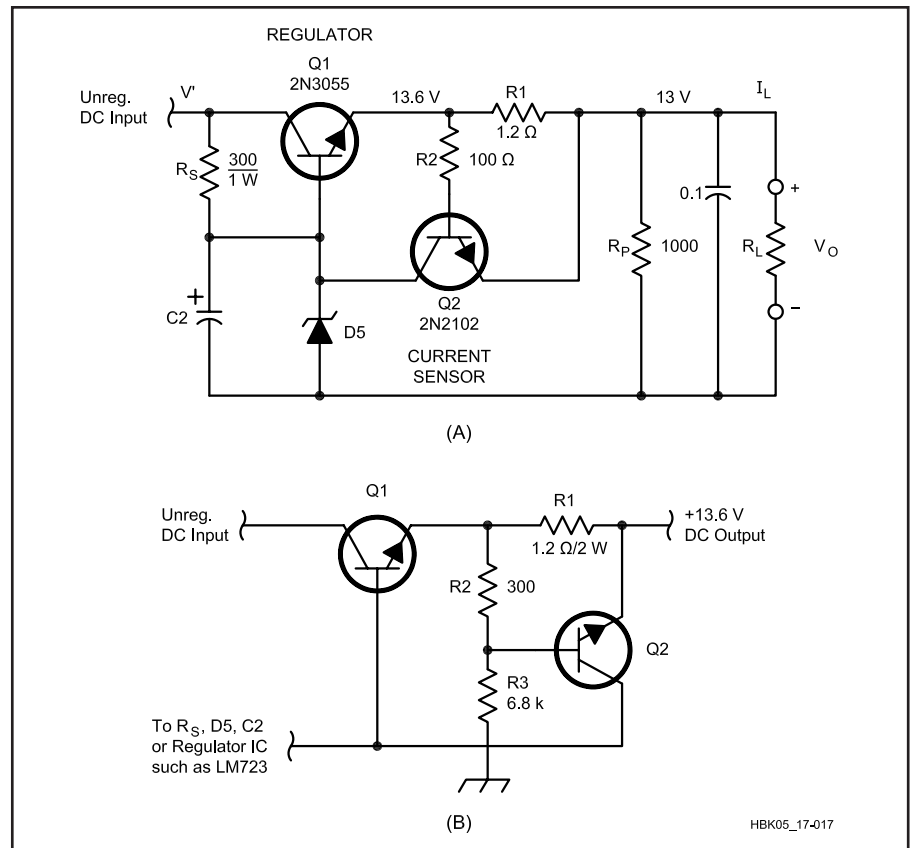

Fig 7.23 — Overload protection for a regulated supply can be implemented by addition of a current-overload-protective circuit, as shown at A. At B, the circuit has been modified to employ current-foldback limiting.

turn Q2 on. This being the case, R1 is chosen for a value that provides a drop of 0.6 V when the maximum safe load current is drawn. In this instance, the drop will be 0.6 V when I_L reaches 0.5 A. R2 protects the base-emitter junction of Q2 from current transients, or from destruction in the event Q1 fails under short-circuit conditions.

When Q2 turns on, some of the current through R_S flows through Q2, thereby depriving Q1 of some of its base current. This action, depending upon the amount of Q1 base current at a precise moment, cuts off Q1 conduction to some degree, thus limiting the current through it.

FOLDBACK CURRENT LIMITING

Under short-circuit conditions, a constant-current type current limiter must still withstand the full source voltage and limited short-circuit current simultaneously, which can impose a very high power dissipation or second breakdown stress on the series pass transistor. For example, a 12 V regulator with current limiting set for 10 A and having a source of 16 V will have a dissipation of 40 W $[(16 \text{ V} - 12 \text{ V}) \times 10 \text{ A}]$ at the point of current limiting (knee). But its dissipation will rise to 160 W under short-circuit conditions $(16 \text{ V} \times 10 \text{ A})$.

A modification of the limiter circuit can cause the regulated output current to decrease with decreasing load resistance beyond the over-current knee. With the output shorted, the output current is only a fraction of the knee current value, which protects the series-pass transistor from excessive dissipation and possible failure. Using the previous example of the 12 V, 10 A regulator, if the short-circuit current is designed to be 3 A (the knee is still 10 A), the transistor dissipation with a short circuit will be only $16 \text{ V} \times 3 \text{ A} = 48 \text{ W}$.

Fig 7.23B shows how the current-limiter

Fig 7.24 — The 1 A regulator shown in Fig 7.23B will fold back to 0.5 A under short-circuit conditions. See text.

example given in the previous section would be modified to incorporate foldback limiting. The divider string formed by R2 and R3 provides a negative bias to the base of Q2, which prevents Q2 from turning on until this bias is overcome by the drop in R1 caused by load current. Since this hold-off bias decreases as the output voltage drops, Q2 becomes more sensitive to current through R1 with decreasing output voltage. See Fig 7.24.

The circuit is designed by first calculating the value of R1 for short-circuit current. For example, if 0.5 A is chosen, the value for R1 is simply $0.6 \text{ V} / 0.5 \text{ A} = 1.2 \Omega$ (with the output shorted, the amount of hold-off bias supplied by R2 and R3 is very small and can be neglected). The knee current is then chosen. For this example, the selected value will be 1.0 A. The divider string is then proportioned to provide a base voltage at the knee that is just sufficient to turn on Q2 (a value of 13.6 V for 13.0 V output). With 1.0 A flowing through R1, the voltage across the divider will be 14.2 V. The voltage dropped by R2 must then be $14.2 \text{ V} - 13.6 \text{ V}$, or 0.6 V. Choosing a divider current of 2 mA, the value of R2 is then $0.6 \text{ V} / 0.002 \text{ A} = 300 \Omega$. R3 is calculated to be $13.6 \text{ V} / 0.002 \text{ A} = 6800 \Omega$.

7.9.4 Three-Terminal Voltage Regulators

The modern trend in regulators is toward the use of three-terminal devices commonly referred to as *three-terminal regulators*. Inside each regulator is a voltage reference, a high-gain error amplifier, temperature-compensated voltage sensing resistors and a pass element. Many currently available units have thermal shut-down, overvoltage protection and current foldback, making them virtually destruction-proof. It is easy to see why

regulators of this sort are so popular when you consider the low price and the number of individual components they can replace.

Three-terminal regulators have connections for unregulated dc input, regulated dc output and ground, and they are available in a wide range of voltage and current ratings. Fixed-voltage regulators are available with output ratings in most common values between 5 and 28 V. Other families include devices that can be adjusted from 1.25 to 50 V.

The regulators are available in several different package styles, depending on current ratings. Low-current (100 mA) devices frequently use the plastic TO-92 and DIP-style cases. TO-220 packages are popular in the 1.5 A range, and TO-3 cases house the larger 3 A and 5 A devices. They are available in surface mount packages too.

Three-terminal regulators are available as positive or negative types. In most cases, a positive regulator is used to regulate a positive voltage and a negative regulator a negative voltage. Depending on the system ground requirements, however, each regulator type may be used to regulate the “opposite” voltage.

Fig 7.25A and B illustrate how the regulators are used in the conventional mode. Several regulators can be used with a common-input supply to deliver several voltages with a common ground. Negative regulators may be used in the same manner. If no other common supplies operate from the input supply to the regulator, the circuits of Fig 7.25C and D may be used to regulate positive voltages with a negative regulator and vice versa. In these configurations the input supply is floated; neither side of the input is tied to the system ground.

Manufacturers have adopted a system of

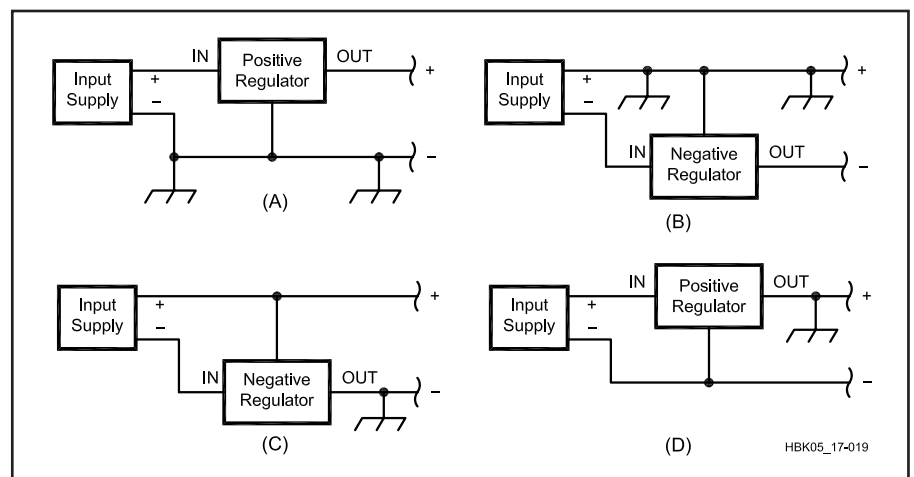

Fig 7.25 — Parts A and B illustrate the conventional manner in which three-terminal regulators are used. Parts C and D show how one polarity regulator can be used to regulate the opposite-polarity voltage.

family numbers to classify three-terminal regulators in terms of supply polarity, output current and regulated voltage. For example, 7805 describes a positive 5 V, 1.5 A regulator and 7905 a negative 5 V, 1.5 A unit. Depending on the manufacturer, the full part number might have a prefix such as LM, UA or MC, along with various suffixes (for example, LM7805CT or MC7805CTG). There are many such families with widely varied ratings available from manufacturers. More information may be found in the **Component Data and References** chapter.

SPECIFYING A REGULATOR

When choosing a three-terminal regulator for a given application, the most important specifications to consider are device output voltage, output current, minimum and maximum input-to-output differential voltages, line regulation, load regulation and power dissipation. Output voltage and current requirements are determined by the load with which the supply will ultimately be used.

Input-to-output differential voltage is one of the most important three-terminal regulator specifications to consider when designing a supply. The differential value (the difference between the voltage applied to the input terminal and the voltage on the output terminal) must be within a specified range. The minimum differential value, usually about 2.5 V, is called the *dropout voltage*. If the differential value is less than the dropout voltage, no regulation will take place. Special *low dropout regulators* with lower minimum differential values are available as well. At the other end of the scale, maximum input-output differential voltage is generally about 40 V. If this differential value is exceeded, device failure may occur.

Increases in either output current or differential voltage produce proportional increases in device power consumption. By employing current foldback, as described above, some manufacturers ensure that maximum dissipation will never be exceeded in normal operation. **Fig 7.26** shows the relationship between output current, input-output differential and current limiting for a three-terminal regulator nominally rated for 1.5 A output current. Maximum output current is available with differential voltages ranging from about 2.5 V (dropout voltage) to 12 V. Above 12 V, the output current decreases, limiting the device dissipation to a safe value. If the output terminals are accidentally short circuited, the input-output differential will rise, causing current foldback, and thus preventing the power-supply components from being over stressed. This protective feature makes three-terminal regulators particularly attractive in simple power supplies.

When designing a power supply around

Fig 7.26 — Effects of input-output differential voltage on three-terminal regulator current.

Fig 7.27 — By varying the ratio of R2 to R1 in this simple LM317 schematic diagram, a wide range of output voltages is possible. See text for details.

Fig 7.28 — The basic LM317 voltage regulator is converted into a constant-current source by adding only one resistor.

a particular three-terminal regulator, input-output voltage characteristics of the regulator should play a major role in selecting the transformer-secondary and filter-capacitor component values. The unregulated voltage applied to the input of the three-terminal device should be higher than the dropout voltage, yet low enough that the regulator does not go into current limiting caused by an excessive differential voltage. If, for

example, the regulated output voltage of the device shown in Fig 7.26 were 12 V, then unregulated input voltages of between 14.5 and 24 V would be acceptable if maximum output current is desired.

In use, all but the lowest-current regulators generally require an adequate external heat sink because they may be called on to dissipate a fair amount of power. Also, because the regulator chip contains a high-gain error amplifier, bypassing of the input and output leads is essential for stable operation.

Most manufacturers recommend bypassing the input and output directly at the leads where they protrude through the heat sink. Solid tantalum capacitors are usually recommended because of their good high-frequency capabilities.

External capacitors used with IC regulators may discharge through the IC junctions under certain circuit conditions, and high-current discharges can harm ICs. Look at the regulator data sheet to see whether protection diodes are needed, what diodes to use and how to place them in any particular application.

Adjustable Regulators

In addition to fixed-output-voltage ICs, high-current, adjustable voltage regulators are available. These ICs require little more than an external potentiometer for an adjustable output range from 5 to 24 V at up to 5 A. The unit price on these items is only a few dollars, making them ideal for test-bench power supplies. A very popular low current, adjustable output voltage three terminal regulator, the LM317, is shown in **Fig 7.27**. It develops a steady 1.25 V reference, V_{REF} between the output and adjustment terminals. By installing R1 between these terminals, a constant current, I1, is developed, governed by the equation:

$$I_1 = \frac{V_{REF}}{R_1} \quad (10)$$

Both I1 and a 100 μ A error current, I2, flow through R2, resulting in output voltage V_O . V_O can be calculated using the equation:

$$V_O = V_{REF} \left(1 + \frac{R_2}{R_1} \right) + I_2 \times R_2 \quad (11)$$

Any voltage between 1.2 and 37 V may be obtained with a 40 V input by changing the ratio of R2 to R1. At lower output voltages, however, the available current will be limited by the power dissipation of the regulator.

Fig 7.28 shows one of many flexible applications for the LM317. By adding only one resistor with the regulator, the voltage regulator can be changed into a constant-current source capable of charging NiCd batteries, for example. Design equations are given in the figure. The same precautions should be

taken with adjustable regulators as with the fixed-voltage units. Proper heat sinking and lead bypassing are essential for proper circuit operation.

INCREASING REGULATOR OUTPUT CURRENT

When the maximum output current from an IC voltage regulator is insufficient to operate the load, discrete power transistors may be connected to increase the current capability. **Fig 7.29** shows two methods for boosting the output current of a positive regulator, although the same techniques can be applied to negative regulators.

In A, an NPN transistor is connected as an emitter follower, multiplying the output current capacity by the transistor beta. The shortcoming of this approach is that the base-emitter junction is not inside the feedback loop. The result is that the output voltage is reduced by the base-emitter drop, and the load regulation is degraded by variations in this drop.

The circuit at B has a PNP transistor

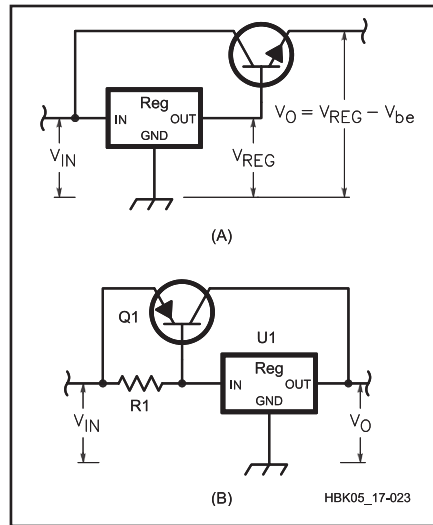

Fig 7.29 — Two methods for boosting the output-current capacity of an IC voltage regulator. Part A shows an NPN emitter follower and B shows a PNP “wrap-around” configuration. Operation of these circuits is explained in the text.

“wrapped around” the regulator. The regulator draws current through the base-emitter junction, causing the transistor to conduct. R1 provides bias voltage for turning on Q1

so that U1 doesn’t see the excess current. For example, a 6 Ω resistor will limit the current U1 sees to 100 mA. The IC output voltage is unchanged by the transistor because the collector is connected directly to the IC output (sense point). Any increase in output voltage is detected by the IC regulator, which shuts off its internal-pass transistor, and this stops the boost-transistor base current.

7.10 “Crowbar” Protective Circuits

Electronic components *do* fail from time to time. In a regulated power supply, the only component standing between an elevated dc source voltage and your transceiver is one transistor, or a group of transistors wired in parallel. If the transistor, or one of the transistors in the group, happens to short internally, your equipment could suffer lots of damage.

To safeguard the load equipment against possible overvoltage, some power-supply manufacturers include a circuit known as a *crowbar*. This circuit usually consists of a

silicon-controlled rectifier (SCR) or thyristor connected directly across the output of the power supply, with an over-voltage-sensing trigger circuit tied to its gate. The SCR is large enough to take the full short-circuit output current of the supply, as if a crowbar were placed across the output terminals, thus the name.

In the event the output voltage exceeds the trigger set point, the SCR will fire, and the output is short circuited. The resulting high current in the power supply (shorted

output in series with a series pass transistor failed short) will blow the power supply’s line fuses. This is a protection for the supply as well as an indicator that something has malfunctioned internally. For these reasons, never replace blown fuses with ones that have a higher current rating.

An example of a crowbar overvoltage protection circuit can be found as a project at the end of this chapter. It provides basic design equations that can be adapted to a wide range of power supply applications.

7.11 DC-DC Switchmode Power Conversion

Very often the power source is dc, such as a battery or solar cell, or the output of an unregulated rectifier connected to an ac source. In most applications high conversion efficiency is desired, both to conserve energy from the source and to reduce heat dissipation in the converter. When high efficiency is needed, some form of switching circuit will be employed for dc-dc power conversion. Besides being more efficient, switching circuits are usually much smaller and lighter than conventional 60Hz, transformer-rectifier circuits because they operate at much higher frequencies — from 25 to 400 kHz or even higher. Switching circuits go by many names; *switching regulators* and *switchmode converters* are just two of the more common names.

The possibility of achieving high conversion efficiency stems directly from the use of switches for the power conversion process, along with low-loss inductive and capacitive elements. An active switch is a device that is either ON or OFF and the state of the switch (ON or OFF) can be controlled with an external signal. The loss in the switch is always the product of the voltage across the switch and the current flowing through it ($P = E \times I$).

In the ON (conducting) state the voltage drop across the switch is small, and in the OFF state the current through the switch is small. In both cases the losses can be small relative to the power level of the converter. During transitions between ON and OFF states, however, there will simultaneously be both substantial voltage across the switch and significant current flowing through it. This results in power dissipation in the switch, called *switching loss*. This loss is minimized by making the switching transitions as short as possible. In this way even though the instantaneous power dissipation may be high, the average loss is low because of the small duty cycle of the transitions. Of course the more frequently the switch operates (higher switching frequency), the higher the average loss will be and this eventually limits the maximum operating frequency. A limitation on the lower end of the switching frequency range is that it needs to be above audible frequencies (>25 kHz).

This is quite different from the linear regulators discussed earlier in which there is always some voltage drop across the pass transistor (which is acting as a controlled variable resistor) while current is flowing through it. As a result the efficiency of a linear regulator can be very low, often 65% or less. Switchmode converters on the other hand will typically have efficiencies in the range of 85 to 95%.

Switchmode circuits can also generate radio-frequency interference (RFI) through VHF because of switching frequency

harmonics and ringing induced by the rapid rise and fall times of voltage and current. In attempting to minimize the ON-OFF transition time, significant amounts of RF energy can be generated. To prevent RFI to sensitive receivers, careful bypassing, shielding and filtering of both input and output circuits is required. (RFI from switchmode or “switching” supplies is also discussed in the chapter on **RF Interference**.)

There are literally hundreds of different switchmode circuits or “topologies” (see Reference 2) but we will only look at a few of those most commonly used by amateurs. Fortunately, the characteristics of the simpler circuits are to a large extent replicated in more complex circuits so that an understanding of the basic circuits provides an entry point to many other circuits.

The following discussion is only an introduction to the basics of switchmode converters. To really get a handle on designing these circuits the reader will have to do some additional reading. Fortunately a very large amount of useful information is freely available on-line. Many useful application notes are available from semiconductor manufacturers, and additional information can be found on the websites of filter capacitor and ferrite core manufacturers (see References 3 and 4). There are also numerous books on

the subject, often available in libraries and used book stores.

Switchmode circuits can and have been implemented with many different kinds of switches, from mechanical vibrators to vacuum and gas tubes to semiconductors. Today however, semiconductors are the universal choice. For converters in the power range typical of amateur applications (a few watts through 2-3 kW) the most common choices of semiconductor switches would be either bipolar junction transistors (BJTs) or power MOSFETs. BJTs have a long history of use in switchmode applications, but to employ BJTs in a reliable and trouble-free circuit requires a relatively sophisticated understanding of them. While the MOSFET must also be used carefully, it is generally easier for a newcomer. The following circuit diagrams will show MOSFETs or generic switch symbols for the switches but keep in mind that all of the circuits can be implemented with other types of switches.

7.11.1 The Buck Converter

A schematic for a *buck converter* is shown in Fig 7.30A. This circuit is called a “buck” converter because the output voltage is always less than or equal to the input voltage. Power is supplied from the dc source (V_s) through

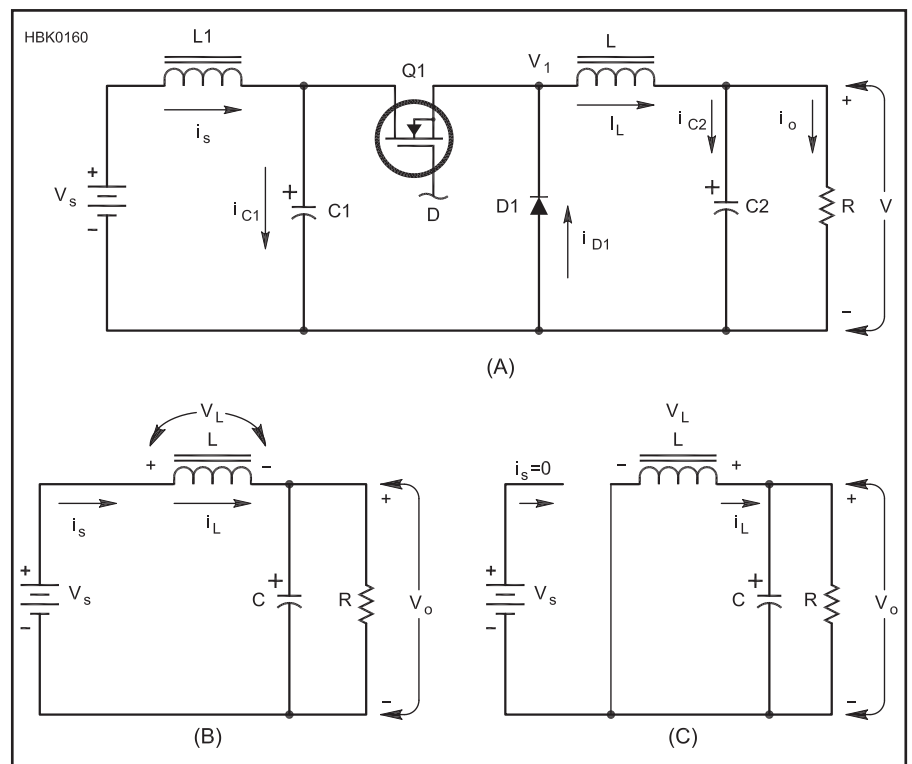

Fig 7.30 — Typical buck converter.

Fig 7.31 — Waveforms in a buck converter.

the input filter (L1, C1) to the drain of the switch (Q1). The load (R) is connected across the output filter (L, C2).

The equivalent circuit when Q1 is ON is shown in Fig 7.30B (where the input filter components are assumed to be part of V_S). V_S is connected to one end of the output inductor (L) and, because $V_O < V_S$, current flows from the source to the output delivering energy from the source to the output and also storing energy in L. At some point Q1 is turned OFF and the current flowing in L commutates (switches) to D1, as shown in Fig 7.30C. (The current in an inductor cannot change instantaneously, so when Q1 turns OFF, the collapsing magnetic field in L pulls current through shunt diode D1, called a *free-wheeling diode*.) The energy in L is now being discharged into the output. This cycle is repeated at the switching frequency (f_s). The ratio of the switch ON-time to the total switching period ($T_s = t_{on} + t_{off} = 1/f_s$) is called the *duty cycle (D)*.

Typical voltage and current waveforms for a buck converter are shown in **Fig 7.31** where V_1 is the voltage at the junction of Q1, D1 and L (see Fig 7.30A).

The interval $0-t_1$ corresponds to the ON time of Q1 and $T_s - t_1$ corresponds to the OFF time ($T_s = t_1 + t_2$). From the waveforms it can be seen that the current in the inductor rises while Q1 is ON and falls while Q1 is OFF. The energy in the inductor is proportional to $L I^2/2$.

The input current (I_s) is pulsating at the switching frequency. This pulsation in the input current is the reason for the input filter (L1 and C1). We need to keep this high frequency noise (the ac component of the pulsation) out of the source. All switchmode converters require some form of filter on the input to

Fig 7.32 — Change in output voltage to input voltage ratio ($M=V_O/V_S$) as a function of switch duty cycle (D).

keep switching noise out of the source. Some form of filter is also required on the output to keep the switching noise out of the load. In Fig 7.30, L and C2 form the output filter. For applications requiring low ripple it would not be unusual to see an additional stage of L-C filtering added to the output.

The voltage waveform (V_1) at the input to the output filter (L and C2) is pulse-width modulated (PWM) and V_O (the dotted line in the waveform for V_1 in Fig 7.31A) is the time average of V_1 . V_O is controlled or regulated by adjusting the duty cycle of Q1 in response to input voltage or output load changes. If we increase D we increase V_O up to the point where $D = 1$ (the switch is ON all the time) and $V_O \approx V_S$. If we never turn Q1 on ($D = 0$) then $V_O = 0$. Normal operation will be somewhere between these extremes.

The inductor current waveform in Fig 7.31 does not go to zero while Q1 is OFF. In other words, not all of the energy stored in L is discharged into the output by the end of each switching cycle. This is a common mode of operation for heavier loads. It is referred to as the *continuous conduction mode* or CCM, where the conduction referred to is the current in L. There is another possibility: during the time Q1 is off all of the energy in L may be discharged and for some period of time the inductor current is zero until Q1 is turned ON again. This is referred to as the *discontinuous conduction mode* or DCM. A typical converter will operate in CCM for heavy loads but as the load is reduced, at some point the circuit operation will change to DCM. CCM is often referred to as the “heavy load” condition and DCM as the “light load” condition.

This distinction turns out to be very important because the behavior of the circuit, for

both small signal and large signal, is radically different between the two modes. **Fig 7.32** shows the relationship between the duty cycle (D) of Q1 and the ratio of the output voltage to the input voltage ($M = V_O/V_S$) as a function of τ_L in Fig 7.32:

$$\tau_L = \left(\frac{L}{R} \right) f_s \quad (12)$$

τ_L is just a convenient way to make Fig 7.32 more general by tying together the variables L, R and f_s . Smaller values for τ_L correspond to lighter loads (larger values for R). As can be seen in Fig 7.32, for very light loads the higher values for D have little effect on the output/input voltage ratio. This is basically charging of the output capacitor (C2) to the peak value of $V_1 \approx V_S$.

For CCM operation, M is a linear function of D. As we vary the load, V_O will remain relatively constant. But when we go into DCM, the relation between D and M is no longer linear and in addition is heavily dependent on the load: V_O will vary as the load is changed unless the duty cycle is varied to compensate. This kind of behavior is typical of all switching regulators, even those not directly related to the buck converter. In fact, we have seen this behavior already in the section on choke input filters in Fig 7.17 where the output voltage is close to the peak input voltage for light loads and decreases as the load increases until a point is reached (I_C) where V_O stabilizes.

In a buck converter the value for the critical inductance (L_C) can be found from:

$$L_C = R \left(\frac{1-M}{2f_s} \right) \quad (13)$$

This looks just like equation 6 (in the earlier section on choke-input filters) with

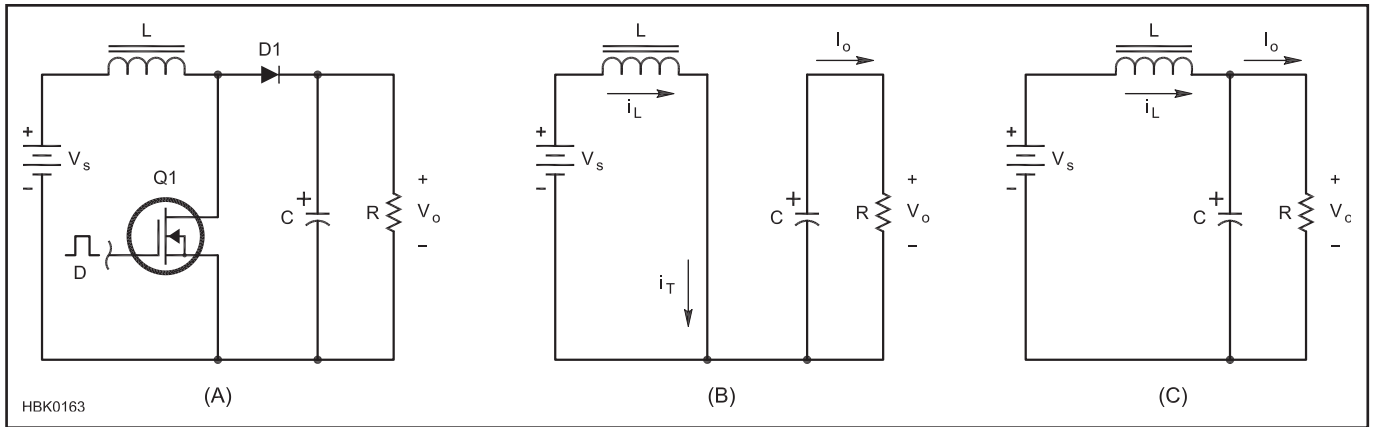

Fig 7.33 — Typical boost converter.

$A = 2fs / (1 - M)$! The two phenomena are the same: peak charging versus averaging of V_L .

7.11.2 The Boost Converter

A *boost converter* circuit is shown in Fig 7.33A. This circuit is called a “boost” converter because the output voltage is always greater than or equal to the input voltage.

When Q1 is ON (Fig 7.33B), L is connected in parallel with the source (V_s) and energy is stored in it. During this time interval load energy is supplied from C. When Q1 turns OFF (Fig 7.33C), L is connected via D1 to the output and the energy in L, plus additional energy from the source, is discharged into the output. The value for L, V_s and length of time it is charged determines the energy stored in L. Again we have the possibilities that either some (CCM) or all (DCM) the energy in L is discharged during the OFF-time of Q1. The variation in the ratio of the output-to-input voltage (M) with duty cycle is shown in Fig 7.34.

As we saw in the buck converter, the conduction mode of L is important. In an ideal converter operating in CCM, the output voltage is substantially independent of load and $M \approx 1 / (1 - D)$. In realistic boost converters there is an important limit on the CCM value for M. In an ideal boost converter you could make the boost ratio (M) as large as you wish but in real converters the parasitic resistances associated with the components will limit the maximum value of M as indicated by the dashed line for CCM operation. The exact shape of this part of the control function will depend on the ratio of the parasitic resistance within the converter to the load resistance (see Reference 2).

There is also another very important practical effect of this limitation on the peak value for M. When the duty cycle is increased beyond the point of maximum M (this occurs at $D = 0.9$ in Fig 7.34), the sign of the slope of the control function changes so that the control loop will change from negative feedback to

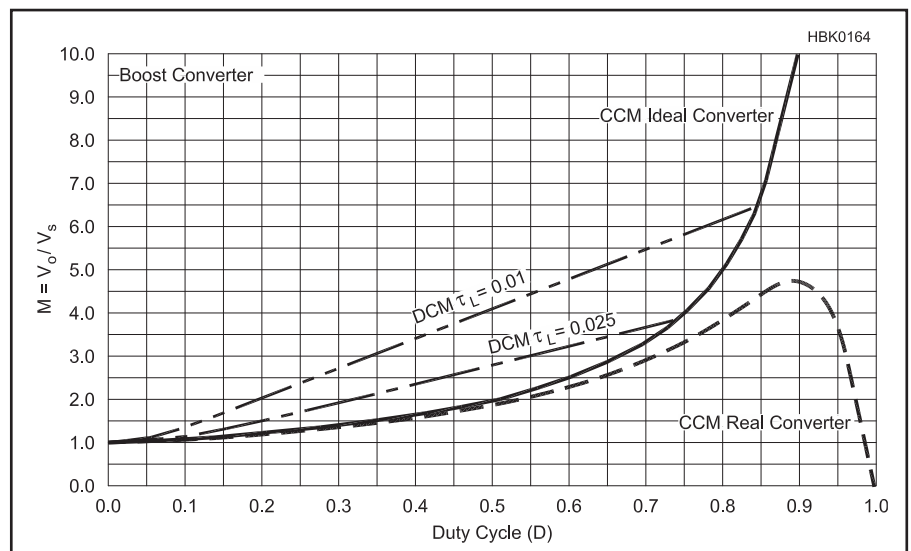

Fig 7.34 — DC control characteristic for a boost converter. $M = V_o/V_s$, $D =$ duty cycle of Q1 and $\tau_L = f_s (L/R)$.

positive feedback. This can cause the converter to latch up under some load conditions if the control circuit allows D to exceed the value at maximum M. In boost converters the design of the control circuit must limit the maximum value for D so that latch-up is not possible although this may be difficult for overload conditions.

As in the case of the buck converter, in DCM the control function for M is very different from what it is in CCM and is strongly dependent on the load R. One advantage of the DCM operation is that the limitation on the maximum value for M because of parasitic circuit resistances is not nearly so pronounced. By operating in DCM it is possible to have $M > 5$.

An important limitation of the boost converter is that with Q1 turned OFF, you have no control over V_o . V_o will simply equal V_s . In addition, when V_s is turned on there will be an inrush current through D1, into C which

cannot be controlled by Q1. In the case of the buck converter, if Q1 is kept OFF when V_s is turned on, there will be no inrush current charging the output filter capacitor (C2). In the buck converter C2 can be charged slowly by ramping up the duty cycle of Q1 during turn-on but this is not possible in the boost converter.

7.11.3 Buck-Boost and Flyback Converters

Fig 7.35 shows an example of a *buck-boost converter*. The name “buck-boost” comes from the fact that the magnitude of the output voltage can be either greater or less than the input voltage.

When S1 is ON, V_s is applied across L and energy is stored in it. During the ON time of Q1, D1 is reverse-biased and non-conducting. The output voltage (V_o) across the load (R) is supported solely from the energy

Fig 7.35 — An example of a buck-boost converter.

stored in C. When S1 is OFF, the energy in L is discharged into C through D1. Note that the polarity of V_o is inverted from V_s : *positive V_s means negative V_o* . The relationship between V_o and V_s as a function of duty cycle is shown in **Fig 7.36**.

This graph closely resembles that for the boost converter (Fig 7.34) with one important exception: $|M|$ begins at zero. This allows the magnitude of the output voltage to be either below or above the source voltage, hence the name “buck-boost.”

FLYBACK CONVERTERS

Simple buck-boost converters are occasionally used, but much more often it is the transformer-coupled version of this converter, referred to as a *flyback converter*, that is employed. The relationship between the flyback and buck-boost converters is illustrated in

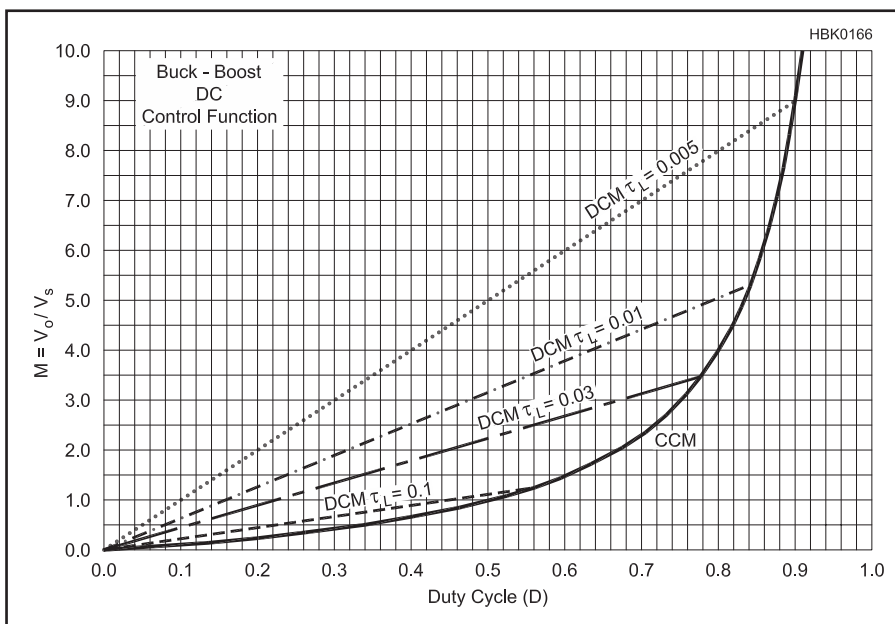

Fig 7.36 — DC control function for an ideal buck-boost converter. $M = V_o/V_s$, $D =$ duty cycle of Q1 and $\tau_L = f_s(L/R)$.

Fig 7.37 — The relationship between buck-boost and flyback converters.

Fig 7.37. In Fig 7.37A we have a standard buck-boost converter, the only change from Fig 7.35 being two parallel and equal windings on the inductor. In Fig 7.37B we remove the links at the top and bottom of the two parallel windings, converting the inductor into a transformer with primary and secondary windings. The only change is that when S1 is ON, current flows in the primary of the transformer and when S1 is OFF, the current flows in the secondary winding delivering the stored energy to the output. At this point the circuit operation is the same except that we have introduced primary-to-secondary galvanic isolation.

We are now free to change the turns ratio from 1:1 to anything we wish. We can also change the polarity of the output voltages and/or add more windings with other voltages and additional loads as shown in Fig 7.37C, a typical example of a flyback converter. These are most often used in the power range of a few watts to perhaps 200 W. For higher power levels other circuits are generally more useful.

The advantages of the flyback converter lie in its simplicity. It requires only one power switch and one diode on each of the output windings. The inductor is also the isolation transformer so you have only one magnetic component. The disadvantage of this circuit is that both in the input and output current waveforms are pulsating. The result is that more filtering is required and the filter capacitors are exposed to high RMS currents relative to the power level.

7.11.4 The Forward Converter

The buck converter has many useful properties but it lacks input-to-output galvanic isolation, the ability to produce output voltages higher than the input voltage, and/or multiple isolated output voltages for multiple loads. We can overcome these drawbacks by inserting a transformer between the switch (S1) and the shunt diode (D1). To make this simple idea work however, we also have to add a diode in series with the output of the transformer (D2), and a third winding (N_R) with another diode (D3) to the transformer. This is done to provide a means for resetting the core (returning the magnetic flux to zero) by the end of each switching cycle. The result is the *forward converter* shown in **Fig 7.38**.

The circuit in A is the one just described. The variation in B uses two switches (S1 and S2, which switch ON and OFF *simultaneously*) instead of one but eliminates the need for a reset winding on the transformer. For the circuit in A and a given input voltage, the voltage across the switch (in the OFF state) will be equal to V_s plus the reset voltage during the OFF-time. Typically the peak switch voltage will be about $2V_s$. In the circuit shown in B the switch voltage is limited to V_s which is

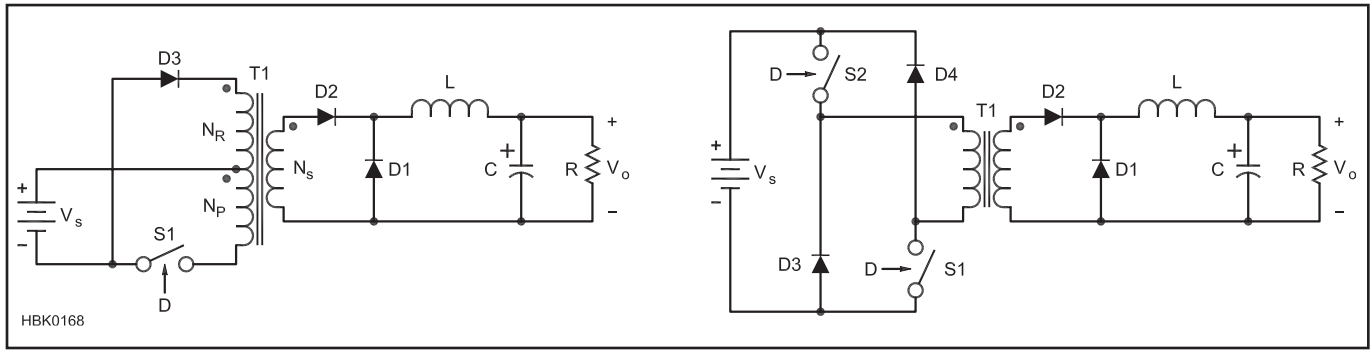

Fig 7.38 — Example of a forward converter.

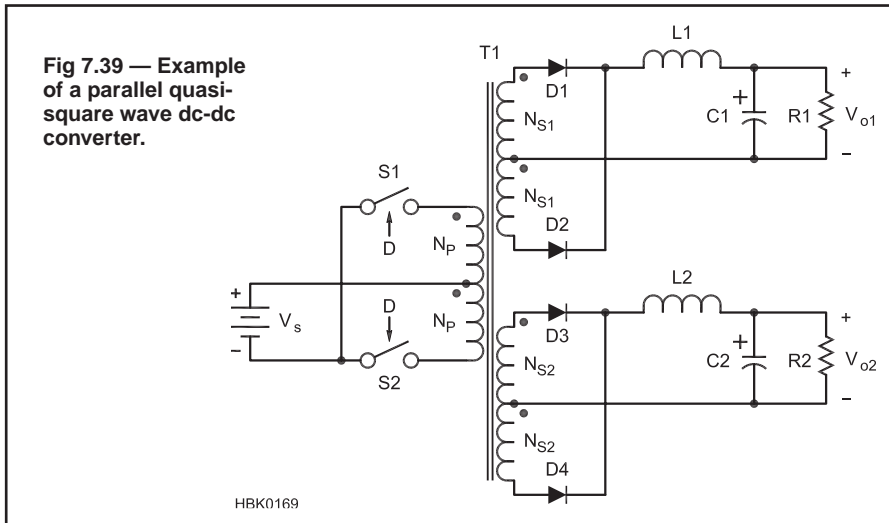

Fig 7.39 — Example of a parallel quasi-square wave dc-dc converter.

output and ± 12 V, lower-current outputs, for example. This converter is typically used for operation from vehicular power with loads up to several hundred watts.

Operating directly from rectified ac utility power usually means that V_s will be 200 V or more. For these applications, Fig 7.40 shows how the switches are configured in either a half- (Fig 7.40A) or full-bridge (Fig 7.40B) circuit.

In A, S1 and S2 switch alternately and are pulse-width modulated (PWM) to control the output. CA and CB are large capacitors that form a voltage divider with $V_s/2$ across each capacitor. The peak switch voltages will be equal to V_s but the switch currents will be $2I_s$. The peak voltage across the primary winding will be $V_s/2$. This circuit would typically be used for off-line applications with output powers of 500 W or so.

In B, S1 and S4 switch simultaneously alternating with S2 and S3 which also switch simultaneously. The output is controlled by PWM. The peak switch voltage will be equal to V_s and the peak switch current close to I_s (the peak value is a little higher due to ripple on the inductor current which is reflected back into the primary winding). The full-bridge circuit is typically used for power levels of 500 W to several kW. C_s is present in the full-bridge circuit to prevent core saturation due to any asymmetry in the primary PWM voltage waveforms.

very helpful at higher line voltages. These circuits behave just like a buck converter except you can now have multiple isolated outputs with arbitrary voltages and polarities. These circuits are typically used in converters with power levels of 100 to 500 W.

7.11.5 Parallel, Half and Full-Bridge Converters

As the power level increases it becomes advantageous to use more switches in a somewhat more complex circuit. For applications

where the input voltage is low (<100 V) and the current high, the push-pull *quasi-square wave* circuit shown in Fig 7.39 is often used.

S1 and S2 are switched on alternately with duty cycles <0.5 . The output voltages are controlled by the duty cycle, D. The peak switch currents are equal to the input current but the peak switch voltages will be $2V_s$.

This circuit is still just a buck converter, but with an isolation transformer added that allows multiple outputs with different voltages above or below the input voltage. It would be very common to have a 5 V, high-current

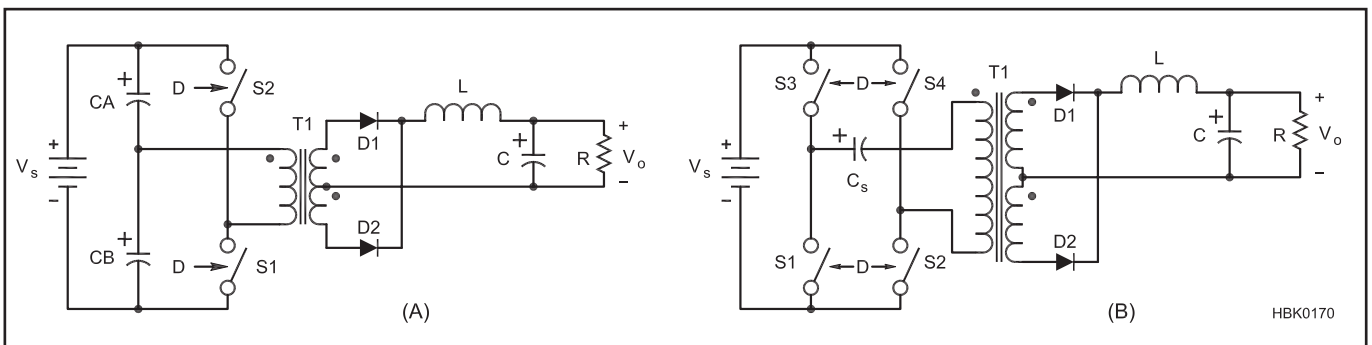

Fig 7.40 — Examples of half and full-bridge quasi-square wave dc-dc converters.

7.11.6 Building Switchmode Power Supplies

Selecting a switching circuit or topology is just the first step in building a practical switchmode power supply. In the actual circuit you will have to sample the output voltage, provide a voltage reference against which to compare the output, include a modulator that will convert the error voltages to a variable-duty cycle signal and finally provide correct drive to the power switches. Fortunately, all of these functions can be provided with readily available integrated circuits and a few external components. These ICs typically come with extensive applications information.

Particularly for low power applications (<100 W) there are ICs that provide all the

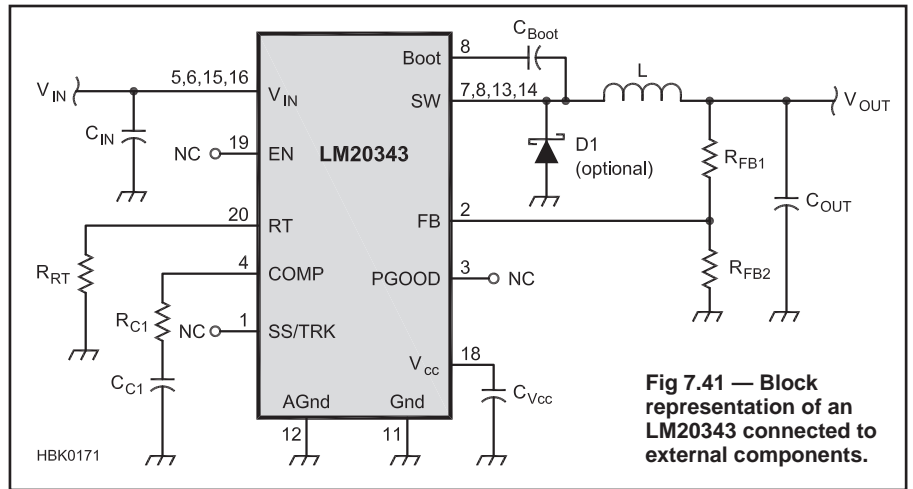

Fig 7.41 — Block representation of an LM20343 connected to external components.

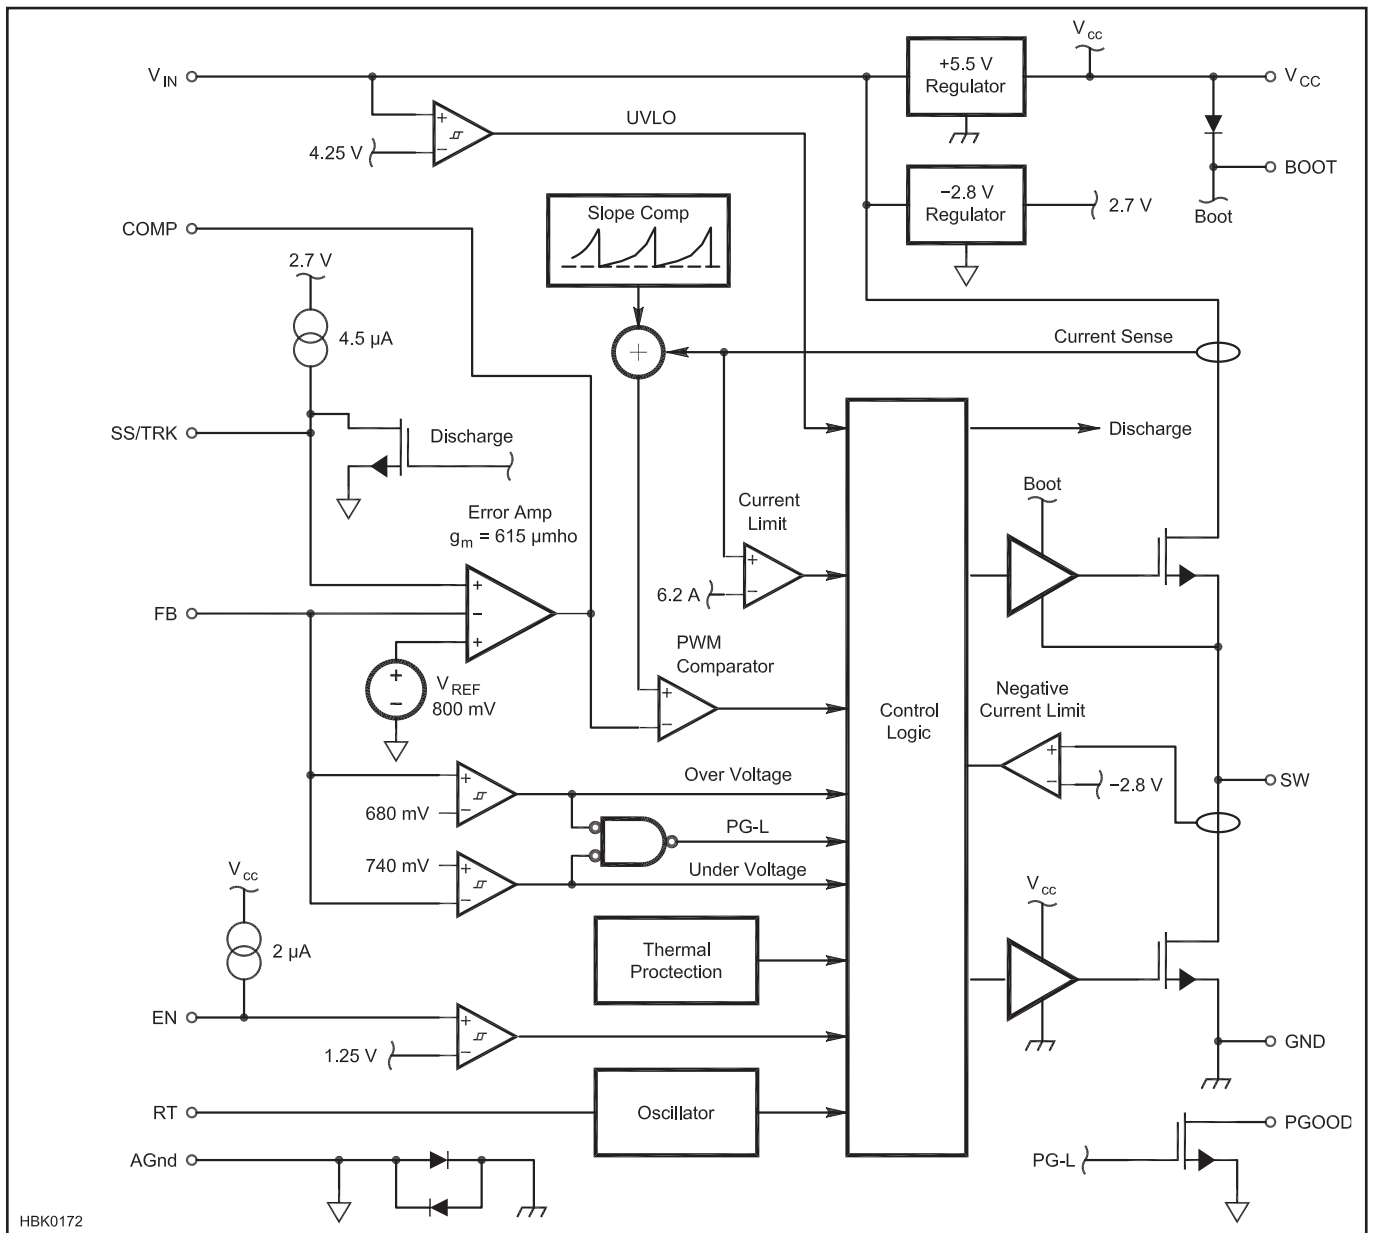

Fig 7.42 — Internal block diagram for the LM20343.

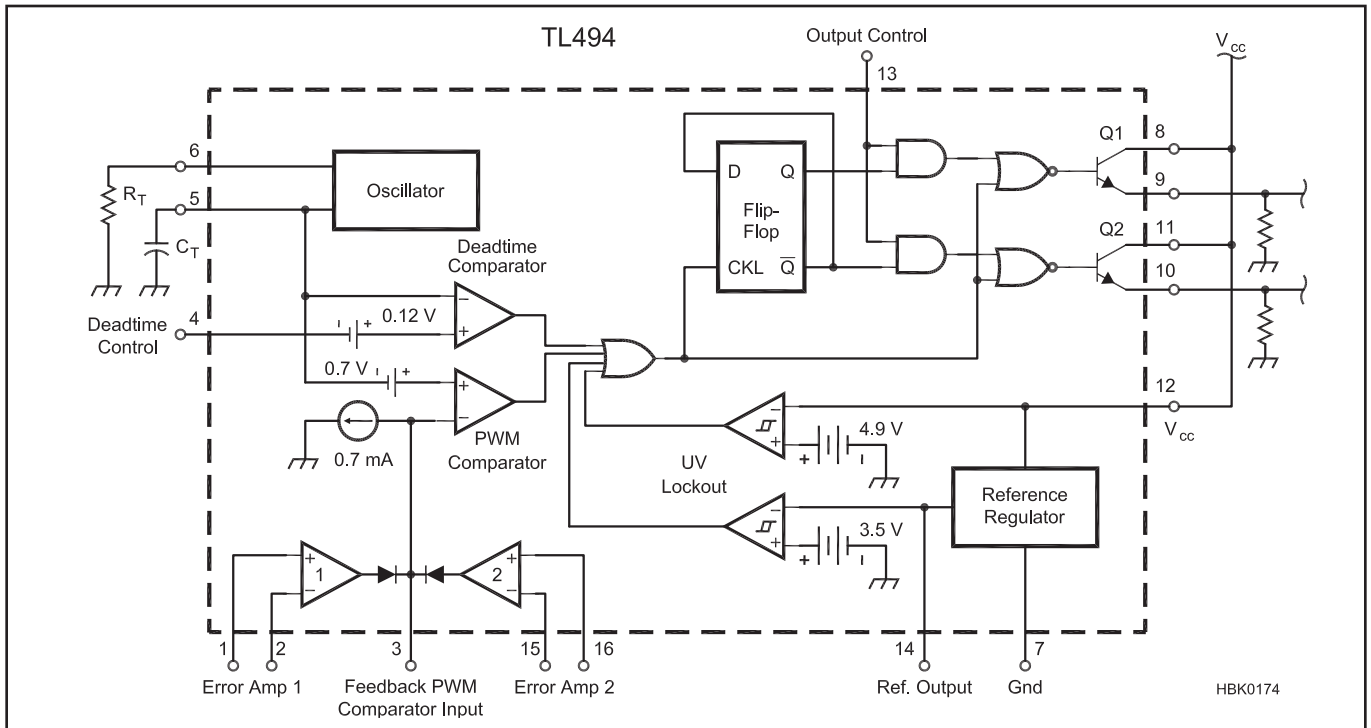

Fig 7.43 — Internal block diagram representation for the TL494.

control functions *and* the power switch. In some cases a power diode is also included. Fig 7.41 gives an example of one of these ICs. Similar ICs are made by many different manufacturers.

The IC provides most of the components for a buck converter but some external components are still needed: filter capacitors (C_{IN} , C_{OUT} , C_{VCC}), the output inductor (L), output voltage sensing (R_{FB1} and R_{FB2}) and components to set the switching frequency (R_{CI} and C_{CI}). The shunt diode (D1) is marked as optional because there is an internal switch that can perform this function for lower powers.

Fig 7.42 and Fig 7.43 show the internal block-diagram of typical voltage regulator control ICs. (See the manufacturer data sheets for application information and reference designs.) In addition to the control functions there are also some protective functions such as input under- and overvoltage protection, over-temperature (thermal) protection, over-current limiting and slow-starting (slowly ramping up D) to limit inrush current at turn-on. ICs similar to this one are available for boost, buck-boost and flyback converters, as

well as many other topologies. There are also ICs available that implement more complex control schemes such as current mode control and feed-forward compensation.

7.11.7 Switchmode Control Loop Issues

We do not have the space in this book to explain all the control issues associated with switchmode converters, but it is important to recognize that designing stable, high performance control loops for switchmode converters is a much more complex task than it would be for a series pass-regulator or an audio amplifier. All we can do here is to alert the reader to some of the issues and suggest consulting Reference 2 with detailed explanations and examples. In addition, there are numerous books and applications notes on switchmode converter design that go into the necessary detail.

The complexities arise from the inherent behavior of switchmode circuits. This behavior is often non-intuitive and sometimes even bizarre. As we've seen already, the dc beha-

avior differs dramatically between CCM and DCM modes of operation. This difference is even more pronounced in the small-signal control-to-output characteristics. It is very common to see poles and zeros in the control system's response (see the **Analog Basics** chapter) that move with input voltage, duty cycle and/or load. Fixed double-poles can change to moving single-poles. Moving right-half-plane zeros (this is a zero with decreasing phase-shift instead of increasing phase-shift with frequency) are inherent in CCM operation of boost and buck-boost circuits and their derivatives. There can also be large signal instabilities such as oscillations at sub-harmonics of the switching frequency and occasionally chaotic response to large load current or line voltage changes.

This is not intended to discourage readers from working with switchmode converters, but to simply alert them in advance to some of the difficulties. Once a basic understanding is achieved, the design of switchmode converters can be very interesting and rewarding.

Switchmode Converter Design Aids

Today, there are hundreds of ICs on the market, from dozens of manufacturers, aimed at controlling the power conversion process. These devices have grown from their simplest forms when introduced over 20 years ago to include a long list of ancillary functions aimed at reducing the supporting circuitry and enhancing the quality and efficiency of the power conversion process. As a result, the task of designing these ICs into the final power conversion circuit has actually become more complex. To the circuit designer who is below the expert level, the task can seem daunting, indeed.

In answer to this problem, many IC manufacturers provide computer-aided design tools that greatly simplify the task of using their products. These tools take several forms, from the most rudimentary cookbook-style guides, to full-fledged circuit simulation tools like *SPICE*. The purpose of these tools is to help the designer pick appropriate

resistors, capacitors and magnetic components for the design, and also to estimate the stresses on the power-handling components.

These design tools fall generally into two types: equation-based design tools and iterative circuit simulators. The differences are that the equation-based tools simply automate the basic design equations of the circuit, providing recommended choices for the components and then solving equations to compute the voltage, current and power stresses on the components. In some cases, thermal analysis is also included.

The simulators, on the other hand, use detailed mathematical models for the components and provide both dc and ac simulation of the circuits. This allows the user to see the dynamic behavior of the circuit. The simulation includes details during the switching intervals and shows rise times, parasitic effects caused by component

capacitance, internal resistance and other characteristics.

In modern power converter design, the magnetic components — transformers, power inductors and filter inductors — can be a challenge to the designer not versed in magnetic design. As a result, the vendors of these parts usually furnish design tools created specifically to the design of these components and/or the proper choice of off-the-shelf versions.

The reader is encouraged to explore design aids available from the websites of manufacturers (**Table 7.A1**). The following is far from complete, but should give the reader valuable insight into the vast array of available tools. Remember also that manufacturers of passive components such as capacitors, resistors, heat sinks and thermal hardware may also have helpful and informative design aids on their websites. — *Chuck Mullett, KR6R*

7.12 High-Voltage Techniques

The construction of high-voltage supplies requires special considerations in addition to the normal design and construction practices used for lower-voltage supplies. In general, the builder needs to remember that physical spacing between leads, connections, parts and the chassis must be sufficient to prevent arcing. Also, the series connection of components such as capacitor and resistor strings needs to be done with consideration for the distribution of voltage stresses across the components. High-voltages can constitute a safety hazard and great care must be taken to limit physical access to components and wiring while high potentials are present.

7.12.1 High-Voltage Capacitors

For reasons of economy and availability, electrolytic capacitors are frequently used for output filter capacitors. Because these capacitors have relatively low voltage ratings (<600 V), in HV applications it will usually be necessary to connect them in series strings to form an equivalent capacitor with the capability to withstand the higher applied voltage. Electrolytic capacitors have relatively high leakage currents (low leakage resistance) especially at higher temperatures.

To keep the voltages across the capacitors in the series string relatively constant, equal-value bypassing resistors are connected across each capacitor. These *equalizing resistors* should have a value low enough to equalize differences in capacitor leakage resistance between the capacitors, while high enough not to dissipate excessive power. Also, capacitor bodies need to be insulated from the chassis and from each other by mounting them on insulating panels, thereby preventing arcing to the chassis or other capacitors in the string. The insulated mounting for the capacitors is often plastic or other insulating material in board form. A typical example from a commercial amplifier that implements some the guidelines given in this section is shown in Fig 7.44.

Equalizing resistors are needed because of differences in dc leakage current between different capacitors in the series string. The data sheet for an electrolytic capacitor will usually give the dc leakage current at 20 °C in the form of an equation. For example:

$$I_{\text{leakage}} = 3\sqrt{CV} \quad (14)$$

where

C = the value in μF

V = the working voltage

I_{leakage} = leakage current in μA .

Keep in mind that the leakage current will

increase as the capacitor temperature rises above 20 °C. A value of 3 to 4 times the 20 °C value would not be unusual because of normal heating.

We can use an approximation which includes allowance for heating to determine the maximum value of the divider resistors:

$$R \leq \frac{V_r - V_m}{I_{\text{leakage}}} \quad (15)$$

where

V_r = the voltage rating of the capacitor

V_m = the voltage across the capacitor during normal operation.

A typical 3000 V power supply might use eight 330 μF , 450 V capacitors in series. In that case, $V_r = 450$ V, $V_m = 375$ V and $I_{\text{leakage}} = 1.2$ mA. This would make $R = 63$ k Ω or a total of 504 k Ω for the resistor string. With 3000 V across the resistor string, the total power dissipation would be 18 W or about 2.25 W per resistor. To be conservative you should use resistors rated for at least 4 W each.

The equalizing resistors may dissipate significant power and become quite warm. It is important that these resistors do not heat the capacitors they are associated with, as this

will increase the capacitor leakage current. You also have to be careful that the heat from the resistors is not trapped under the plastic support panels. The best practice is to place the resistors above the capacitors and their mounting structure allowing the heat to rise unobstructed as shown in Fig 7.44.

OIL-FILLED CAPACITORS

For high voltages, oil-filled paper-dielectric capacitors are superior to electrolytics because they have lower impedance at high frequencies, higher leakage resistance and are available with much higher working voltages. These capacitors are available with values of several microfarads and have working voltage ratings of thousands of volts. On the other hand, they can be expensive, heavy and bulky.

Oil-filled capacitors are frequently offered for sale at flea markets at attractive prices. One caution: It is best to avoid older oil-filled capacitors because they may contain polychlorinated biphenyls (PCBs), a known cancer-causing agent. Newer capacitors have eliminated PCBs and have a notice on the case to that effect. Older oil-filled capacitors should be examined carefully for any

Fig 7.44 — Example of the filter capacitor/bleeder resistor installation in a high voltage power supply.

signs of leakage. Contact with leaking oil should be avoided, with careful washing of the hands after handling. Do not dispose of any oil-filled capacitors with household trash, particularly older units. Contact your local recycling agency for information about how to dispose of them properly.

7.12.2 High-Voltage Bleeder Resistors

Bleeder resistors across the output are used to discharge the stored energy in the filter capacitors when the power supply is turned off and should be given careful consideration. These resistors provide protection against shock when the power supply is turned off and dangerous wiring is exposed. A general rule is that the bleeder should be designed to reduce the output voltage to 30 V or less within 30 seconds of turning off the power supply.

Take care to ensure that the maximum voltage rating of the resistor is not exceeded. In a typical divider string, the resistor values are high enough that the voltage across the resistor is not dissipation limited. The voltage limit is typically related to the insulation intrinsic to the resistor. Resistor maximum voltage ratings are usually given in the manufacturer's data sheet and can be found online. Two major resistor manufacturers are Ohmite Electronics (www.ohmite.com) and Stackpole Electronics (www.seielect.com).

A 2 W carbon composition resistor will have a maximum voltage rating of 500 V. As a rough estimate, larger wire-wound power resistors are typically rated at 500 V_{RMS} per inch of length — but check with the manufacturer to be sure.

The bleeder will consist of several resistors in series. Typically wire-wound power resistors are used for this application. One additional recommendation is that two separate (redundant) bleeder strings be used, to provide safety in the event one of the strings fails. When electrolytic capacitors are used, the equalizing resistors can also serve as the bleeder resistor but they should be redundant. Again, give careful attention to keeping the heat from the resistors away from the capacitors as shown in Fig 7.44.

In the example given above for calculating the equalizing resistor value, eight 330 μ F capacitors in series created the equivalent of a 41 μ F capacitor with a 3000 V rating. The total resistance across the capacitors was $8 \times 63 \text{ k}\Omega = 504 \text{ k}\Omega$. This gives us a time constant ($R \times C$) of about $R \times C \approx 21$ seconds. To discharge the capacitors to 30 V from 3000 V would take about four time constants (about 84 seconds) which is well over a minute. To get the discharge time down to 30 seconds would require reducing the equalizing resistors to 25 $\text{k}\Omega$ each. The bleeder power dissipation

would then be:

$$P = \frac{V^2}{R} = \frac{3000^2}{200,000} = 45 \text{ W} \quad (16)$$

For a 2 or 3 kV power supply, this is a reasonable value but it is still a significant amount of power and you need to make sure the resulting heat is properly managed.

7.12.3 High-Voltage Metering Techniques

Special considerations should be observed for metering of high-voltage supplies, such as the plate supplies for linear amplifiers. This is to provide safety to both personnel and to the meters themselves.

To monitor the current, it is customary to place the ammeter in the supply return (ground) line. This ensures that both meter terminals are close to ground potential. Placing the meter in the positive output line creates a hazard because the voltage on each meter terminal would be near the full high-voltage potential. Also, there is the strong possibility that an arc could occur between the wiring and coils inside the meter and the chassis of the amplifier or power supply itself. This hazardous potential cannot exist with the meter in the negative leg.

Another good safety practice is to place a low-voltage Zener diode across the terminals of the ammeter. This will bypass the meter in the event of an internal open circuit in the meter. A 1 W Zener diode will suffice since the current in the metering circuit is low.

The chapter on **RF Power Amplifiers** contains examples of how to perform current and voltage metering in high voltage supplies and amplifiers. In the past, amplifier articles have shown the meters mounted on plastic boards with stand-off insulators behind a plastic window in the amplifier or power supply front panel. While this can work it is not considered good practice today. It is usually possible to arrange the metering so that the meters are close to ground potential and may be safely mounted on the front panel of either the amplifier or the power supply.

For metering of high voltage, the builder should remember that resistors to be used in multiplier strings will often have voltage-breakdown ratings well below the total voltage being sampled. Usually, several identical series resistors will be used to reduce voltage stress across individual resistors. A basic rule of thumb is that these resistors should be limited to a maximum of 200 V, unless rated otherwise. For example, in a 2000 V power supply, the voltmeter multiplier should have a string of 10 resistors connected in series to distribute the voltage equally. The comments on resistor voltage rating in the sections on capacitor equalization and bleeder resistors apply to this case, as well.

7.12.4 High-Voltage Transformers and Inductors

Usable transformers and filter inductors can often be found at amateur flea markets but frequently these are very old units, often dating from WWII. The hermetically-sealed military components are likely to still be good, especially if they have not been used. Open-frame units, with insulation that has been directly exposed to the atmosphere and moisture for long periods of time, should be considered suspect. These units can be checked by running what is called a “hipot test” (high potential test). This involves a low current, variable output voltage power supply with a high-value resistor in series with the output. Unfortunately this equipment is seldom available to amateurs. Some motor repair shops will have an insulation tester called a “Megger” and may be willing to perform an insulation test on a transformer or inductor for you. This is not a completely definitive test but will certainly detect any gross problems with the insulation.

An alternative would be to perform the transformer tests discussed earlier with a variable autotransformer on the ac input. Slowly increase the input voltage until full line voltage is reached and let the transformer run for an hour or two while watching to see if there are any signs of failure. Doing this test in a dark room makes it easier to see any visible corona discharge, another sign of insulation problems. Because the transformer terminals will be at full voltage great care should be taken to avoid contact with the HV terminals. Some form of transparent insulating shield for the test setup is necessary.

7.12.5 Construction Techniques for High-Voltage Supplies

Layout and component arrangement in HV supplies requires some additional care beyond those for lower voltage projects. The photographs in the **RF Power Amplifiers** chapter are a good start, but there are some points which may not be obvious from the pictures.

SHARP EDGES

Sharp points, board edges and/or hardware with ragged edges can lead to localized intensification of the electric field's strength, resulting in a possible breakdown. One common offender is the component leads on the soldered side of a printed-circuit board. These are usually soldered and then cut off leaving a small but often very sharp point. The best way to handle this is to cut the lead as close to the board as practical and form a small solder ball or mound around the cutoff lead end. An example of these suggestions is given in **Fig 7.45**. The protruding component wire

Fig 7.45 — Example of a high voltage board with a solder ball on a protruding lead and the use of a cap nut to terminate the end of a screw thread.

near the top would have a high field gradient. Below that we see a wire cut short with a rounded mound of solder covering the end of the wire.

The ends of bolts with sharp threads often protrude beyond the associated nut. One way to eliminate this is to use the dome-style nuts (cap nuts) that capture the end of the bolt or screw, forming a nicely rounded surface. An example of a cap nut is shown in Fig 7.45.

Sheet metal screws, with their needle-sharp ends, should be avoided if possible. Sheet metal screws used to close metal housings at high potential should have the screw tips inside the enclosure, which would be normal in most cases. You must also be careful of the tips of sheet metal screws that protrude on the inside of an outer enclosure. If these are in proximity to circuits at high potential, they can also lead to arcing. Keeping sheet metal screw tips well away from high voltage circuitry is the best defense.

Small pieces of sheet metal that may be part of a structure at high potential should have their edges rounded off with a file. Copper traces near the edges of circuit boards do not benefit from rounding, however. In fact, filing may make the edge sharper, ragged and more prone to breakdown. In critical areas, a small solid round wire can be soldered to the edges of a copper trace to form a rounded edge as illustrated at the right side of Fig 7.45.

INSULATORS

Some portions of the circuit may be mounted on insulators or plastic sheets. A new, clean insulator should easily withstand 10 kV per inch without creepage or breakdown across the insulating surface, but over time that surface will accumulate dirt and dust. Reducing the high-voltage stress across insulators to 5 kV per inch would be more conservative.

In theory the spacing between two smooth surfaces across an air gap can be much smaller, perhaps 20 to 30 kV per inch or even higher. But given the uncertainties of layout and voltage gradients around hardware, wiring, components and board edges, sticking with 5 kV per inch is good idea even for air gaps.

This separation will seldom cause construction layout problems unless you are trying to build a very compact unit.

FUSES

Sometimes a fuse will be placed in series with a high voltage output to provide protection in case of load arcing. These fuses pose special problems. When a fuse blows, the fuse element will at least melt and perhaps even vaporize. There may be an interval when most, if not all, the output voltage appears across the fuse but the fuse has not stopped conducting. That is, there can be a sustained arc in the fuse.

Fuses have voltage ratings that are the maximum voltages across the fuse for which the arc can be expected to quench quickly. The standard 0.25×1.25 inch fuses used in the input ac line are typically rated for 250 V. While no doubt these ratings are conservative, this type of fuse cannot be expected to reliably clear an arc with 2 to 3 kV across the fuse and should not be used in series with a high-voltage output.

Fuses with very high voltage ratings do exist however. Unfortunately, for the most part these HV fuses are for utility applications. They are physically large and not available in low current ratings. Fuses specifically rated for low currents ($<2A$) and several kV exist but may be very hard to locate. Even if you have a suitable fuse, care must be taken that the fuse holder can withstand the voltage. Normally high voltage fuses are mounted with end clips on an insulated board.

7.12.6 High-Voltage Safety Considerations

The voltages present in HV power supplies are potentially lethal. Every effort must be made to restrict physical access to any high potentials. A number of steps can be taken:

- 1) Build the power supply within a closed box, preferably a metal one.
- 2) Install interlocks on removable panels used for access to the interior. An interlock is usually a normally-open microswitch in series with the input power line. The microswitch is

Fig 7.46 — Example of a grounding stick or hook to discharge capacitor energy safely. The end of the wire is connected to ground and the hook is touched to the capacitor terminals to discharge them. A diagram showing how to construct a grounding stick is shown at B.

positioned so that it can be closed only when the overlying panel has been secured in place. When the panel is removed the switch moves to the open position, removing power from the supply.

3) As noted previously, the use of a bleeder resistor to rapidly discharge the capacitors is mandatory.

4) To further protect the operator when accessing the inside of a high-voltage power

supply, a grounding hook like that shown in **Fig 7.46A** should be used to positively discharge each capacitor by touching the hook to each capacitor terminal. The hook is connected to the chassis via the wire shown and held by the insulated handle. It is normal practice to leave the hook in place across the capacitors while the supply is being worked on, just in case primary power is inadvertently

applied. When the work is finished, remove the hook and replace the covers on the power supply.

Fig 7.46B shows how to construct a grounding stick of your own. A large screw eye or hook is substituted for the hook. It is important that the grounding wire be left *outside* the handle so that any hazardous voltages or currents will not be present near your hand or body.

7.13 Batteries

A battery is a group of individual *cells*, usually series-connected to give some desired multiple of the *cell voltage*. The cell voltage is usually in the range of 1 to 4 V. Each chemical system used in the cell gives a particular nominal voltage that will vary with temperature and state of charge. This must be taken into account to make up a particular battery voltage. For example, four 1.5 V carbon-zinc cells make a 6 V battery and six 2 V lead-acid cells make a 12 V battery. **Table 7.1** lists the dimensions of commonly used batteries.

The following sections on battery types and usage consist primarily of excerpts from *Batteries in a Portable World* by Isidor Buchmann, CEO of Cadex Electronics (www.cadex.com), a leading manufacturer of battery charging and related equipment. The ARRL appreciates having been given permission to use this material. The book discusses the issues summarized here (and many others) in detail. The reader is directed to the original text for more complete information. This summary is intended to present and compare the various options commonly used by amateurs. Additional information and an extensive battery glossary is provided online at www.batteryuniversity.com.

Batteries are divided into two categories: *primary* (non-rechargeable) and *secondary* (rechargeable). Secondary batteries are expected to account for more than 80% of global battery use by 2015. The most common types of battery chemistry are lithium, lead and nickel-based systems.

Batteries store energy well and for a considerable length of time. Primary batteries hold more energy than secondary, and their *self-discharge* is lower. Alkaline cells are good for 10 years with minimal losses. Lead, nickel and lithium-based batteries need periodic recharges to compensate for lost power. **Fig 7.47** illustrates the energy and power densities of lead acid, nickel-cadmium (NiCd), nickel-metal-hydride (NiMH), and the lithium-ion family (Li-ion).

Rather than giving batteries unique names by type, they are broadly distinguished by the following characteristics:

Battery Safety

In addition to the precautions given for each type of battery, the following precautions apply to all battery types. Always follow the manufacturer's advice! Extensive application information can be found on manufacturer's websites.

Hydrogen gas escaping from storage batteries can be explosive. Keep flames or any kind of burning material away, including cigarettes, cigars, pipes and so on. Use and charge batteries in well-ventilated areas to prevent hydrogen gas from building up.

No battery should be subjected to unnecessary heat, vibration or physical shock. The battery should be kept clean. Frequent inspection for leaks is a good idea. Electrolyte that has leaked or sprayed from the battery should be cleaned from all surfaces. The electrolyte is chemically active and electrically conductive, and may ruin electrical equipment. Acid may be neutralized with sodium bicarbonate (baking soda), and alkalis (found in NiCd batteries) may be neutralized with a weak acid such as vinegar. Both neutralizers will dissolve in water and should be quickly washed off. Do not let any of the neutralizer enter the battery.

Keep a record of the battery use, and include the last output voltage and, for lead-acid storage batteries, the hydrometer reading. This allows prediction of useful charge remaining, and the recharging or procuring of extra batteries, thus minimizing failure of battery power during an excursion or emergency.

Batteries can contain a number of hazardous materials such as lead, cadmium, mercury or acid, and some thought is needed for their disposal at the end of useful life. Municipal and county waste disposal sites and recycling centers will usually accept lead acid batteries because they can readily be recycled. Other types of batteries are typically not recycled and should be treated as hazardous waste. Most disposal sites and recycling centers will have occasional special programs for accepting household hazardous waste. Hardware and electronic stores may have battery recycling programs, as well. Take advantage of them.

Table 7.1
Dimensions of Common Standard Cells

Size	Dimensions	Notes
D	34 × 61 mm	
C	25.5 × 50 mm	
A	17 × 50 mm	Only available for NiCd; also available in half-length size
AA	14.5 × 50 mm	
AAA	10.5 × 44.5 mm	
AAAA	8.3 × 42.5 mm	Typical size of cell making up 9 V batteries
N	12 × 32 mm	
9 V	48.5 × 26.5 × 17.5 mm	Contains six AAAA cells in series, snap terminals
18650	18 × 65 mm	Commonly used in lithium-ion battery packs
Lantern	115 × 68.2 × 68.2	Spring terminals
CR2016	20 × 1.6 mm	Coin cell
CR2025	20 × 2.5 mm	Coin cell
CR2032	20 × 3.2 mm	Coin cell

Alkaline Specifications of Standard Batteries at Low Load

Battery Type	Nominal Voltage (V)	Rated Capacity (mAh)	Voltage Cutoff (V)	Rated Load (Ω)	Discharge C-rate
9 V	9	570	4.8	620	0.025
AAA	1.5	1150	0.8	75	0.017
AA	1.5	2870	0.8	75	0.007
C	1.5	7800	0.8	39	0.005
D	1.5	17,000	0.8	39	0.0022

(Table courtesy of Cadex)

Chemistry — the families of chemicals used to make the battery. The most common chemistries are lead, nickel and lithium.

Voltage — the nominal open circuit voltage (OCV), which varies with chemistry and the number of cells connected in series.

Size — standard sizes of batteries or cells, such as AAA, AA, C and D.

Capacity (C) — the specific energy in ampere-hours (Ah).

Cold Cranking Amps (CCA) — a starter battery's ability to supply high load current at -18°C (0°F) as specified by the vehicle standard SAE J357.

Specific energy — battery capacity in watt-hours per kilogram (Wh/kg)

Specific power — indicates the loading capability or the amount of current the battery can provide in watts/kilogram (W/kg)

C-rate — charge and discharge rate specified in units of C (capacity). At 1 C, the battery charges or discharges at a current numerically equal to its Ah rating. For example, a 2000 mAh battery discharging at 1 C is supplying a current of 2 A. At 0.5 C, the current would be 1 A, and so forth.

Load — whatever draws energy from the battery. Internal battery resistance and depleting the battery's state of charge cause the voltage to drop.

Primary batteries have one of the highest energy densities. One of the most common primary batteries is the *alkaline-manganese*, or alkaline battery. The *carbon-zinc* or *Leclanché battery* is less expensive but holds less energy than the alkaline battery. Although secondary batteries have improved, a regular household alkaline cell provides 50% more energy than lithium-ion.

Primary batteries tend to have high internal resistance, which limits the discharge to light loads. This reduces the battery's specific power, even though its specific energy may be quite high. Non-rechargeable lithium metal and alkaline batteries are commonly used in low power applications such as clocks, meter LCDs, keyers and so forth.

Manufacturers of primary batteries specify specific energy at a small fraction of C and the batteries are allowed to discharge to a very low voltage of 0.8 volts per cell. Fig 7.48 compares primary and secondary batteries discharged at a rate of 1 C. The primary (alkaline and lithium) batteries are unable to deliver their rated specific energy at heavy loads. Table 7.2 gives typical specifications for alkaline batteries at light loads, such as operating a handheld radio during receive.

If recharging is available, using primary batteries can be expensive — about thirty-fold higher than for secondary batteries. Amateurs using batteries in the field, particularly for emergency communications, may want to maintain the ability to use primary batteries for times when recharging for secondary batteries is not available.

7.13.1 Choices of Secondary Batteries

The following discussion examines today's most popular secondary battery systems according to specific energy, years of service life, load characteristics, safety, price, self-discharge, environmental issues, maintenance and disposal. **Table 7.3** compares the characteristics of four commonly used rechargeable battery systems showing average

performance rating at the time of publication in 2013.

The lithium-ion family is divided into three major battery types, so named by their cathode oxides, which are cobalt, manganese and phosphate. The characteristics of these Li-ion systems are as follows:

Lithium-ion-cobalt or **lithium-cobalt** (LiCoO₂) — Has high specific energy with moderate load capabilities and modest service life.

Lithium-ion-manganese or **lithium-manganese** (LiMn₂O₄) — Is capable of high charge and discharge currents but has low specific energy and modest service life.

Lithium-ion-phosphate or **lithium-phosphate** (LiFePO₄) — often abbreviated LiPo. Is similar to lithium-manganese; nominal voltage is 3.3 V/cell; offers long cycle life, has a good safety record but exhibits higher self-discharge than other Li-ion systems.

Another type of lithium-ion cell is the

Table 7.3
Characteristics of Commonly Used Rechargeable Batteries

Specification	Lead Acid	NiCd	NiMH	Li-ion Cobalt	Li-ion Manganese	Li-ion Phosphate
Specific energy (Wh/kg)	30-50	45-80	60-120	150-190	100-135	90-120
Internal resistance ¹ (mΩ)	<100 12 V pack	100-200 6 V pack	200-300 6 V pack	150-300 7.2 V	25-75 ² per cell	25-50 ² per cell
Cycle life ⁴ (80% DoD)	200-300	1000 ³	300-500 ³	500-1000	500-1000	1000-2000
Fast-charge time	8-16 h	1 h typical	2-4 h	2-4 h	1 h or less	1 h or less
Overcharge tolerance	High	Moderate	Low	Low. Cannot tolerate trickle charge	Low. Cannot tolerate trickle charge.	Low. Cannot tolerate trickle charge.
Self-discharge/month (room temp)	5%	20% ⁵	30% ⁵	<10% ⁶	<10% ⁶	<10% ⁶
Cell voltage (nominal)	2 V	1.2 V ⁷	1.2 V ⁷	3.6 V ⁸	3.8 V ⁸	3.3 V
Peak load current (best result)	5C ⁹ (0.2 C)	20 C (1 C)	5 C (0.5 C)	>3 C (<1 C)	>30 C (<10 C)	>30 C (<10 C)
Operating temp. ¹⁰ (discharge only)	-20 to 60° C	-40 to 60° C	-20 to 60° C	-20 to 60° C	-20 to 60° C	-20 to 60° C
Maintenance requirement	3-6 months ¹¹	30-60 days	60-90 days	Not required	Not required	Not required
Safety requirements	Thermally stable	Thermally stable, fuse protection common	Thermally stable, fuse protection common	Protection circuit mandatory	Protection circuit mandatory	Protection circuit mandatory
In use since	Late 1800s	1950	1990	1991	1996	2006
Toxicity	Very high	Very high	Low	Low	Low	Low

Table Notes:

¹ Internal resistance of a battery pack varies with milliampere-hour (mAh) rating, wiring and number of cells. Protection circuit of lithium-ion adds about 100 mΩ.

² Based on 18650 cell size. Cell size and design determines internal resistance.

³ Cycle life is based on battery receiving regular maintenance.

⁴ Cycle life is based on the depth of discharge (DoD). Shallow DoD improves cycle life.

⁵ Self-discharge is highest immediately after charge. NiCd loses 10% in the first 24 hours, then declines to 10% every 30 days. High temperature increases self-discharge.

⁶ Internal protection circuits typically consume 3% of the stored energy per month

⁷ The traditional voltage is 1.25 V; 1.2 V is more commonly used.

⁸ Low internal resistance reduces the voltage drop under load and Li-ion is often rated higher than 3.6 V/cell. Cells marked 3.7 V and 3.8 V are fully compatible with 3.6 V.

⁹ Capable of high current pulses; needs time to recuperate.

¹⁰ Applies to discharge only; charge temperature is more confined.

¹¹ Maintenance may be in the form of equalizing or topping charge to prevent sulfation

(Table courtesy of Cadex)

popular *lithium-ion-polymer* or *Li-polymer*. While Li-ion systems get their name from their unique cathode materials, Li-polymer differs by having a distinct architecture in which a gelled electrolyte replaces the usual porous separator between the anode and cathode. The gelled electrolyte acts as a catalyst to enhance the electrical activity of the other battery materials.

7.13.2 Lead Acid Batteries

Most lead acid batteries used today are *maintenance-free* types in which the liquid electrolyte is sealed inside the battery in liquid or gel form. Two similar types are used: the *sealed lead acid* (SLA) and the *valve-regulated lead acid* (VRLA). SLA batteries have capacities up to about 30 Ah. VRLA batteries are larger and have capacities from 30 Ah to several thousand Ah. **Table 7.4** summarizes the advantages and limitations of lead acid battery systems.

Applying the right voltage limit when charging lead acid systems is critical and will be a compromise between capacity when recharged and maintaining the battery's internal materials. A low charge limit voltage may shelter the battery but this causes poor performance and a buildup of *sulfation* on the negative plate. A high voltage limit improves performance but it promotes irreversible grid corrosion on the positive plate. Temperature also changes the voltage threshold.

Lead acid does not lend itself to fast charging and a fully saturated charge requires 14 to

16 hours. The battery must always be stored at full state-of-charge to avoid sulfation. Lead acid is not subject to memory, but correct charge and float voltages are important to get a long life (see the section on charging below). While NiCd loses approximately 40% of its stored energy in three months, lead acid self-discharges the same amount in one year.

Lead acid batteries are inexpensive on cost-per-watt basis but are less suitable for repeated deep cycling. A full discharge causes strain and each discharge/charge cycle permanently robs the battery of a small amount of capacity. The fading becomes more acute as the battery falls below 80% of its nominal capacity. Depending on the depth of discharge and operating temperature, lead acid for deep-cycle applications provides 200 to 300 discharge/charge cycles.

High temperature reduces the number of available cycles. As a guideline, every 8° C (13° F) rise above the optimum temperature of 25° C (77° F) cuts battery life in half.

Lead acid batteries are rated at a 5-hour (0.2 C) and 20-hour (0.05 C) discharge, and the battery performs best when discharged slowly. Lead acid can deliver high pulse currents of several C if done for only a few seconds, making lead acid well suited as a *starter battery*.

STARTER AND DEEP-CYCLE BATTERIES

The *starter* battery is designed to crank an engine with a momentary high power burst; the *deep-cycle* battery, on the other hand, is

built to provide continuous power. The starter battery is made for high peak power and does not tolerate deep cycling well. The deep-cycle battery has a moderate power output but permits cycling.

Starter batteries have a CCA rating in amperes and a very low internal resistance. Deep-cycle batteries are rated in Ah or minutes of runtime. A starter battery cannot be swapped with a deep-cycle battery and vice versa because of their different internal construction. **Table 7.5** compares the typical life of starter and deep-cycle batteries when deep-cycled.

ABSORBENT GLASS MAT (AGM)

AGM is an improved lead acid battery in which the electrolyte is absorbed in a mat of fine glass fibers. This makes the battery spill-proof. AGM has very low internal resistance, is capable of delivering high currents and offers long service even if *occasionally* deep-cycled. It also stands up well to high and low temperatures and has a low self-discharge. AGM has a higher specific power rating for high load currents and allows faster charge times (up to five times faster) than conventional lead acid. AGM has a slightly lower specific energy and higher manufacturing cost.

AGM batteries are sensitive to overcharging. They can be charged to 2.40 V/cell without problems but the float charge should be reduced to 2.25 to 2.30 V/cell and summer temperatures may require lower voltages. Automotive charging systems designed for flooded lead acid often have a fixed float voltage setting of 14.40 V (2.40 V/cell) and a direct replacement with an AGM battery could result in overcharge on a long drive.

Heat can be a problem for AGM and other gelled electrolyte batteries. Manufacturers recommend halting charge if the battery core reaches 49° C (120° F). However, AGM batteries can sit in storage for long periods before a recharge to prevent sulfation becomes necessary.

7.13.3 Nickel-based Batteries

NICKEL-CADMIUM (NiCd)

The standard NiCd remains one of the most rugged and forgiving batteries but needs proper care to attain longevity. Nickel-based batteries also have a flat discharge curve that ranges from 1.25 to 1.0 V/cell. **Table 7.6** summarizes the advantages and limitations of NiCd battery systems.

NICKEL-METAL-HYDRIDE (NiMH)

NiMH provides 40% higher specific energy than standard NiCd, but the decisive advantage is the absence of toxic metals. NiMH also has two major advantages over Li-ion: price and safety. NiMH is offered in AA and AAA sizes.

NiMH is not without drawbacks. It has a

Table 7.4

Advantages and Limitations of Lead Acid Batteries

Advantages Inexpensive and simple to manufacture; lowest cost per watt-hour
Mature and well-understood technology; provides dependable service
Low self-discharge; lowest among rechargeable batteries
High specific power, capable of high discharge currents
Limitations Low specific energy; poor weight-to-energy ratio
Slow charge; fully saturated charge takes 14 hours
Must always be stored in charged condition
Limited cycle life; repeated deep-cycling reduces battery life
Flooded version requires watering
Not environmentally friendly
Transportation restrictions on the flooded type
(Table courtesy of Cadex)

Table 7.5

Cycle Performance of Starter and Deep-Cycle Batteries

Depth of Discharge	Starter Battery	Deep-cycle Battery
100%	12-15 cycles	150-200 cycles
50%	100-120 cycles	400-500 cycles
30%	130-150 cycles	1000 and more cycles

(Table courtesy of Cadex)

Table 7.6**Advantages and Limitations of NiCd Batteries**

Advantages	Fast and simple charging even after prolonged storage High number of charge/discharge cycles; provides over 1000 charge/discharge cycles with proper maintenance Good load performance; rugged and forgiving if abused Long shelf life; can be stored in a discharged state Simple storage and transportation; not subject to regulatory control Good low-temperature performance Economically priced; NiCd is the lowest in terms of cost per cycle Available in a wide range of sizes and performance options
Limitations	Relatively low specific energy compared with newer systems Memory effect; needs periodic full discharges Environmentally unfriendly; cadmium is a toxic metal and cannot be disposed of in landfills High self-discharge; needs recharging after storage

(Table courtesy of Cadex)

Table 7.7**Advantages and Limitation of NiMH Batteries**

Advantages	30-40% higher capacity than a standard NiCd Less prone to memory than NiCd Simple storage and transportation; not subject to regulatory control Environmentally friendly; contains only mild toxins Nickel content makes recycling profitable
Limitations	Limited service life; deep discharge reduces service life Requires complex charge algorithm Does not absorb overcharge well; trickle charge must be kept low Generates heat during fast-charge and high-load discharge High self-discharge; chemical additives reduce self-discharge at the expense of capacity Performance degrades if stored at elevated temperatures; should be stored in a cool place at about 40% state-of-charge

(Table courtesy of Cadex)

Table 7.8**Characteristics of the Four Most Commonly Used Lithium-ion Batteries**

Specifications	<i>Li-cobalt</i> <i>LiCoO₂ (LCO)</i>	<i>Li-manganese</i> <i>LiMn₂O₄ (LMO)</i>	<i>Li-phosphate</i> <i>LiFePO₄ (LFP)</i>	<i>NMC</i> ¹ <i>LiNiMnCoO₂</i>

Table Notes¹ NMC (nickel-manganese-cobalt), NCM, CMN, CNM, MNC and MCN are basically the same. The order of Ni, Mn and Co does not matter much² Application and environment govern cycle life; the numbers do not always apply correctly³ Requires protection circuit and cell balancing of multi cell pack. Requirements for small formats with 1 or 2 cells can be relaxed⁴ Needs cell balancing and voltage protection⁵ A fully charged battery raises the thermal runaway temperature, a partial charge lowers it

(Table courtesy of Cadex)

lower specific energy than Li-ion and also has high self-discharge, losing about 20% of its capacity within the first 24 hours, and 10% per month thereafter. New types of NiMH such as the Eneloop from Sanyo, ReCyko by GP and others have reduced the self-discharge by a factor of six, increasing storage life by the same amount at the sacrifice of some capacity. **Table 7.7** summarizes the advantages and limitations of NiMH battery systems.

7.13.4 Lithium-based Batteries

The specific energy of Li-ion is twice that of NiCd and the high nominal cell voltage of 3.60 V as compared to 1.20 V for nickel systems contributes to this gain. The load characteristics are good, and the flat discharge curve offers effective utilization of the stored energy in a desirable voltage spectrum of 3.70 to 2.80 V/cell. Li-ion batteries vary in performance according to the choice of cathode materials. **Table 7.8** presents the characteristics of common Li-ion battery chemistries and **Table 7.9** summarizes the advantages and limitations of lithium-ion battery systems.

Lithium-polymer employs a gelled electrolyte in a micro-porous separator between the anode and cathode. Li-polymer is a construction technique and not a type of battery chemistry, so it can be applied to any of the lithium battery chemistries. Most Li-polymer battery packs are based on Li-cobalt. Charge and discharge characteristics of Li-polymer are identical to other Li-ion systems and this chemistry does not require a special charger.

Fig 7.49 compares the specific energy of lead, nickel and lithium-based systems. While Li-cobalt is the clear winner in terms of higher

Table 7.9

Advantages and Limitations of Li-ion Batteries

Advantages	High specific energy Relatively low self-discharge; less than half that of NiCd and NiMH Low maintenance. No periodic discharge is needed; no memory
Limitations	Requires protection circuit to limit voltage and current Subject to aging, even if not in use (life span is similar to other chemistries) Transportation regulations apply when shipping in larger quantities

(Table courtesy of Cadex)

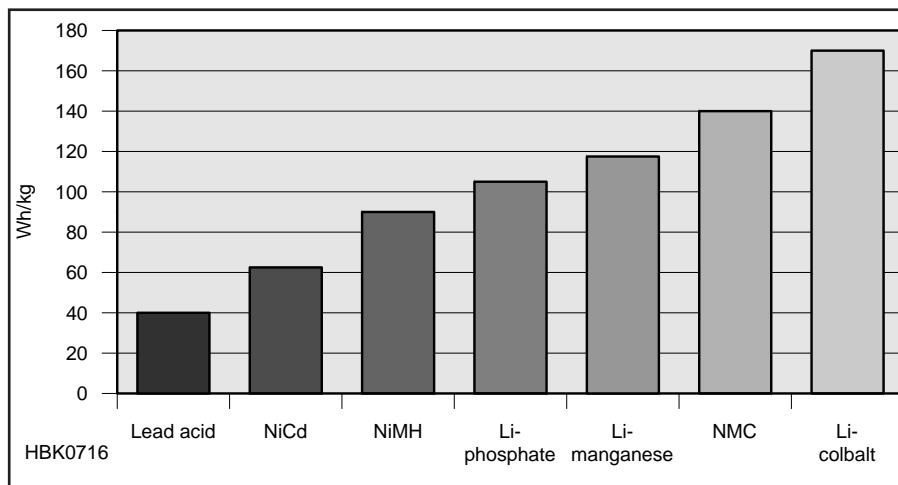

Fig 7.49 — Typical energy densities of lead, nickel- and lithium-based batteries

capacity than other systems, this only applies to specific energy. In terms of specific power and thermal stability, Li-manganese and Li-phosphate are superior.

7.13.5 Charging Methods

The performance and longevity of rechargeable batteries are to a large extent governed by the quality of the charger. Choosing a quality charger is important considering the costs of battery replacement and poor performance.

CHARGERS

This discussion focuses on third-party chargers designed to charge and maintain individual cells or batteries. *Fleet chargers* designed for maintaining many batteries of a common type in a company or agency

environment are often provided by the equipment OEM and usually have special features for battery conditioning.

“Smart” chargers include valuable additional features beyond simply applying current to a battery. Temperature protection is particularly important to slow or prevent charging below freezing or above recommended thresholds when the battery is hot. Advanced lead acid chargers adjust the float and trickle charge thresholds based on temperature and battery age. **Table 7.10** summarizes the types of third-party chargers.

There are two common charge methods: voltage limiting (VL) and current limited (CL). Lead and lithium-based chargers cap the voltage at a fixed threshold. When reaching the cutoff voltage, the battery begins to saturate and the current drops while receiving

the remaining charge on its own timetable. Full charge detection occurs when the current drops to a designated level.

Nickel-based batteries charge with a controlled current and the voltage is allowed to fluctuate freely. A slight voltage drop after a steady rise indicates a fully charged battery. The voltage drop method works well in terminating a fast charge, but the charger should detect and protect against shorted or mismatched cells. Most chargers include temperature sensors to end the charge if the temperature exceeds a safe level. (Some batteries also have internal temperature sensors.)

A temperature rise is normal as nickel-based batteries approach full charge. When in “ready” mode, the battery must cool down to room temperature. Heat causes stress and prolonged exposure to elevated temperature shortens battery life. Extended trickle charge also inflicts damage on nickel-based batteries, which should not be left in the charger continuously or beyond a few days.

A lithium-based battery should not get warm in a charger, and if this happens either the battery or charger may be faulty. Li-ion chargers do not apply a trickle charge and disconnect the battery electrically when fully charged. If the battery is left in the charger, a recharge may occur when its open circuit voltage drops below a set threshold. It is not necessary to remove Li-ion batteries from a charger.

SIMPLE GUIDELINES WHEN BUYING A CHARGER

- Use the correct charger for battery chemistry. Most chargers service one chemistry only.
- The battery voltage must agree with the charger. Do not charge if different.
- The Ah rating of a battery can be somewhat higher or lower than specified on the charger. A larger battery will take longer to charge than a smaller one and vice versa.
- The higher the amperage of the charger, the shorter the charge time will be, subject to limits on how fast the battery can be charged.
- Accurate charge termination and correct trickle charge prolong battery life.
- When fully saturated, a lead acid charger should switch to a lower voltage; a nickel-based charger should have a trickle charge;

Table 7.10

Charger Characteristics

Type	Chemistry	C-rate (C)	Time	Charge Termination
Slow	NiCd, Lead acid	0.1	14 h	Continuous low charge or fixed timer. Subject to overcharge. Remove battery when charged.
Rapid	NiCd, NiMH, Li-ion	0.3-0.5	3-6 h	Senses battery by voltage, current, temperature, and time-out timer
Fast	NiCd, NiMH, Li-ion	1	1+ h	Same as rapid charger with faster service
Ultra-Fast	Li-ion, NiCd, NiMH	1-10	10-60 min	Applies ultra-fast charge to 70% SoC; limited to specialty batteries

All values specified over 0°C to 45°F (32°F to 113°F) range

(Table courtesy of Cadex)

a Li-ion charger provides no trickle charge.

- Chargers should have a temperature override to end charge on a malfunctioning battery.

- Observe the temperature of the charger and battery. Lead acid batteries stay cool during charge; nickel-based batteries elevate the temperature toward the end of charge and should cool down after charge; Li-ion batteries should stay cool throughout charge.

SLOW CHARGERS

This type of charger applies a fixed current of about 0.1 C (one-tenth of the rated capacity) as long as the battery is connected. Slow chargers have no full-charge detection, charge current is always applied, and the charge time for a fully discharged battery is 14 to 16 hours. Most slow chargers have no “ready” indicator.

When fully charged, a slow charger keeps NiCd batteries lukewarm to the touch. Some overcharge is acceptable and the battery does not need to be removed immediately when ready. Leaving the battery in the charger can cause internal crystal growth that leads to “memory effects” in NiCd batteries.

Charging a battery with a lower Ah rating than specified for the charger will cause the battery to heat up as it approaches full charge due to the higher charging rate. Because slow chargers have no provision to lower the current or terminate the charge, the excessive heat will shorten the life of the battery.

The opposite can occur when a slow charger is charging a larger battery than it is rated for. In this case, the battery may never reach full charge and remains cold. Battery performance will be poor because of insufficient charge. Repeated partial charging can also cause crystal growth and memory effects.

RAPID CHARGERS

Falling between a slow and fast charger, the rapid charger is designed for nickel and lithium-based batteries. Unless specially designed, the rapid charger cannot service both types of batteries.

Rapid chargers are designed to charge fully discharged batteries and battery packs in 3 to 6 hours. When full charge is reached, the charger switches to a “ready” state. Most rapid chargers include temperature protection.

FAST CHARGERS

The fast charger typically applies charge at a 1 C rate so that a fully discharged battery is recharged in a little over 1 hour. As the battery approaches full charge, the charger may reduce the charge current (particularly for NiCd), and when the battery is fully charged, the charger switches to a trickle or maintenance charge mode.

Most nickel-based fast chargers accommodate NiCd and NiMH batteries and apply the same charging algorithm, but cannot charge Li-ion batteries. To service a Li-ion

pack, specialty dual-mode chargers can read a security code on the battery to switch to the right charger setting.

Lead acid batteries cannot be fast-charged and the term “fast charge” is a misnomer for lead acid chargers. Most lead acid chargers charge the battery in 14 hours; anything slower may be a compromise. Lead acid can be charged relatively quickly to 70% of full charge with the important saturation charge consuming the remaining time. A partial charge at high rate is acceptable provided the battery receives a fully saturated charge once every few weeks to prevent sulfation.

ULTRA-FAST CHARGERS

Large NiCd and Li-ion batteries can be charged at a very high rate (10 C is typical) up to 70% of full charge. Ultra-fast charging stresses batteries. If possible, charge the battery at a more moderate current. An ultra-fast charger should offer user-selectable rates to optimize the charging requirements.

At a rate of 10 C, a battery can be charged in a few minutes but several conditions must be observed:

- The battery must be designed to accept an ultra-fast charge.

- Ultra-fast charging only applies during the first charge phase and charge current must be lowered once the 70% state-of-charge (SoC) threshold is reached.

- All cells in a pack must be balanced and in good condition. Older batteries with high internal resistance will heat up and are no longer suitable for ultra-fast charging.

- Ultra-fast charging can only be done at moderate temperatures. Low temperatures slow the chemical reaction and the unabsorbed energy results in gassing and heat buildup.

- The charge must include temperature compensation and other safety provisions to end the charge if the battery is overly stressed.

CHARGING FROM A USB PORT

The universal serial bus (USB) interface has become ubiquitous on computers and consumer electronics. It is increasingly used on radio equipment. A drawing and pin connections for the USB interface are available in the **Component Data and References** chapter.

USB hubs are specified to provide 5 V and 500 mA of current. (Current can only flow out of a USB interface.) While this would be enough to charge a small Li-ion battery, it could overload the hub if other devices are attached. Many hubs limit the current and will shut down if overloaded, so charging capacity is quite limited.

The most common USB chargers are designed for single-cell Li-ion batteries. The charge begins with a constant current charge to 4.20 V/cell, at which point the voltage levels off and current begins to decrease. Due to

voltage drops in the USB cable and charger circuit, the hub may not be able to fully charge the battery. This will not damage a Li-ion battery but it will deliver shorter than expected runtimes.

CHARGING LEAD ACID

Lead acid batteries should be charged in three stages as shown in **Fig 7.50**:

1 — constant-current charge

2 — topping charge

3 — float charge

The constant-current charge applies the bulk of the charge and takes up roughly half of the required charge time. The topping charge continues at a lower charge current and provides saturation. The float charge compensates for the loss caused by self-discharge.

During the constant-current charge the battery charges to 70% SoC in 5 to 8 hours and the remaining 30% is supplied by the slower topping charge that lasts another 7 to 10 hours. The topping charge is essential for the well-being of the battery. If topping charge is not performed, the battery will eventually lose the ability to accept a full charge and performance will decrease because of sulfation. The float charge maintains the battery at full charge.

The switch to topping charge happens when the battery reaches the set voltage limit. Current begins to drop as the battery starts to saturate and full charge is reached when the current decreases to 3% of the rated current. A battery with high leakage may never reach this level and a timer is required to start charging termination.

The correct setting of the charge voltage is critical, ranging from 2.3 to 2.45 V per cell. The threshold is selected as a compromise between charging to maximum capacity and creating internal corrosion and gassing. The battery voltage also shifts with temperature, with warmer temperatures requiring slightly lower voltage thresholds. If variable voltage thresholds are not available in the charger, it is better to use a lower voltage threshold for safety.

Once fully charged through saturation, the battery should not dwell at the *topping voltage* for more than 48 hours and must be reduced to the *float voltage* level. This is especially critical for sealed systems because they are less able to tolerate overcharge than the flooded type due to heating and gas (hydrogen) generation. The recommended float voltage of most lead acid batteries is 2.25 to 2.27 V/cell. Manufacturers recommend lowering the float charge at ambient temperatures above 29° C (85° F). Not all chargers feature float charge. If the charger remains at the topping voltage and does not drop below 2.30 V/cell, remove the charger after a maximum of 48 hours of charge.

Aging batteries develop imbalances between cells that can result in overcharge and

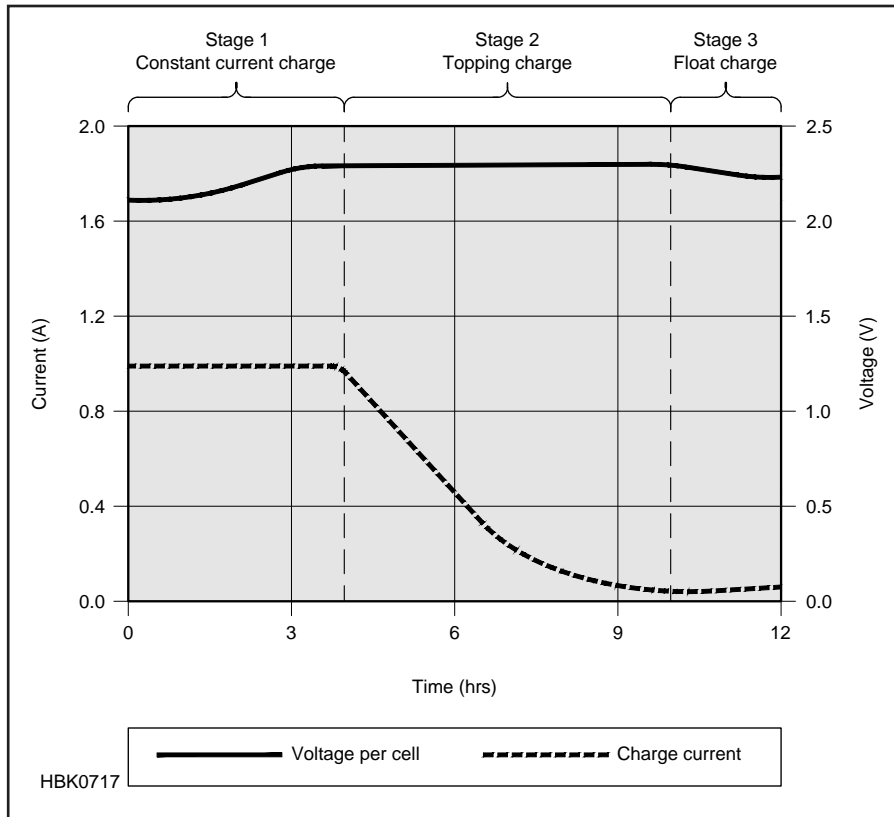

Fig 7.50 — Charge stages of a lead acid battery. The battery is fully charged when the current drops to a pre-determined level or levels out in stage 2. The float voltage must be reduced at full charge. (Courtesy of Cadex)

gassing from weak cells. This can also cause a strong cell to be undercharged and develop sulfation. Some battery manufacturers have developed cell-balancing devices that compensate for cell imbalance.

Lead acid batteries must always be stored in a charged state. A topping charge should be applied every six months to prevent the voltage from dropping below 2.10 V/cell. With AGM, these requirements can be somewhat relaxed.

Measuring the open circuit voltage (OCV) while in storage provides a reliable indication of the battery's state-of-charge (SoC). A voltage of 2.10 V at room temperature indicates a charge of about 90%. (That is equivalent to 12.6 V for a typical six-cell "12 V" lead acid battery.) Such a battery is in good condition and needs only a brief full charge prior to use. If the OCV is lower, the battery must be charged to prevent sulfation. Cool temperatures increase OCV slightly and warm temperatures lower it. Use OCV as an SoC indicator after the battery has rested for a few hours to allow the effects of charging to dissipate.

SIMPLE GUIDELINES FOR CHARGING LEAD ACID BATTERIES

- Charge in a well-ventilated area. Hydrogen gas generated during charging is explosive.

- Choose the appropriate charge program for flooded, gel and AGM batteries. Follow the manufacturer's specifications of voltage thresholds.

- Charge lead acid batteries after each use to prevent sulfation. Do not store on low charge.

- The plates of flooded batteries must always be fully submerged in electrolyte. Fill battery with distilled or de-ionized water to cover the plates if low. Never add electrolyte.

- Fill water level to designed level *after* charging. Overfilling a discharged battery can result in overflow and acid spillage.

- Formation of gas bubbles in a flooded lead acid battery is an indication of approaching full charge.

- Reduce float charge if the ambient temperature is higher than 29° C (85° F).

- Do not allow a lead acid battery to freeze and never charge a frozen battery.

- Do not charge at temperatures above 49° C (120° F).

CHARGING NICKEL-CADMIUM

Battery manufacturers recommend that new NiCd batteries be slow-charged for 16 to 24 hours before use. A slow charge brings all cells in a battery pack to an equal charge level. This is important because each cell within the

NiCd battery may have self-discharged at its own rate. Furthermore, during long storage the electrolyte tends to gravitate to the bottom of the cell and the initial trickle charge helps redistribute the electrolyte to eliminate dry spots on the separator. The cells will reach optimal performance after several charge/discharge cycles.

Full-charge Detection by Temperature

Full-charge detection of sealed nickel-based batteries is more complex than for lead acid and lithium-ion systems. Low-cost chargers often use temperature sensing to end the fast-charge, but this can be inaccurate due to internal and external temperature differences. Charger manufacturers use 50° C (122° F) as the temperature cutoff. Although any prolonged temperature above 45° C (113° F) is harmful, brief overshoot is acceptable if temperature will drop quickly when the charger changes to the "ready" state.

Some microprocessor-controlled chargers sense the rate of temperature increase with time, using the rapid temperature rise toward the end of charge to trigger the "ready" state. This is referred to as *delta temperature over delta time* or dV/dt . A rate of 1° C (1.8° F) per minute terminates charging. This keeps the battery cooler, but the cells need to charge reasonably fast for temperature to rise at the required rate. An absolute temperature of 60° C (140° F) terminates charging under any circumstances.

Chargers relying on temperature inflict harmful overcharges when fully charged batteries are inserted into the charger, such as if a hand-held radio is left in the charger between each use. This is not the case with Li-ion batteries where the charger uses voltage as the SoC indicator.

Full-charge Detection by Voltage Signature

Advanced chargers terminate charging when a defined voltage signature or profile with time occurs, referred to as *negative delta V* or NDV. This provides more precise full-charge detection for nickel-based batteries than temperature-based methods. Charging is terminated when the battery voltage drops as full charge is reached. NDV is the recommended method for NiCd cells that do not include an internal thermistor for temperature control and avoids overcharging of fully-charged batteries. NDV requires a charge rate of at least 0.5 C to generate a reliably measurable change in voltage and works best with fast charging. At a charge rate of 1 C, a fully discharged battery is recharged in about an hour.

Fig 7.51 illustrates the relationship of cell voltage, pressure, and temperature of a charging NiCd battery. Up to about 70% SoC, the

Fig 7.51 — Charge characteristics of a NiCd cell. Above 70% state-of-charge, temperature and cell pressure rise quickly. NiMH has similar charge characteristics. (Courtesy of Cadex)

battery accepts almost all of the energy supplied (called *charge efficiency*). Above 70%, the battery loses ability to accept charge, begins to generate gases so that pressure rises, and temperature increases rapidly.

Ultra-high-capacity NiCd batteries tend to heat up more than standard batteries when charging at 1 C and higher rates due to their higher internal resistance. Applying a high current during initial charge and tapering to a lower rate achieves good results with all nickel-based batteries and moderates temperature rise.

Some chargers can “burp” a charging battery by applying a load to generate a discharge pulse to cause gases to recombine and lower internal pressure. The result is a cooler and more effective charge than with conventional dc charging. Pulse charging does not apply to lead and lithium-based systems.

After full charge, the NiCd battery receives a trickle charge of between 0.05 C and 0.1 C to compensate for self-discharge. To avoid possible overcharge, trickle charging should be done at the lowest possible rate and the batteries should be removed from the charger after more than a few days.

CHARGING NICKEL-METAL-HYDRIDE

The charging algorithm for NiMH is similar to NiCd with the exception that NiMH is more complex. The NDV method of measuring full charge has difficulty because the voltage drop at full charge is very small — about

5 mV/cell. As a result, modern chargers combine the various methods of measuring voltage and temperature into a composite algorithm that reacts depending on battery condition.

Some advanced chargers apply an initial fast charge at 1 C. After reaching a certain voltage threshold, a few minutes rest is taken to allow the battery to cool. Charging then resumes at lower currents as the charge progresses to full charge. This is known as the “step-differential charge” and works well for all nickel-based batteries, achieving an extra capacity of about 6% above basic chargers. A drawback of this method is that the fast-charge stress on the battery will shorten overall battery life by 10 to 20%.

NiMH cannot absorb overcharge well and the trickle charge current must be limited to around 0.05 C. In comparison, a basic NiCd charger trickle charges at 0.1 C. This higher trickle charge and the need for sensitive full-charge detection render the basic NiCd chargers unsuitable for NiMH batteries. On the other hand, NiCd cells can be charged in a NiMH charger at the lower trickle charge rate.

Slow charging should not be used for NiMH batteries. At the charging rate of 0.1 to 0.3 C, the voltage and temperature profiles make it very difficult to measure full charge accurately so the charger must depend on a timer. Harmful overcharge will occur if a fixed timer is used, particularly when charging partially or fully charged batteries. The same is true for charging old batteries with reduced capacity.

Inexpensive chargers are prone to incorrect charging because of the difficulty in correctly sensing full charge. Remove the batteries from the charger when you think they are fully charged. For high charge rates, remove the batteries when they are warm to the touch. It is better to remove the batteries and recharge them before use than to leave them in the charger where they might be overcharged and damaged.

SIMPLE GUIDELINES ON CHARGING NICKEL-BASED BATTERIES

- Do not charge at high or freezing temperatures; room temperature is best.
- Do not use chargers that allow the batteries to heat; remove the batteries when warm to the touch.
- Nickel-based batteries are best fast charged.
- NiMH chargers can charge NiCd batteries but not vice versa.
- High charge current or overcharging on an aging battery may cause heat build-up.
- Do not leave a nickel-based battery in the charger for long periods, even with correct trickle charge. Remove and apply a brief charge before use.
- Nickel- and lithium-based batteries require different charge algorithms and cannot share the same charger unless it can switch between the different chemistries.

CHARGING LITHIUM-ION

The Li-ion charger is a voltage-limiting device that is similar to the lead acid system. The difference lies in a higher voltage per cell, tighter voltage tolerance and the absence of trickle or float charge at full charge. Li-ion cannot accept overcharge — any extra charging causes stress.

Most Li-ion cells charge to 4.20 V/cell with a tolerance of ± 50 mV/cell. **Fig 7.52** shows the voltage and current signature as lithium-ion passes through the stages for constant current and topping charge. The charge rate of a typical consumer Li-ion battery is between 0.5 and 1 C in Stage 1 and the charge time is about three hours. Manufacturers recommend charging the 18650 cell at 0.8 C or less. The cell should remain cool during the charging process although there may be a slight temperature rise of a few degrees when reaching full charge. Full charge occurs when the battery reaches the voltage threshold and the current drops to 3% of the rated current, or if the charging current reaches a constant value and does not decrease further. The latter may be due to elevated self-discharge.

Li-ion does not need to be fully charged, as is the case with lead acid, nor is it desirable to do so. In fact, it is better not to fully charge so as not to stress the battery. Choosing a lower voltage threshold or eliminating saturation

Fig 7.52 — Charge stages of lithium ion. Li-ion is fully charged when the current drops to a predetermined level or levels out at the end of Stage 2. In lieu of trickle charge, some chargers apply a topping charge when the voltage drops to 4.05 V/cell (Stage 4). (Courtesy of Cadex)

charge prolongs battery life at the cost of reduced runtime. Without a saturation stage, the battery is usually charged to around 85% of capacity.

Once charging is terminated, the battery voltage begins to drop and this eases the voltage stress. Over time, the open circuit voltage (OCV) will settle to between 3.60 and 3.90 V/cell. A battery receiving a fully saturated charge will keep the higher voltage longer than a battery that was fast charged and terminated without a saturation charge.

If a lithium-ion battery must be left in the charger for operational readiness, some chargers apply a brief topping charge to compensate for the small self-discharge of the battery and its protective circuit. It is common to let the battery voltage drop to 4.00 V/cell and then recharge to 4.05 V/cell to reduce voltage-related stress and prolong battery life. Battery-powered devices should be turned off when charging their battery. Otherwise, the *parasitic load* of the device can confuse the charger, distorting the charge cycle and stressing the battery.

Overcharging Lithium-ion

Lithium-ion systems operate safely within the designated operating voltages; however, the battery becomes unstable if inadvertently charged to a voltage higher than specified. Prolonged charging above 4.30 V/cell forms plating of metallic lithium on the anode, while

the cathode material becomes an oxidizing agent, loses stability and produces CO₂. Cell pressure rises until the internal *current interrupt device* (CID) disconnects the current at 1380 kPa (200 psi).

Should the pressure rise further, a safety membrane bursts open at 3450 kPa (500 psi) and the cell might eventually vent with flame. The thermal runaway moves lower when the battery is fully charged; for Li-cobalt this threshold is between 130-150° C (266-302° F), for nickel-manganese-cobalt (NMC) between 170-180° C (338-356° F), and manganese is 250° C (482° F). Li-phosphate enjoys similar and better temperature stabilities than manganese.

Lithium-ion is not the only battery that is a safety hazard if overcharged. Lead and nickel-based batteries are also known to melt down and cause fires if improperly handled. Properly designed charging equipment is paramount for all battery systems.

SIMPLE GUIDELINES FOR CHARGING LITHIUM-BASED BATTERIES

- A battery-powered device should be turned off while charging.
- Charge at a moderate temperature. Do not charge below freezing.
- Lithium-ion does not need to be fully charged; a partial charge is better.
- Chargers use different methods for

“ready” indication and may not always indicate a full charge.

- Discontinue using a charger and/or battery if the battery gets excessively warm.
- Before prolonged storage, apply some charge to bring a pack to about half charge.

SUMMARY OF CHARGING

Batteries have unique needs and **Table 7.11** explains how to satisfy these needs with correct handling. Because of similarities within the battery families, only lead, nickel and lithium systems are covered. Along with these guidelines, you can prolong battery life by following three simple rules: keep the battery at moderate temperatures, control the level and rate of discharge, and avoid abusing the battery.

7.13.6 Discharge Methods

C-RATE

According to the definition of *coulomb*, a current of 1 ampere is a flow of 1 coulomb (C) of charge per second. Today, the battery industry uses *C-rate* to scale the charge and discharge current of a battery.

Most portable batteries are rated at 1 C, meaning that a 1000 mAh battery that is discharged at 1 C should under ideal conditions provide a current of 1000 mA for 1 hr. The same battery discharging at 0.5 C would provide 500 mA for 2 hours, and at 2 C, the 1000 mAh battery would deliver 2000 mA for 30 minutes. 1 C is also known as a one-hour discharge; a 0.5 C is a two-hour discharge, a 2 C is a half-hour discharge, and so on.

A battery’s capacity—the amount of energy a battery can hold—can be measured with a *battery analyzer*. The analyzer discharges the battery at a calibrated current while measuring the time it takes to reach its specified end-of-discharge voltage. If a 1000 mAh battery could provide 1000 mA for 1 hour, 100% of the battery’s nominal energy rating would be reached.

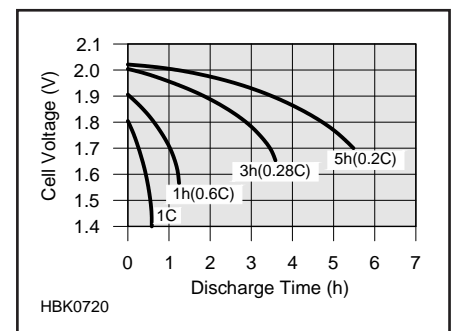

Fig 7.53 — Typical discharge curves of lead acid as a function of C-rate. Smaller batteries are rated at a 1 C discharge rate. Due to sluggish behavior, lead acid is rated at 0.2 C (5 hours) and 0.05 C (20 hours). (Courtesy of Cadex)

Table 7.11
Best Charging Methods

<i>Frequently Asked Question</i>	<i>Lead Acid (Sealed, flooded)</i>	<i>Nickel-Based (NiCd and NiMH)</i>	<i>Lithium-ion (Li-ion, Polymer)</i>
How should I prepare a new battery?	Battery comes fully charged. Apply topping charge	Charge 14-16 h. Priming may be needed.	Apply a topping charge before use. No priming needed
Can I damage a battery with incorrect use?	Yes, do not store partially charged, keep fully charged	Battery is robust and the performance will improve with use.	Keep some charge. Low charge can turn off protection circuit.
Do I need to apply a full charge?	Yes, partial charge causes sulfation.	Partial charge is fine.	Partial charge better than a full charge.
Can I disrupt a charge cycle?	Yes, partial charge causes no harm.	Interruptions can cause heat buildup.	Yes, partial charge causes no harm.
Should I use up all battery energy before charging?	No, deep discharge wears the battery down. Charge more often.	Apply scheduled discharges only to prevent memory.	No, deep discharge wears the battery down.
Do I have to worry about "memory"?	No memory	Discharge NiCd every 1-3 months.	No memory
How do I calibrate a "smart" battery?	Not applicable	Apply discharge/charge when the fuel gauge gets inaccurate. Repeat every 1-3 months.	Apply discharge/charge when the fuel gauge gets inaccurate. Repeat every 1-3 months.
Must I remove the battery when fully charged?	Depends on charger; needs correct float voltage	Remove after a few days in charger.	Not necessary; charger turns off
How do I store my battery?	Keep cells above 2.10 V, charge every 6 months	Store in cool place; a total discharge causes no harm.	Store in cool place partially charged, do not fully drain
Is the battery allowed to heat up during charge?	Battery may get lukewarm toward the end of charge.	Battery gets warm but must cool down on ready.	Battery may get lukewarm toward the end of charge.
How do I charge when cold?	Slow charge (0.1C): 0°-45° C (32°-113° F) Fast charge (0.5-1C): 5°-45° C (41°-113° F)	Slow charge (0.1C): 0°-45° C (32°-113° F) Fast charge (0.5-1C): 5°-45° C (41°-113° F)	Do not charge above 50° C (122° F) Do not charge above 50° C (122° F)
Can I charge at hot temperatures?	Above 25° C, lower threshold by 3 mV/°C.	Battery will not fully charge when hot	Do not charge above 50° C (122° F)
What should I know about chargers?	Charger should float at 2.25-2.30 V/cell when ready.	Battery should not get too hot; should include temp sensor.	Battery must stay cool; no trickle charge when ready.

(Table courtesy of Cadex)

If the discharge only lasted 30 minutes before reaching the specified voltage, the battery has a capacity of 50% of its nominal rating.

When discharging a battery at different rates a higher C-rate will produce a lower capacity reading due to the internal resistance turning some of the energy into heat instead of delivering it as current to a load. Lower C-rate discharges will produce a higher capacity.

For example, to obtain a reasonably good capacity rating, manufacturers commonly rate lead acid batteries at 0.05 C, or a 20-hour discharge. **Fig 7.53** illustrates the discharge times of a lead acid battery at various loads expressed in C-rate.

DEPTH OF DISCHARGE

The end-of-discharge voltage for lead

acid is 1.75 V/cell; for nickel-based systems it is 1.00 V/cell; and for most Li-ion it is 3.00 V/cell. At this level, roughly 95% of the battery's stored energy has been spent and voltage would drop rapidly if discharge were to continue. Most devices prevent operation beyond the specified end-of-discharge voltage. When removing the load after discharge, the voltage of a healthy battery gradually recovers toward the nominal voltage.

Because of internal resistance, wiring, protection circuits and contact resistance, a high load current lowers the battery voltage and the end-of-discharge voltage threshold should be lowered accordingly. The cutoff voltage should also be lowered when discharging at very cold temperatures. **Table 7.12** shows typical end-of-discharge voltages of various

battery chemistries. The lower end-of-discharge voltage for higher loads compensates for the losses from internal battery resistance.

Since the cells in a battery pack can never be perfectly matched, a negative voltage potential can occur across a weaker cell on a multi-cell pack if the discharge is allowed to continue beyond a safe cutoff point. Known as *cell reversal*, the weak cell suffers damage to the point of developing a permanent electrical short circuit. The larger the number of cells in the pack, the greater the likelihood that a cell might reverse under heavy load. Over-discharge, particularly at low temperatures, is a large contributor to battery failure of cordless power tools, especially for nickel-based packs. Li-ion packs have protection circuits and the failure rate is lower.

Table 7.12**Recommended End-of-Discharge Voltages in V/Cell**

End-of-discharge	Li-manganese	Li-phosphate	Lead-acid	NiCd/NiMH
Normal load	3.00	2.70	1.75	1.00
Heavy load	2.70	2.45	1.40	0.90

(Table courtesy of Cadex)

DISCHARGING AT HIGH AND LOW TEMPERATURES

Batteries achieve optimum service life if used at 20° C (68° F) or slightly below, and nickel-based chemistries degrade rapidly when cycled at high ambient temperatures. Higher temperature operation lowers internal resistance and speeds up the chemical reactions but shortens service life if prolonged.

The performance of all battery chemistries drops drastically at low temperatures. At -20° C (-4° F) most nickel, lead, and lithium-based batteries stop functioning. Although NiCd can be used down to -40° C (-40° F), the permissible discharge is only 0.2 C (5-hour rate). Lead acid also has the problem of the electrolyte freezing which can crack the enclosure. Lead acid electrolyte also freezes more easily at a low charge.

SIMPLE GUIDELINES FOR DISCHARGING BATTERIES

- Battery performance decreases with cold temperature and increases with heat.
- Heat increases battery performance but shortens cycle life by a factor of two for every 10° C (18° F) above 25-30° C (18° F above 77-86° F).
- Only charge at moderate temperatures. Check the manufacturer's specifications for charging below freezing.
- Use heating blankets if batteries need rapid charging at cold temperatures.
- Prevent over-discharging. Cell reversal can cause an electrical short circuit.
- Use a larger battery if repetitive deep discharge cycles cause stress.
- A moderate dc discharge is better for a battery than pulsed loads.
- Lead acid systems are sluggish and require a few seconds of recovery between heavy loads.

7.13.7 Battery Handling

This section touches on the most important aspects of handling batteries when they are new, during their service life, and how to store and dispose of them.

FORMATTING AND PRIMING BATTERIES

Rechargeable batteries may not deliver their full rated capacity when new and will require *formatting* — a process that essentially

completes the manufacturing process. Li-ion systems require less care in this regard, but cycling these batteries after long storage has been reported to improve performance. *Priming* is a conditioning cycle that is applied to improve battery performance during usage or after prolonged storage. Priming applies mainly to nickel-based batteries.

Formatting of lead acid batteries occurs by applying a charge, followed by a discharge and recharge as part of regular use. Gradually increase the load on a new battery, allowing it to reach full capacity after 50 to 100 cycles.

Manufacturers advise to trickle charge a nickel-based battery pack for 16 to 24 hours when new and after a long storage. This allows the individual cells to reach an equal charge level. A slow charge also helps to redistribute the electrolyte to eliminate dry spots on the separator that may have formed due to gravity. Applying several charge/discharge cycles through normal use or with a battery analyzer completes the formatting process. This can require from five to seven cycles or as many as 50 cycles depending on battery quality.

Cycling also restores lost capacity when a nickel-based battery has been stored for

six months or longer. Storage time, state-of-charge, and storage temperature all affect battery recovery. The longer the storage and the higher the temperature, the more cycles are required to regain full capacity.

Lithium-ion does not need formatting when new, nor does it require the level of maintenance that nickel-based batteries do. Maximum capacity is available immediately. A discharge/charge cycle may be beneficial for calibrating a "smart" battery but this does not improve the internal chemistry.

STORING BATTERIES

The recommended storage temperature for most batteries is 15° C (59° F) and the extreme allowable temperature is -40° C to 50° C (-40° F to 122° F) for most chemistries. While lead acid must be kept at full charge during storage, nickel and lithium-based chemistries should be stored at around 40% state-of-charge.

Storage will always cause batteries to age. **Table 7.13** illustrates the *recoverable capacity* of lithium and nickel-based batteries at various temperatures and charge levels over one year. Recoverable capacity is the available battery capacity after storage with a full charge.

A sealed lead acid battery can be stored up to two years. It is important to apply a charge when the battery falls to 70% SoC, typically 2.07 V/cell or 12.42 V for a 12 V pack.

Nickel-metal-hydride can be stored for about three years. The capacity drop that occurs during storage can partially be reversed with priming.

Primary alkaline and lithium batteries can be stored for up to 10 years with minimum capacity loss.

SIMPLE GUIDELINES FOR STORING BATTERIES

- Remove batteries from equipment and store in a dry and cool place.
- Avoid freezing. Batteries freeze more easily if in a discharged state.
- Charge lead acid before storing and monitor the voltage frequently; apply a charge if below 2.10 V/cell.
- Nickel-based batteries can be stored for five years and longer, prime before use.

Testing and Monitoring Batteries

Several sections of the "Testing and Monitoring" chapter from *Batteries in a Portable World* are provided on the CD-ROM accompanying this book. The information covers measuring internal resistance and state-of-charge, measuring capacity, and special techniques for measuring nickel- and lithium-based batteries.

Table 7.13**Estimated Recoverable Capacity After Storage For 1 Year**

Temp (°C)	Lead acid at full charge	Nickel-based at any charge	Lithium-ion (Li-cobalt)	
			40% charge	100% charge
0	97%	99%	98%	94%
25	90%	97%	96%	80%
40	62%	95%	85%	65%
60	38% (after 6 months)	70%	75%	60% (after 3 months)

(Table courtesy of Cadex)

- Lithium-ion must be stored in a charged state, ideally 40%.
- Discard Li-ion if the voltage has stayed below 2.00 V/cell for more than a week.

RECYCLING BATTERIES

The main objective for recycling batteries is to prevent hazardous materials from entering landfills. Lead acid and NiCd batteries are of special concern.

Under no circumstances should batteries be incinerated, as fire can cause an explosion. Wear approved gloves when touching electrolyte. On exposure to skin, flush with water immediately. If eye exposure occurs, flush with water for 15 minutes and consult a physician immediately.

Automotive and larger lead acid batteries can be recycled through auto parts stores and battery dealers. A recycling fee is usually charged when the battery is purchased.

Smaller batteries, including smaller SLA, can be recycled at many electronics and hardware stores, or your local municipal recycling center. Perform an Internet search for battery recyclers in your area.

It is helpful to create a specific location or designate a container for spent batteries at your home, office or workbench. This makes it easy to recycle the batteries by keeping them together in one spot.

7.13.8 DC-AC Inverters

For battery-powered operation of ac-powered equipment, dc-ac inverters are used. An inverter is a dc-to-ac converter that provides 120 V ac. Inverters come with varying degrees of sophistication. The simplest type of inverter switches directly at 60 Hz to produce a square-wave output. This is no problem for lighting and other loads that don't care about the input waveform. However, some equipment will work poorly or not at all when supplied with square wave power because of the high harmonic content of the waveform.

The harmonic content of the inverter output waveform can be reduced by the simple expedient of reducing the waveform duty cycle from 50% (for the square wave) to about 40%. For many loads, such as computers and other electronic devices, this may still not be adequate, and so many inverters use waveform shaping to approximate a sine-wave output. The simplest of these methods is a resonant inductor-capacitor filter. This adds significant weight and size to the inverter. Most modern inverters use high-frequency pulse-width modulation (PWM) techniques to synthesize the 60 Hz sinusoidal output waveform, much like a switching power supply. See Fig 7.54.

Inverters are usually rated in terms of their VA or "volt-ampere product" capability although sometimes they will be rated in watts. Care is required in interpreting inverter

Fig 7.54 — Output waveforms of typical dc-ac inverters. At A, the output of a modified sine wave inverter. Note the stepped square waves. At B, the output of a "pure sine wave" inverter. Note the close approximation of a commercial ac sine wave.

ratings. A purely resistive load operating from a sinusoidal voltage source will have a sinusoidal current flowing in phase with the voltage. In this case, VA, the product of the voltage (V) and the current (A), will equal the actual power in watts delivered to the load so that the VA and the watt ratings are the same. Some loads, such as motors and many rectifier power supplies, will shift the phase of load current away from the source voltage; or the load current will flow in short pulses as shown earlier for capacitor input filters. In these cases (which are very common), the VA product for that type of load can be much larger than the delivered power in watts. In the absence of detailed knowledge of the load characteristics it is prudent to select an inverter with a VA or wattage capability of 25% or more above the expected load.

7.13.9 Selecting a Battery for Mobile Operation

There are two basic modes of mobile operation: *in-motion*, and *stationary*. Each mode has unique power requirements and thus different battery requirements. To satisfy these needs, there are three basic battery types. It is important to understand the differences between the types and to apply them properly.

Standard vehicle batteries are referred to as *SLI* (starting, lights, ignition) or just *starter* batteries. Their primary function is to start the engine and then act as a power filter for the alternator which is the actual long-term power source. The most important rating of an SLI battery is the *cold cranking amps* (CCA) rating — the number of amps that the battery can produce at 32 °F (0 °C) for 30 seconds.

Batteries designed for repeated cycles of charging and discharging use are often called *deep-cycle* although the term is widely over-used. A true deep-cycle battery is designed to be repeatedly discharged to 20% remaining capacity. The term "deep cycle" is a misnomer, as all lead-acid batteries are considered discharged when their output voltage drops below 10.5 V at some specified current draw as outlined by the Battery Council Institute (BCI—www.batterycouncil.org). At 10.5 V, a six-cell lead-acid battery is considered discharged.

Marine batteries are designed to be stored without charging for up to two years, yet still maintain enough power to start a marine engine. Contrary to common practice, they're not really designed for extended low-current power delivery. Marine batteries often have hybrid characteristics between SLI and deep-cycle batteries.

To differentiate true deep-cycle batteries from SLI and marine batteries, examine a battery's *reserve capacity* (RC). A battery's RC rating is the number of minutes that the battery can deliver 25 A while maintaining an output voltage above 10.5 V. RC batteries typically have RC ratings 20% or more higher than SLI batteries and perhaps 50% higher under ICAS (intermittent, commercial, and amateur service) conditions. A deep-cycle battery has a lower CCA rating than an SLI battery due to its internal construction that favors long-term power delivery over high-current starting loads.

With these facts in mind, we can now select the correct battery for our style of mobile operating. For in-motion operation with power outputs up to 200 W, a second trunk-mounted battery is seldom needed if the power cabling wire size is chosen correctly. (See the **Assembling a Station** chapter for information on wire sizes in mobile applications.)

When an amplifier is added for higher output power levels, it is often less expensive to add a second trunk-mounted battery than to install larger cables to the main battery. In these cases, the second battery can be of almost any type, as long as it is lead-acid. The second battery should be connected in parallel to the vehicle's main SLI battery. The battery's ampere-hour rating should be close to that of the vehicle's main SLI battery.

All secondary wiring should be properly fused, as outlined in the **Assembling a**

Station chapter's section on mobile installations. The use of relays and circuit breakers should be avoided. Remember, should a short circuit occur, good-quality lead-acid batteries can deliver upwards of 3000 A which exceeds the break circuit ratings of most relays and circuit breakers. A better solution is a FET switch such as those made by Perfect Switch (www.perfectswitch.com).

Assuming the second battery is mounted inside the vehicle's passenger compartment or in the trunk, it should be an AGM type. AGM (Absorption Glass Mat) batteries do not outgas explosive hydrogen gas under normal operating conditions. Flooded (liquid electrolyte) batteries should *never* be used in an enclosed environment.

For stationary operation, select a battery with a large RC rating because it will not be continuously charged. There are two main considerations; the ampere-hour rating (Ah) and the reserve capacity rating, typically listed as C/8, C/10, or C/20, with units of hours. (C is the battery's capacity in Ah.) Dividing the Ah rating by the load amperage (8, 10 or 20 A) will give you the reserve capacity in hours, but the actual ampere-hours any given battery can deliver before the voltage reaches 10.5 V (nominal discharge level) will vary with the load, both average and peak. Heavier loads will reduce the actual ampere-hours available.

Automotive batteries are arranged in BCI group sizes (www.rtpnet.org/teaa/bci-group.html), from 21 through 98. Generally speaking, the larger the group size the larger the battery and the higher the Ah rating. For example, size 24 (small car) has an average rating of 40 Ah, and size 34 (large car) has an average rating of 55 Ah. Exact ratings, including their reserve capacity, are available from the manufacturers' websites listed below. A good rule of thumb is to select a battery as physically large as you have room for, consistent with the highest RC rating for any given Ah rating.

Batteries are heavy, and need to be properly secured inside a battery box or by using factory-supplied brackets. For example, a BIC group 34 (average SLI size) battery weighs about 55 pounds. Some battery models (such as the Optima) come supplied with mounting brackets and terminal protection covers. Even though battery boxes aren't always needed, they should be used as a safety precaution to prevent accidental contact with the terminals and can protect the battery from external items. Battery restraints should be adequate to provide 6 Gs of lateral and 4 Gs of vertical retention, ruling out sheet metal screws and most webbing material. Use the proper brackets!

There are three other considerations: isolating the battery electrically, recharging the

battery, and output voltage regulation. Diode-based battery isolators are not all equal. Models with FET bypass switches are the preferred type because of the low voltage-drop across the FET.

If you have wired the battery in parallel with the vehicle's main SLI battery, recharging is taken care of whenever the vehicle is running. If you plan on operating in stationary mode, you'll need a separate recharging system. Most vehicle factory-installed trailer wiring systems also include a circuit for charging RV or boat "house" batteries. Check with your dealer's service personnel about these options.

Voltage regulators, commonly called "battery boosters," are almost a necessity for stationary operation. A model with a low-voltage cutoff should be used to avoid discharging the battery below 10.5 V, as discharging a lead-acid battery beyond this point drastically reduces its charge-cycle life — the number of full-charge/full-discharge cycles. (See the November 2008 *QST* Product Review column.)

7.14 Glossary of Power Source Terms

Bleeder — A resistive load across the output or filter of a power supply, intended to quickly discharge stored energy once the supply is turned off.

Boost converter — A switchmode converter in which the output voltage is always greater than or equal to the input voltage.

Buck converter — A switchmode converter in which the output voltage is always less than or equal to the input voltage.

Buck-boost converter — A switchmode converter in which the magnitude of the output voltage can be either greater or less than the input voltage.

C-rate — The charging rate for a battery, expressed as a ratio of the battery's ampere-hour rating.

CCA (cold cranking amps) — A measure of a battery's ability to deliver high current to a starter motor.

Circular mils — A convenient way of expressing the cross-sectional area of a

round conductor. The area of the conductor in circular mils is found by squaring its diameter in mils (thousandths of an inch), rather than squaring its radius and multiplying by pi. For example, the diameter of 10-gauge wire is 101.9 mils (0.1019 inch). Its cross-sectional area is 10380 CM, or 0.008155 square inches.

Core saturation (magnetic) — That condition whereby the magnetic flux in a transformer or inductor core is more than the core can handle. If the flux is forced beyond this point, the permeability of the core will decrease, and it will approach the permeability of air.

Crowbar — A last-ditch protection circuit included in many power supplies to protect the load equipment against failure of the regulator in the supply. The crowbar senses an overvoltage condition on the supply's output and fires a shorting device (usually an SCR) to directly short-circuit the supply's output and protect

the load. This causes very high currents in the power supply, which blow the supply's input-line fuse.

Darlington transistor — A package of two transistors in one case, with the collectors tied together, and the emitter of one transistor connected to the base of the other. The effective current gain of the pair is approximately the product of the individual gains of the two devices.

DC-DC converter — A circuit for changing the voltage of a dc source to ac, transforming it to another level, and then rectifying the output to produce direct current.

Deep-cycle — A battery designed for repeated charge-discharge cycles to 20% of remaining capacity.

Equalizing resistors — Equal-value bypassing resistors placed across capacitors connected in series for use in a high-voltage power supply to keep the voltages across the capacitors in the string relatively constant.

- Fast recovery rectifier** — A specially doped rectifier diode designed to minimize the time necessary to halt conduction when the diode is switched from a forward-biased state to a reverse-biased state.
- Flyback converter** — A transformer-coupled version of the **buck-boost converter**.
- Forward converter** — A **buck converter** with multiple isolated outputs at different voltage levels and polarities.
- Foldback current limiting** — A special type of current limiting used in linear power supplies, which reduces the current through the supply's regulator to a low value under short circuited load conditions in order to protect the series pass transistor from excessive power dissipation and possible destruction.
- Ground fault (circuit) interrupter (GFI or GFCI)** — A safety device installed between the household power mains and equipment where there is a danger of personnel touching an earth ground while operating the equipment. The GFI senses any current flowing directly to ground and immediately switches off all power to the equipment to minimize electrical shock. GFCIs are now standard equipment in bathroom and outdoor receptacles.
- Input-output differential** — The voltage drop appearing across the series pass transistor in a linear voltage regulator. This term is usually stated as a minimum value, which is that voltage necessary to allow the regulator to function and conduct current. A typical figure for this drop in most three-terminal regulator ICs is about 2.5 V. In other words, a regulator that is to provide 12.5 V dc will need a source voltage of at least 15.0 V at all times to maintain regulation.
- Inverter** — A circuit for producing ac power from a dc source.
- Li-ion** — Lithium-ion, a type of rechargeable battery that is about $\frac{1}{3}$ the weight and $\frac{1}{2}$ the volume of a **NiCd** battery of the same capacity.
- Low dropout regulator** — A three-terminal regulator designed to work with a low minimum input-output differential value.
- Marine** — A battery designed to retain significant energy over long periods of time without being continuously charged.
- NiCd** — Nickel cadmium, a type of rechargeable battery.
- NiMH** — Nickel metal hydride, a type of rechargeable battery that does not contain toxic substances.
- Peak inverse voltage (PIV)** — The maximum reverse-biased voltage that a semiconductor is rated to handle safely. Exceeding the peak inverse rating can result in junction breakdown and device destruction.
- Power converter** — Another term for a power supply.
- Power processor** — Another term for a power supply.
- Primary battery** — A battery intended for one-time use and then discarded.
- RC (reserve capacity)** — A measure of a battery's ability to deliver current over long periods.
- Regulator** — A device (such as a Zener diode) or circuitry in a power supply for maintaining a constant output voltage over a range of load currents and input voltages.
- Resonant converter** — A form of dc-dc converter characterized by the series pass switch turning on into an effective series-resonant load. This allows a zero current condition at turn-on and turn-off. The resonant converter normally operates at frequencies between 100 kHz and 500 kHz and is very compact in size for its power handling ability.
- Ripple** — The residual ac left after rectification, filtration and regulation of the input power.
- RMS** — Root Mean Square. Refers to the effective value of an alternating voltage or current, corresponding to the dc voltage or current that would cause the same heating effect.
- Secondary battery** — A battery that may be recharged many times. Also called a *storage battery*.
- Secondary breakdown** — A runaway failure condition in a transistor, occurring at higher collector-emitter voltages, where hot spots occur due to (and promoting) localization of the collector current at that region of the chip.
- Series pass transistor, or pass transistor** — The transistor(s) that control(s) the passage of power between the unregulated dc source and the load in a regulator. In a linear regulator, the series pass transistor acts as a controlled resistor to drop the voltage to that needed by the load. In a switch-mode regulator, the series pass transistor switches between its ON and OFF states.
- SLI (starter, lights, ignition)** — An automotive battery designed to start the vehicle and provide power to the lighting and ignition systems.
- SOA (Safe Operating Area)** — The range of permissible collector current and collector-emitter voltage combinations where a transistor may be safely operated without danger of device failure.
- Surge** — A moderate-duration perturbation on a power line, usually lasting for hundreds of milliseconds to several seconds.
- Switching regulator** — Another name for a switchmode converter.
- Switchmode converter** — A high-efficiency switching circuit used for dc-dc power conversion. Switching circuits are usually much smaller and lighter than conventional 60 Hz, transformer-rectifier circuits because they operate at much higher frequencies — from 25 to 400 kHz or even higher.
- Three-terminal regulator** — A device used for voltage regulation that has three leads (terminals) and includes a voltage reference, a high-gain error amplifier, temperature-compensated voltage sensing resistors and a pass element.
- Transient** — A short perturbation or "spike" on a power line, usually lasting for microseconds to tens of milliseconds.
- Varistor** — A surge suppression device used to absorb transients and spikes occurring on the power lines, thereby protecting electronic equipment plugged into that line. Frequently, the term MOV (Metal Oxide Varistor) is used instead.
- Volt-Amperes (VA)** — The product obtained by multiplying the current times the voltage in an ac circuit without regard for the phase angle between the two. This is also known as the apparent power delivered to the load as opposed to the actual or real power absorbed by the load, expressed in watts.
- Voltage multiplier** — A type of rectifier circuit that is arranged so as to charge a capacitor or capacitors on one half-cycle of the ac input voltage waveform, and then to connect these capacitors in series with the rectified line or other charged capacitors on the alternate half-cycle. The voltage doubler and tripler are commonly used forms of the voltage multiplier.
- Voltage regulation** — The change in power supply output voltage with load, expressed as a percentage.

7.16 Power Source Projects

Construction of a power supply or accessory — basic to all of the radio equipment we operate and enjoy — can be one of the most rewarding projects undertaken by a radio amateur. Final testing and adjustment of most power-supply projects requires only a voltmeter, and perhaps an oscilloscope — tools commonly available to most amateurs.

General construction techniques that may be helpful in building the projects in this chapter are outlined in the **Construction Techniques** chapter. Other chapters in the *Handbook* contain basic information about the components that make up power supplies.

Safety must always be carefully considered during design and construction of any power supply. Power supplies contain potentially lethal voltages, and care must be taken to guard against accidental exposure. For example, electrical tape, insulated tubing (“spaghetti”) or heat-shrink tubing is recommended for covering exposed wires, components leads, component solder terminals and tie-down points. Whenever possible, connectors used to mate the power supply to the outside world should be of an insulated type designed to prevent accidental contact.

Connectors and wire should be checked for voltage and current ratings. Always use wire with an insulation rating higher than the working voltages in the power supply. For supply voltages above 300 V, use wire with insulation rated accordingly. The **Component Data and References** chapter contains a table showing the current-carrying capability of various wire sizes. Scrimping on wire and connectors to save money could result in flashover, melt-down or fire.

All fuses and switches should be placed in the hot circuit(s) only. The neutral circuit should not be interrupted. Use of a three-wire (grounded) power connection will greatly reduce the chance of accidental shock. The proper wiring color code for 120 V circuits is: black — hot; white — neutral; and green

— ground. For 240 V circuits, the second hot circuit generally uses a red wire.

POWER SUPPLY PRIMARY-CIRCUIT CONNECTOR STANDARD

The International Commission on Rules for the Approval of Electrical Equipment (CEE) standard for power-supply primary-circuit connectors for use with detachable cable assemblies is the CEE-22. The CEE-22 has been recognized by the ARRL and standards agencies of many countries. Rated for up to 250 V, 6 A at 65 °C, the CEE-22 is the most commonly used three-wire (grounded), chassis-mount primary circuit connector for electronic equipment in North America and Europe. It is often used in Japan and Australia as well.

When building a power supply requiring 6 A or less for the primary supply, a builder would do well to consider using a CEE-22 connector and an appropriate cable assembly, rather than a permanently installed line cord. Use of a detachable line cord makes replacement easy in case of damage. CEE-22 compatible cable assemblies are available with a wide variety of power plugs including most types used overseas.

Some manufacturers even supply the CEE-22 connector with a built-in line filter. These connector/filter combinations are especially useful in supplies that are operated in RF fields. They are also useful in digital equipment to minimize conducted interference to the power lines.

CEE-22 connectors are available in many styles for chassis or PC-board mounting. Some have screw terminals; others have solder terminals. Some styles even contain built-in fuse holders.

7.16.1 Four-Output Switching Bench Supply

This project by Larry Cicchinelli, K3PTO,

describes the four-output bench power supply shown in **Fig 7.55** with three positive outputs and one negative output. The three positive outputs use identical switching regulator circuits that can be set independently to any voltage between 3.3 V and 20 V at up to 1 A. The fourth output is a negative regulator capable of about 250 mA. As built, the supply has two fixed outputs and two variable outputs, but any module can be built with variable output. (Construction diagrams and instructions, a complete parts list, and additional design details are included on this *Handbook's* CD-ROM.)

The only dependency among the outputs is that they are all driven by a single transformer. The transformer used is rated at 25 V and 2 A — good for 50 W. Assuming that the regulator IC being used has a 75% efficiency, a total of about 37 W is available from the power supply outputs.

One of the features of a switching regulator is that you can draw more current from the outputs than what the transformer is supplying — at a lower voltage, of course — as long as you stay within the 37 W limit and maximum current for the regulator. Most of the discussion in this article will be about the

Fig 7.55 — The front panel of the four-output switching supply.

CONSTRUCTION DETAILS

Both the DPM and the regulators use pin headers for all of the connections that come off the boards (see the parts list for details). This allows assembly of the subsystems without having to consider any attached wires. Wire lengths can be determined later, then install the mating connectors on the wires and simply push them onto the pins.

PC boards are available from FAR Circuits (www.farcircuits.net), a company that provides a lot of boards for ham-related projects. A caution regarding the circuit boards is in order—the boards do not have plated through holes so you will have to be sure that you solder the through-hole components on *both* sides of the board.

Artwork for the PC board layout, Gerber files, and a drill file are available on the CD-ROM included with this book. The schematic capture software *DipTrace* was used in the development of this project. Source files for the schematic and PCB files are also available on the CD-ROM.

7.16.2 12 V, 15 A Linear Power Supply

This power supply is a linear 12 V, 15 A design by Ed Oscarson, WA1TWX. It is suitable for typical mobile radios and offers adjustable output voltage and current limiting. Supply regulation is excellent, typically exhibiting a change of less than 20 mV from no load to 15 A. This basic design, with heftier components and additional pass transistors, can deliver over 30 A—enough to supply a 100 W class transceiver. (All numbered notes, additional circuit design information, a discussion of how to change the supply voltage and/or current ratings, construction and testing notes, a PCB template and a complete parts list are available on the CD-ROM included with this *Handbook*.)

CIRCUIT DESCRIPTION

Fig 7.59 is the supply's schematic. The ac line input is fused by F1, switched on and off by S1 and filtered by FL1. F1 and S1 are rated at about ¼ of the output current requirement (for 15 A output, use a 4 or 5 A slow-blow fuse or a similarly rated circuit breaker). FL1 prevents any RF from the secondary or load from coupling into the power line and prevents RF on the power line from disturbing supply operation. If your ac power line is clean, and you experience no RF problems, you can eliminate FL1, but it's inexpensive insurance.

When discharged, filter capacitor C1 looks like a short circuit across the output of rectifier U2 when ac power is applied. That usually subjects the rectifier and capacitor to a large inrush current, which can damage them. Fortunately a simple and inexpensive

means of inrush-current limiting is available. Keystone Carbon Company (and others) produce a line of inrush-current limiters (thermistors) for this purpose. The device (RT1) is placed in series with one of the transformer primary leads. RT1 has a current rating of 6 A¹, and a cold resistance of 5 Ω. When it's hot, RT1's resistance drops to 0.11 Ω. Such a low resistance has a negligible effect on supply operation. Thermistors run *hot* so they must be mounted in free air, and away from anything that can be damaged by heat.^{2,3}

The largest and most important part in the power supply is the transformer (T1). If purchased new, it can also be the most costly. Fortunately, a number of surplus dealers offer power transformers that can be used in this supply.

T1 produces 17 V ac RMS at 20 A; the center tap is not used. Bridge rectifier U2 provides full-wave rectification. Full-wave rectification reduces the ripple component of current that flows in the filter capacitor, resulting in less power dissipation in the capacitor's internal resistance. U2's voltage rating should be at least 50 V, and its current rating about 25% higher than the normal load requirement; a 2 A bridge rectifier will do. U2 is secured to the chassis or a heat sink because it dissipates heat.

C1 is a computer-grade electrolytic. Any capacitor value from 15,000 to 30,000 μF will suffice. This version uses a 19,000 μF, 40 V capacitor. The capacitor's voltage rating should be at least 50% higher than the expected no-load rectified dc voltage. In this supply, that voltage is 25 V, and a 40 V capacitor provides enough margin.

R5, a 75 Ω, 20 W bleeder resistor, is connected across C1's terminals to discharge the supply when no load is attached or one is removed. Any resistance value from 50 Ω to 200 Ω is fine; adjust the resistor's wattage rating appropriately.

At the terminals of C1, we have a dc voltage, but it varies widely with the load applied. When keying a CW transmitter or switching a rig from receive to full output, 5 V swings can result. The dc voltage also has an ac ripple component of up to 1.5 V under full load. Adding a solid-state regulator (U1) provides a stable output voltage even with a varying input and load.

VOLTAGE REGULATOR IC AND PASS TRANSISTORS

The LM723 used at U1 has a built-in voltage reference and sense amplifier, and a 150 mA drive output for a pass-transistor array. U1's voltage reference provides a stable point of comparison for the internal regulator circuitry. In this supply, it's connected to the

¹See the full article on the *Handbook* CD-ROM for a list of numbered notes.

non-inverting input of the voltage-sense op amp. The reference is set internally to 7.15 V, but the absolute value is not critical because an output-voltage adjustment (R12) is provided. What is important is that the voltage is stable, with a specified variation of 0.05% per 1000 hours of operation. This is more than adequate for the supply.

For the regulator to work properly, its ground reference must be at the same point as the output ground terminal. The best way to ensure this is to use the output GROUND terminal (J4) as a single-point ground for all of the supply grounds. Run wires to J4 from each component requiring a ground connection. Fig 7.59 attempts to show this graphically through the use of parallel connections to a single circuit node.

The output pass transistor array consists of a TIP112 Darlington-pair transistor (Q5) driving three 2N3055 power transistors (Q1-Q3). This two-stage design is less efficient than connecting the power transistors directly to the LM723, but Q5 can provide considerably more base current to the 2N3055s than the 150 mA maximum rating of the LM723. You can place additional 2N3055s in parallel to increase the output current capacity of the supply.

This design is not fussy about the pass transistors or the Darlington transistor used. Just ensure all of these devices have voltage ratings of at least 40 V. Q5 must have a 5 A (or greater) collector-current rating and a beta of over 100. The pass transistors should be rated for collector currents of 10 A or more, and have a beta of at least 10.⁵

Resistors R17, R18 and R19 prevent leakage current through the collector-base junction from turning on the transistor by diverting it around the base-emitter junction. When the pass transistors are hot, at the V_{CE} encountered in this design, the leakage current can be as high as 3 mA. The resulting drop across the 33 Ω resistors is 0.1 V—safely below the turn-on value for V_{BE}.

When unmatched transistors are simply connected in parallel they usually don't equally share the current.⁶ By placing a low-value resistor in each transistor's emitter lead (emitter-ballasting resistors, R1-R3), equal current sharing is ensured. When a transistor with a lower voltage drop tries to pass more current, the emitter resistor's voltage drop increases, allowing the other transistors to provide more current. Because the voltage-sense point is on the load side of the resistors, the transistors are forced to dynamically share the load current.

With a 5 A emitter current, 0.25 V develops across each 0.05 Ω resistor, producing 1.25 W of heat. Ideally, a resistor's power rating should be at least twice the power it's called upon to dissipate. To help the resistors dissipate the heat, mount them on a heat sink,

side of R4. R8 and potentiometer R14 connect between the positive output terminal (J3) and the negative side of M2 to provide calibration adjustment. The values of R8 and R14 are determined by the coil-current requirements of the meter used. (Digital panel meters or a dedicated DMM can be used instead of separate analog meters.)

OUTPUT WIRING AND CROWBAR CIRCUIT

The supply output is connected to the outside world by two heavy-duty banana jacks, J3 and J4. C2, a 100 µF capacitor, is soldered directly across the terminals to prevent low-frequency oscillation. C6, a 0.1 µF capacitor, is included to shunt RF energy to ground. Heavy-gauge wire must be used for the connections between the pass transistors and J3 and between chassis ground and J4. The voltage-sense wire must connect directly to J3 and U2's ground pin must connect directly to J4 (see Fig 7.59). This provides the best output voltage regulation.

An over-voltage crowbar circuit prevents the output voltage from exceeding a preset limit. If that limit is exceeded, the output is shunted to ground until power is removed. If the current-limiting circuitry in the supply is working properly, the supply current-limits to the preset value. If the current limiting is not functioning, the crowbar causes the ac-line fuse to blow. Therefore, it's important to use the correct fuse size: 4 to 5 A for a 15 A supply. The crowbar circuit is a simple design based

on an SCR's ability to latch and conduct until the voltage source is removed. The SCR (Q4) is connected across output terminals J3 and J4. (The SCR can also be connected directly across the filter capacitor, C1, for additional protection.) R10 and potentiometer R16 in series with the Q4's gate provide a means of adjusting the trip voltage. The prototype crowbar is set to conduct at 15 V. The S6025L SCR is rated at 25 A and should be mounted on a metal chassis or heat sink. (Note: Some SCRs are isolated from their mounting tabs, others are not. The S6025L and the 65-ampere S4065J are isolated types. If the SCR you use is not isolated, use a mica washer or thermal pad to insulate it from the chassis or heat sink.)

The bold lines in Fig 7.59 indicate high-current paths that should use heavy-gauge (#10 or #12 AWG) wire. Traces that are connected to the output terminals in the schematic by individual lines should be connected directly to the terminals by individual wires. This establishes a 4-wire measurement, where the heavy wires carry the current (and have voltage drops) and the sense wires carry almost no current and therefore voltage errors are not caused by voltage drops in the wiring. If desired, the sense wire can be carried out to the load, but that may introduce noise into the sense feedback circuit, so use caution if that is done.

7.16.3 13.8 V, 5 A Linear Power Supply

This power supply was designed by Ben Spencer, G4YNM, provides 13.8 V dc at 5 A, suitable for many low-power transceivers and accessories. It features time-dependent current limiting and short-circuit protection, thermal overload protection within the safe operating area of the regulator IC, and overvoltage protection for the equipment it powers. The prototype supply powers a 25 W transmitter that continually draws 4.5 A.

Construction, testing and calibration are straightforward, requiring no special skills or equipment. Many of the components can be found in junk boxes, or purchased at hamfests or from mail-order suppliers.

CIRCUIT DESCRIPTION

Fig 7.60 is the power supply schematic. Incoming ac line current is filtered by a chassis-mounted line filter (FL1) and, after passing through the fuse (F1), is routed S1 to T1.

U1 rectifies, and C1 filters, the ac output of T1. U2 is an LM338K voltage regulator. This IC features a continuous output of 5 A, with a guaranteed peak output of 7 A, on-chip thermal and safe-operating-area protection for itself, and current limiting. U2's output voltage is set by two resistors (R2 and R3) and a trimmer potentiometer (R8), which allows for adjustment over a small range. U2's input and output are bypassed by C2, C3, and C4.

D1 and D2 protect U2 against these capacitors discharging through it.

Overvoltage protection is provided by an SCR, Q1, across the regulator input. Normally, Q1 presents an open circuit, but under fault conditions, it's triggered and short-circuits the unregulated dc input to ground. This discharges C1 and blows F2, reducing the possibility of damage to any connected equipment.

U3, an overvoltage-protection IC, continuously monitors the output voltage. When the output voltage rises above a predetermined level, U3 starts charging C5. If the overvoltage duration is sufficiently long, U3 triggers Q1. This built-in delay (about 1 ms) allows short transient noise spikes on the output voltage to be safely ignored while still triggering the SCR if a true fault occurs. The monitored voltage is set by R5 and R6 and trimmer potentiometer R9, which allows for adjustment over a limited range.

D3 protects the supply from reverse-polarity discharge from connected equipment. The presence of output voltage is indicated by an LED, DS1. R7 is a current limiting resistor for DS1.

CONSTRUCTION

How you construct your supply depends on the size of the components and enclosure you use. General physical layout is not important, although there are a couple of areas that require some attention. In the unit shown in Fig 7.61, FL1, the fuse holders, S1, the heat sink. DS1 and the binding posts are mounted on the front and rear enclosure panels. T1 and the PC board are secured to the enclosure's bottom plate. C1's mounting clamp is attached to the rear panel. Bleeder resistor R1 is connected directly across C1's terminals. D3 is soldered directly across the output binding posts.

U2, D1, D2 and R3 are all mounted directly on the heat sink with the transistor pins and solder lugs acting as a terminal strip. It's important to keep R3 attached as closely as possible to U2's terminals to prevent instability. Use a TO-3 mounting kit and heat-conductive grease or thermal pad to electrically isolate U2 from the heat sink.

Mount U2, C1, and the PC board close to each other and keep the wire runs between these components as short as possible. Excessively long wire runs may lead to unpredictable behavior.

Cover all ac-input wiring (use insulated wire and heat-shrink tubing) to prevent electrical shock and route the ac wiring away from the dc wiring. Mount the heat sink on the enclosure with fins oriented vertically. Louvers or ventilation holes in the cabinet will help cool internal components.

TEST AND CALIBRATION

An accurate multimeter covering ranges of

30 V dc and 10 A dc is required. A variable resistive load with a power rating of 100 W is also needed; this can be made using a heat-sink-mounted 2N3055 power transistor and a couple of components as shown in the next project.

First, set R8 (OUTPUT VOLTAGE) fully clockwise and R9 (OVERVOLTAGE) fully counterclockwise. Insert a fuse in the dc line at F2. Connect the ac line, turn on S1 and check that DS1 lights. Measure the output voltage: it should be about 12 V. Adjust R8 counterclockwise until you obtain 14.2 V output; this sets the trip voltage.

While monitoring the output voltage, gradually adjust R9 clockwise until the voltage suddenly falls to zero. This indicates that the SCR has triggered and blown F2. Disconnect the ac line cord from the wall socket. *Don't make any adjustment to R9!* Instead, adjust R8 fully clockwise.

With the ac line cord removed, check that F2 is open. Replace F2 with a new fuse (now you know why two of the three fuses are called for). Reconnect the ac line cord, and while continually monitoring the output voltage, gradually adjust R8 until Q1 again triggers at 14.2 V, blowing F2. If you find the adjustment of R9 to be too sensitive, use a 500 Ω potentiometer in its place and reduce the value of R5 (if necessary) to provide the required adjustment range.

Again disconnect the line cord from the wall socket, set R8 fully clockwise, replace F2 (there's the third fuse!) and reset R8 for 13.8 V. This completes the voltage calibration and overvoltage protection tests. The power supply is now set to 13.8 V output, with the overvoltage protection set for 14.2 V.

Adjust the variable resistive load to maximum resistance and connect it to the power supply output in series with the ammeter. Turn on the power supply and gradually adjust R10 until a current of 5 A flows. Decrease the resistance further and check that the current limits between 5.5 A and 0.5 A.

Finally, be thoroughly unpleasant and apply a short circuit via the ammeter. Check that the current-limiting feature operates correctly. The prototype limited at approximately 3.5 A. Disconnect the ac line cord and test equipment, dose up the case and your power supply is ready for service.

7.16.4 Adjustable Resistive Load

Fig 7.62 shows the schematic of an adjustable resistive load that can be used to test and adjust power supplies at currents up to 10 A if the 2N3055 transistor is mounted on an adequate heat sink. R1 and R2 vary the base bias to control the collector current of Q1. For extended use, be sure to use a large heat sink with adequate ventilation. Use heavy wire

Fig 7.61 — Physical layout of the 13.8 V, 5 A power supply. On the rear panel, left, are the ac-line filter and F1. The regulator's heat sink is at the middle of the panel and F2 is to the right. At the bottom of the enclosure, in front of T1, is the diode bridge rectifier. Because C1 is too tall to mount vertically within the Hammond #14260 cabinet, its mounting clamp is secured to the inside rear panel. Immediately to the right of C1 is the PCB board. On the front panel are the on/off switch, LED power-on indicator and output-voltage binding posts.

through the current meter to the collector and from the emitter of Q1.

7.16.5 Inverting DC-DC Converter

It's often the case that you need +V and -V when all you have is +V. For example, you need +12 V and -12 V, but all that's available is +12 V. It would be really handy to have a "black box" that would give you -V out when you put +V in, and work over a range of voltages without adjustment. This project by Jim Stewart, which originally appeared in the January 2013 issue of *Nuts and Volts Magazine* (www.nutsvolts.com), fills that need by using a switchmode voltage mirror to supply more than 100 mA without a significant drop in voltage.

The following text summarizes how the circuit works. A PDF version of the complete article is included on the CD-ROM that

comes with this book. It contains more details about the circuit's design, plus construction and testing information. A PCB and parts kit is available from the *Nuts and Volts* online store, as well. An ExpressPCB file (PV2NV.PCB) is available for download at www.nutsvolts.com/index.php?/magazine/article/january2013_Stewart.

CIRCUIT DESIGN

The circuit in Fig 7.63 is a buck-boost dc-dc converter as described earlier in this chapter. This particular design has five important parameters:

- Input voltage: V_{IN}
- Output voltage: V_{OUT}
- Load resistance: R_{LOAD}
- Oscillation frequency: f
- Inductance value: L

The parameters are related to each other by $f \times L < (V_{IN} / V_{OUT})^2 \times (R_{LOAD} / 8)$. For $V_{IN} = V_{OUT}$, the equation simplifies to

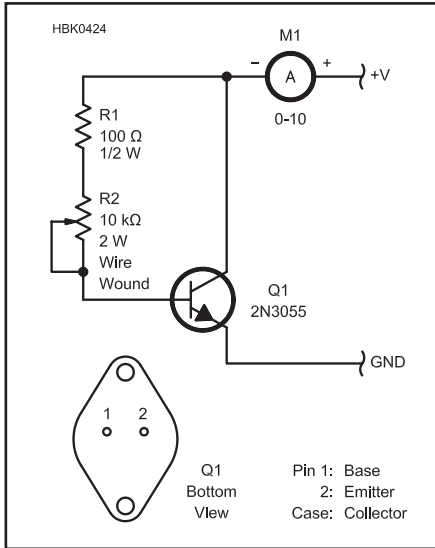

Fig 7.62 — An active resistive load to use in testing power supplies up to 10 A with adequate heat sinking. Adjustment of R2 is sensitive.

M1 — Multimeter or ammeter capable of measuring 10 A.
Q1 — 2N3055; mount on heat sink.

$f \times L < (R_{LOAD}/8)$. (See the complete article on the CD-ROM for the derivation of these equations.)

Fig 7.63 shows the schematic of the circuit. A square wave oscillator (U2) drives a MOSFET (Q2) that, in turn, drives a PNP switching transistor (Q3). The oscillator is enabled/disabled by the output of the comparator (U1) with inputs that are a set point voltage (V_S on the comparator's + input) and a feedback voltage (V_F at the comparator's - input). (Comparators are described in the **Analog Fundamentals** chapter.) The frequency of the oscillator is $f = 1/2.2(R7 \times C3)$.

When the output voltage, V_{OUT} , is the correct value, V_S exceeds V_F by a few μV and the oscillator is disabled by Q1 so that the PNP switch is off. When V_S is less than V_F , the oscillator is enabled and the PNP transistor switches on and off. V_S is half the input voltage $V_S = V_{IN}/2$ as set by the R3-R4 voltage divider.

V_F is set by the R1-R2 divider to equal $V_{IN}/2$ when the output voltage $V_{OUT} = -V_{IN}$. D2 is a commutating diode that blocks +V from the output while charging the inductor. It then provides a current path for the discharging inductor to transfer charge to the output capacitor.

The switching action continues until the voltage on the capacitor equals $-V_{IN}$. At that point, the comparator disables the oscillator and Q3 stays OFF. When voltage across

the capacitor drops, the comparator enables the oscillator and the inductor is pumped up again.

Since there is a single input voltage, each op-amp uses a resistor divider to "split the rail" to create a signal ground. That allows the negative input to sense positive and negative voltages with respect to the positive input. C2 and C4 bypass the signal grounds to the supply voltage ground.

C1 and C5 are low-ESR (equivalent series resistance — see the **Electrical Fundamentals** chapter) aluminum electrolytic capacitors. Tantalum capacitors might be a bit better, but are more expensive. ESR determines how much power the capacitor can safely dissipate. $P_{DISS} = I_{RC}^2 \times ESR$, where I_{RC} is the ac ripple current in the capacitor. The capacitors chosen are rated for a maximum ripple current of 840 mA.

D1 and D2 are Schottky diodes that can go from conducting to non-conducting very quickly, allowing a high switching frequency. They also have a low voltage drop when conducting to reduce power loss. D1 limits the output voltage in case the feedback fails.

Q3 is a ZTX550 PNP transistor, chosen because its specifications suit this application well:

- Maximum power dissipation, $P_{MAX} = 1 W @ 25^\circ C$
- Maximum continuous collector current, $I_C = 1 A$

C1 — 220 μF , 35 V (Digi-Key part #493-1578-ND or equiv).
C2 — 0.1 μF , 50 V, ceramic.
C3 — 1 nF film, 5% (Digi-Key part #399-5871-ND or equiv).
C4 — 0.1 μF , 50 V, ceramic.
C5 — 220 μF , 35 V (Digi-Key part #493-1578-ND or equiv).

D1, D2 — Schottky, 1 A, 1N5819 or equiv.
L1 — 220 μH (Digi-Key part #811-1316-ND or equiv).
Q1, Q2 — 2N7000.
Q3 — ZTX550 PNP.
R1, R3, R4, R8, R9 — 100 k Ω , 1/4 W, 1%.
R2 — 301 Ω , 1/4 W, 1%.

R5, R6, R11, R12 — 1 k Ω , 1/4 W, 1%.
R7, R10 — 10 k Ω , 1/4 W, 1%.
U1, U2 — CA3140.
Terminal Blocks (optional) — Two-position, 5 mm spacing (Jameco part #2094485 or equiv).

- Maximum collector-base voltage, $V_{CBO} = 60\text{ V}$
- Maximum saturation voltage, $V_{CE} = 0.25\text{ V @ } I_C = 150\text{ mA}$
- Transition frequency, $f_T = 150\text{ MHz}$ minimum
- Package: E-Line (slightly smaller than TO-92)

For this design, the chosen values are $L = 220\text{ }\mu\text{H}$, $f = 45\text{ kHz}$, and $R_{LOAD} = 100\text{ }\Omega$. Verifying that $f \times L$ is less than $R_{LOAD} / 8$, $f \times L = (45 \times 10^3) \times (220 \times 10^{-6}) = 9900 \times 10^{-3} = 9.9\text{ }\Omega$ and $R_{LOAD} / 8 = 100 / 8 = 12.5\text{ }\Omega$ which is less than $R_{LOAD} / 8 = 12.5$. Higher values of R_{LOAD} (lower output current) also satisfy the equation. Increasing the value of L or f will require that the circuit be tested to verify that it works.

7.16.6 High-Voltage Power Supply

This two-level, high-voltage power supply was designed and built by Dana G. Reed, WILC. It was designed primarily for use with

an RF power amplifier. The supply is rated at a continuous output current of 1.5 A, and will easily handle intermittent peak currents of 2 A. The 12 V control circuitry and the low-tap setting of the plate transformer secondary make it straightforward to adapt the design to homemade tube amplifiers.

The step-start circuit is straightforward and ensures that the rectifier diodes are current-limited when the power supply is first turned on. A 6 kV meter is used to monitor high-voltage output.

Fig 7.64 is a schematic diagram of the bi-level supply. An ideal power supply for a high-power linear amplifier should operate from a 240 V circuit, for best line regulation. A special, hydraulic/magnetic circuit breaker also serves as a disconnect for the plate transformer primary. Don't substitute a standard circuit breaker, switch or fuses for this breaker; fuses won't operate quickly enough to protect the amplifier or power supply in case of an operating abnormality. The 100 k Ω , 3 W bleeder resistors are of stable metal-oxide film design. These resistors are

wired across each of the 14 capacitors to equalize voltage drops in the series-connected bank. This choice of bleeder resistor value provides a lighter load (less than 25 W total under high-tap output) and benefits mainly the capacitor-bank filter by yielding much less heat as a result. A reasonable, but longer bleed-down time to fully discharge the capacitors results — about nine minutes after power is removed. A small fan is included to remove any excess heat from the power supply cabinet during operation.

POWER SUPPLY CONSTRUCTION

The power supply can be built in a $23\frac{1}{2} \times 10\frac{3}{4} \times 16$ -inch cabinet. The plate transformer is quite heavy, so use $\frac{1}{8}$ -inch aluminum for the cabinet bottom and reinforce it with aluminum angle for extra strength and stability. The capacitor bank will be sized for the specific capacitors used. This project employed $\frac{3}{8}$ -inch thick polycarbonate for reasonable mechanical stability and excellent high-voltage isolation. The full-wave bridge consists of four commercial diode block assemblies.

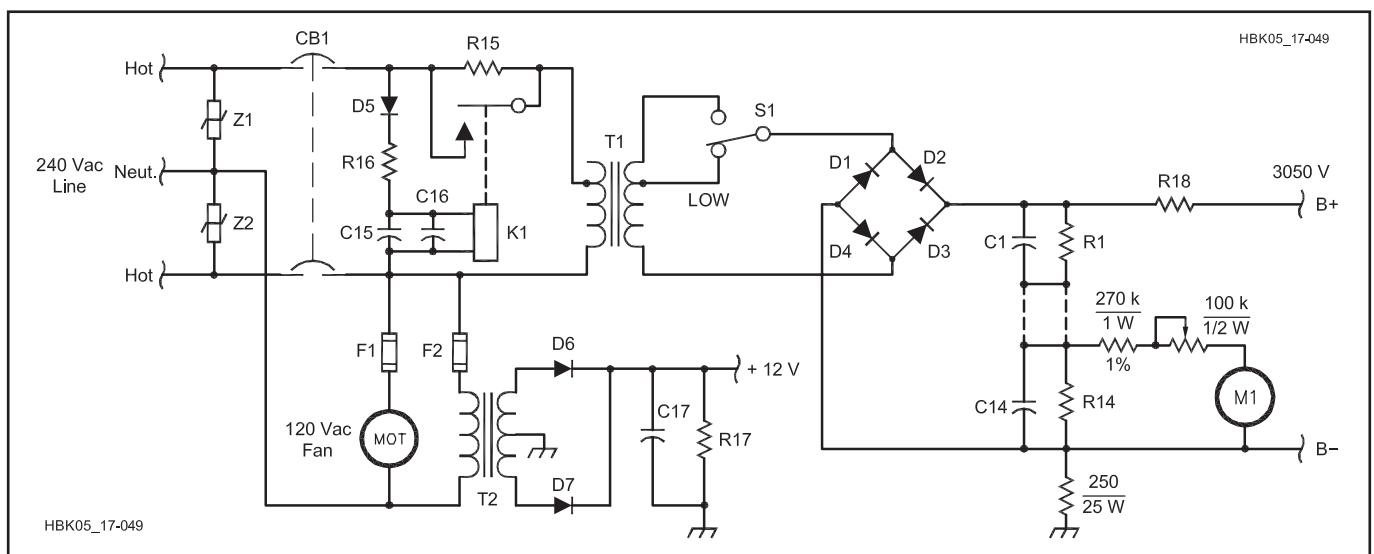

Fig 7.64 — Schematic diagram of the 3050 V/5400 V high-voltage power supply.

- C1-C14 — 800 μF , 450 V electrolytic.
- C15, C16 — 4700 μF , 50 V electrolytic.
- C17 — 1000 μF , 50 V electrolytic.
- CB1 — 20 A hydraulic/magnetic circuit breaker (TE Connectivity/Potter & Brumfield W68-X2Q12-20 or equiv). 40 A version required for commercial applications/ service (TE Connectivity/Potter & Brumfield W92-X112-40).
- D1-D4 — String of 1000 PIV, 6 A diodes (6A10 or equiv).
- D5 — 1000 PIV, 3 A, 1N5408 or equiv.
- D6, D7 — 200 PIV, 3 A, 1N5402 or equiv.
- F1, F2 — 0.5 A, 250 V (Littelfuse 313 Series, 3AG glass body or equiv).
- K1 — DPDT power relay, 24 V dc coil; both poles of 240 V ac/25 A contacts in parallel (TE Connectivity/Potter & Brumfield PRD-11DYO-24 or equiv).

- M1 — High-voltage meter, 6 kV dc full scale. (Important: Use a 1 mA or smaller meter movement to minimize parallel-resistive loading at R14. Also, select series meter-resistor and adjustment-potentiometer values to calibrate your specific meter. Values shown are for a 1 mA meter movement.)
- MOT1 — Cooling fan, 119 mm, 120 V ac, 30-60 CFM, (EBM Pabst 4800Z or equiv).
- R1-R14 — Bleeder resistor, 100 k Ω , 3 W, metal oxide film.
- R15 — 50 Ω , 100 W.
- R16 — 3.9 k Ω , 25 W.
- R17 — 30 Ω , 25 W.
- R18 — 20 Ω , 50 W.
- S1 — Ceramic rotary, 2 position tap-select switch (optional). Voltage rating between tap positions should be at least

- 2.5 kV. Mount switch on insulated or ungrounded material such as a metal plate on standoff insulators, or an insulating plate, and use only a *nonconductive* or otherwise *electrically-isolated* shaft through the front panel for safety.
- T1 — High-voltage plate transformer, 220/240 V primary, 2000/3500 V, 1.5 A CCS JK secondary, Hypersil C-core (Hammond Engineering, www.hammg.com). Primary 220 V ac line voltage to obtain modest increase in specified secondary voltage levels.
- T2 — 120 V primary, 18 V CT, 2 A secondary (Mouser 41FJ020).
- Z1-Z2 — 130 V MOV.

POWER SUPPLY OPERATION

When the front-panel breaker is turned on, a single 50 Ω, 100 W power resistor limits primary inrush current to a conservative value as the capacitor bank charges. After approximately two seconds, step-start relay K1 actuates, shorting the 50 Ω resistor and allowing full line voltage to be applied to the plate transformer. No-load output voltages under low- and high-tap settings as configured and shown in Fig 7.64 are 3050 V and 5400 V, respectively. Full-load levels are somewhat lower, approximately 2800 V and 4900 V. If a tap-select switch is used as described in the schematic parts list, it should only be switched when the supply is off.

7.16.7 Reverse-Polarity Protection Circuits

The following material was collected from various public-domain sources by Terry Fletcher, WA0ITP (www.wa0itp.com/revpro.html) and published in the QRP Quarterly, Spring 2012 issue. (www.qrparci.org)

DC power is the standard for most amateur radios and accessories, usually a nominal 12 V (10.5 to 13.8 V). There are many different types of connectors used for dc power — from screw terminals to custom-molded multi-pin designs. This makes it easy to accidentally apply power with reversed polarity and damage equipment. Even a few milliseconds of reversed power can be sufficient to destroy a semiconductor or burn out a narrow PCB trace. This can be a particular problem when using 9 V batteries as it is easy to reverse the snap-on connector when changing or installing a battery.

The following collection of circuits illustrates ways to protect equipment from reverse-polarity dc power. The suitability of the circuits depends on the equipment and power source. All dc power sources, particularly batteries, should be fused or current-limited to mitigate fire hazards and other damage from overheating wires and other conductors.

Fig 7.65 shows several passive circuits that dissipate some power due to the series forward voltage drop of the diodes. At currents above 1 A, the power dissipated can easily exceed 1 W and the maximum junction temperature of the diode can be exceeded without some sort of thermal protection or heat sinking. (The shunt diode circuit in Fig 7.65D does not dissipate power.) Fig 7.66 shows two methods of using an electromechanical relay that avoid the forward voltage drop of diode-based protection circuits. Which circuit you choose depends on the type of equipment and constraints on power dissipation and voltage drop.

PASSIVE CIRCUITS

Blocking diode (Fig 7.65A) — A series

diode is very simple and inexpensive. Its PIV rating should be at least twice the expected applied voltage — 50 V PIV is a good minimum value for automotive and 12 V dc use. Its maximum average forward current rating should be several times the expected maximum steady-state current draw.

Remember that a silicon junction diode's forward voltage drop, V_f , is at least 0.6 V and can approach 1.0 V at high forward current. This can result in significant power dissipation ($P = V_f \times I_f$) and cause the diode's maximum rated junction temperature to be exceeded unless some means of cooling the diode is provided.

The forward voltage drop of the diode will also reduce the voltage available to the equipment being powered. This will raise the minimum allowable power supply voltage

for the equipment to operate properly. For example, if a piece of equipment is rated to operate properly at or above 11 V, a series diode with $V_f = 0.6$ V raises the minimum allowable power supply voltage to $11 + 0.6 = 11.6$ V. This may be significant in battery-powered installations.

The Schottky barrier diode shown as an alternate may be a better choice due to its forward voltage drop being lower by several tenths of a volt, reducing power dissipation. A Schottky diode may be used in place of any of the diodes in Figures 7.65 and 7.66. Be sure the reverse current leakage of the Schottky diode is acceptable.

Full-wave bridge rectifier (Fig 7.65B) — The full-wave circuit has the advantage of always supplying voltage with the proper polarity to the equipment being powered.

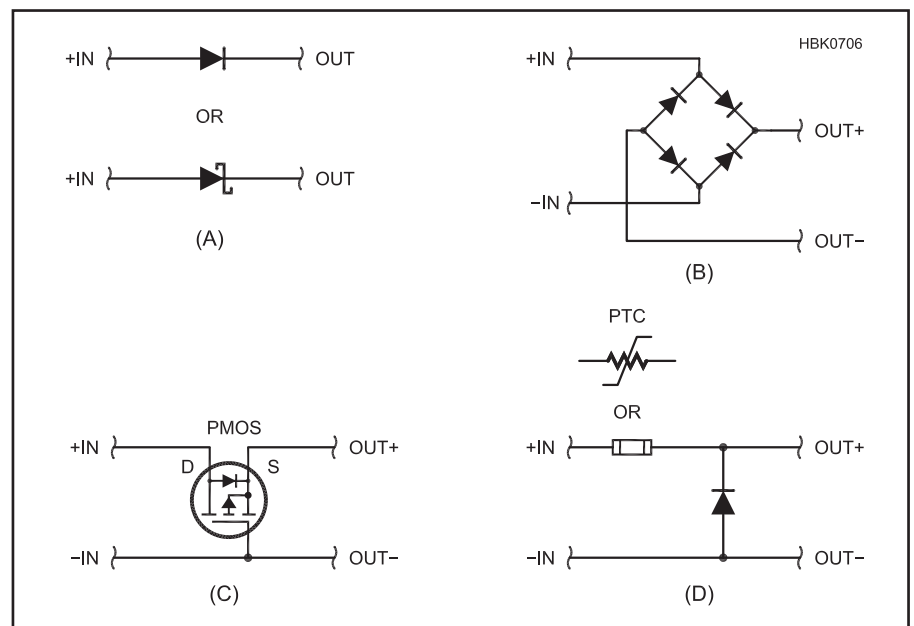

Fig 7.65 — Passive circuits for reverse-polarity protection. Series diode (A). Full-wave rectifier (B). PMOS MOSFET with integral body diode shown as separate component (C). Shunt diode (D). Schottky barrier diodes may be used in all circuits as a substitute for silicon junction rectifiers. See text for circuit comparison.

Fig 7.66 — Relay-based circuits for reverse-polarity protection. Normally-closed contacts (A) and normally-open contacts (B). See text for circuit comparison.

Full-wave rectifiers are also available as integrated packages, making them easy to install. Remember that the forward voltage drop and power dissipation of this circuit will be twice that of the single series diode because two diodes are always in series with supply current.

PMOS P-channel MOSFET (Fig 7.65C) — This circuit uses a P-channel enhancement-mode (PMOS) MOSFET that conducts current with the gate connected as shown. PMOS devices have low on-resistance ($R_{ds(on)}$) and high maximum current ratings. Devices with on-resistance of 0.050 Ω and lower are commonly available. For more information about using PMOS and NMOS devices for polarity protection see Maxim Electronics Application Note 636, “Reverse-Current Circuitry Protection” (www.maxim.com/app-notes/index.mvp/id/636). N-channel devices may also be used in the current return or ground lead, but opening the return connection can create other problems inside the equipment and with other devices on the same power circuits.

Shunt diode with fuse (Fig 7.65D) — These configurations use a single diode that acts to blow a fuse (either a fusible-link or positive temperature coefficient PTC resettable device) if reverse polarity voltage is applied. The advantage of this circuit is that no power is dissipated by the diode during normal operation. The diode must be sufficiently rated to handle the high surge current from shorting the power source and have current ratings significantly higher than the fuse current rating.

If the diode fails shorted or in a low-resistance state, it will continue to blow the fuse until replaced. If the diode fails open or high-resistance, it will no longer protect the circuit. If shunt diode protection is used and the fuse opens, check the diode to be sure it has not failed as well.

RELAY-BASED CIRCUITS

Relay-based circuits have the advantage of little to no voltage drop, even at high currents as long as the contact ratings are sufficient. The circuits are more complex than the diode-based circuits in the preceding section but can generally handle more current and are not damaged by reverse polarity voltages. The circuits reset themselves automatically.

Relay with normally-closed contacts (Fig 7.66A) — There is no current drain through the relay coil until reverse-polarity is applied. However, there will be a few milliseconds during which reverse polarity voltage is applied if no power switch (S1) is used or the power switch is closed. This is generally enough time for damage to occur so this circuit is only recommended if a power switch is used to turn the equipment ON and OFF.

Relay with normally-open contacts (Fig 7.66B) — The relay contacts close and

supply power to the equipment only when applied voltage has the proper polarity. The relay coil draws current continuously during normal operation. This may be unacceptable for low-power and battery-powered equipment.

7.16.8 Automatic Sealed Lead-Acid Battery Charger

After experiencing premature failure of the battery in his Elecraft K2 transceiver, Bob Lewis, AA4PB, began searching for an automatic battery charger. Although this charger was designed specifically for use with the Power-Sonic PS-1229A sealed lead-acid (SLA) battery used in the Elecraft K2 transceiver, its design concepts have wide ranging applications for battery operated QRP rigs of all types. Comments pertaining to the SLA batteries and chargers apply across the board and the charger described here can be used with any similar battery. (See the Batteries section of this chapter for more information on SLA batteries.)

USING A THREE-MODE CHARGER

The author first attempted to use a commercial automatic three-mode charger. However, most three-mode chargers work by sensing current and are never intended to charge a battery under load.

Three-mode chargers begin the battery charging process by applying a voltage to the battery through a 500 mA current limiter. This stage is known as *bulk-mode* charging. As the battery charges, its voltage begins to climb. When the battery voltage reaches 14.6 V the charger maintains the voltage at that level and monitors the battery charging current. This is known as the *absorption mode*, sometimes called the *overcharge mode*. By this time, the battery has achieved 85% to 95% of its full charge. As the battery continues to charge — with the voltage held constant at 14.6 V — the charging current begins to drop.

When the charging current falls to 30 mA, the three-mode charger switches to *float mode* and lowers the applied voltage to 13.8 V. At 13.8 V, the battery becomes self-limiting, drawing only enough current to offset its normal self-discharge rate. This works great — until you attach a light load to the battery, such as a receiver. The K2 receiver normally draws about 220 mA. When the charger detects a load current above 30 mA, it’s fooled into thinking that the battery needs charging, so it reverts to the absorption mode, applying 14.6 V to the battery. If left in this condition, the battery is overcharged, shortening its service life.

UC3906 IC CHARGERS

Chargers using the UC3906 SLA

charge-controller IC work just like the three-mode charger described earlier except that their return from float mode to absorption mode is based on voltage rather than current. Typically, once the charger is in float mode it won’t return to absorption mode until the battery voltage drops to 90% of the float-mode voltage (or about 12.4 V). Although this is an improvement over the three-mode charger, it still has the potential for overcharging a battery to which a light load is attached.

First, let’s look at the situation where a UC3906-controlled charger is in absorption mode and you turn on the K2 receiver, applying a load. The battery is fully charged, but because the load is drawing 220 mA, the charging current never drops to 30 mA and the charger remains in absorption mode, thinking that it is the battery that is asking for the current. As with the three-mode charger, the battery is subject to being overcharged.

If we remove the load by turning off the K2, the current demand drops below 30 mA and the charger switches to float mode (13.8 V). When the K2 is turned on again, because the charger is able to supply the 220 mA for the receiver, the battery voltage doesn’t drop, so the charger stays in float mode and all is well. However, if the transmitter is keyed (increasing the current demand), the charger can’t supply the required current, so it’s taken from the battery and the battery voltage begins to drop. If we un-key the transmitter before the battery voltage reaches 12.4 V, the charger stays in float mode. Now it takes much longer for the charger to supply the battery with the power used during transmit than it would have if the charger had switched to absorption mode.

Let’s key the transmitter again, but this time keep it keyed until the battery voltage drops below 12.4 V. At this point, the charger switches to the absorption mode. When we un-key the transmitter, we’re back to the situation where the charger is locked in absorption mode until we turn off the receiver.

WHY WORRY?

So why this concern about overcharging an SLA battery? At 13.8 V, the battery self-limits, drawing only enough current to offset its self-discharge rate (typically about 0.001 times the battery capacity, or 2.9 mA for a 2.9 Ah battery). An SLA battery can be left in this float-charge condition indefinitely without overcharging it. At 14.6 V, the battery takes more current than it needs to offset the self-discharge. Under this condition, oxygen and hydrogen are generated faster than they can be recombined, so pressure inside the battery increases. Plastic-cased SLA batteries such as the PS-1229A have a one-way vent that opens at a couple of pounds per square inch pressure (PSI) and releases the gases into the atmosphere. This results in drying the

gelled electrolyte and shortening the battery's service life. Both undercharging and overcharging need to be avoided to get maximum service life from the battery.

Continuing to apply 14.6 V to a 12 V SLA battery represents a relatively minor amount of overcharge and results in a gradual deterioration of the battery. Applying a potential of 16 V or excessive bulk-charging current to a small SLA battery from an uncontrolled solar panel can result in serious overcharging. Under these conditions, the overcharging can cause the battery to overheat, which causes it to draw more current and result in *thermal runaway*, a condition that can warp electrodes and render a battery useless in a few hours. To prevent thermal runaway, the maximum current and the maximum voltage need to be limited to the battery manufacturer's specifications.

DESIGN DECISION

To avoid the potential of overcharging a battery with an automatic charger locked up by the load, the author decided to design a charger that senses battery voltage rather than current in order to select the proper charging rate. A 500 mA current limiter sets the maximum bulk rate charge to protect the battery and the charger's internal power supply.

Like the three-mode chargers, when a battery with a low terminal voltage is first connected to the charger, a constant current of 500 mA flows to the battery. As the battery charges, its voltage begins to climb. When the battery voltage reaches 14.5 V, the charger switches off. With no charge current flowing to the battery, its voltage now begins to drop. When the current has been off for four seconds, the charger reads the battery voltage. If the potential is 13.8 V or less, the charger switches back on. If the voltage is still above 13.8 V, the charger waits until it drops to 13.8 V before turning on. The result is a series of 500 mA current pulses varying in width and duty cycle to provide an average current just high enough to maintain the battery in a fully charged condition. Because the repetition rate is very low (a maximum of one current pulse every four seconds) no RFI is generated that could be picked up by the K2 receiver. Because the K2's critical circuits are all well-regulated, slowly cycling the battery voltage between 13.8 V and 14.5 V has no ill effects on the transmitted or received signals.

As the battery continues to charge, the pulses get narrower and the time between pulses increases (a lower duty cycle). Now when the K2 receiver is turned on and begins drawing 220 mA from the battery, the battery voltage drops more quickly so the pulses widen (the duty cycle increases) to supply a higher average current to the battery and make up for that taken by the receiver. When the

K2 transmitter is keyed, it draws about 2 to 3 A from the battery. Because the charger is current limited to 500 mA, it is not able to keep up with the transmitter demands. The battery voltage drops and the charger supplies a constant 500 mA. The battery voltage continues to drop as it supplies the required transmit current. When the transmitter is unkeyed, the battery voltage again begins to rise as the charger replenishes the energy used during transmit. After a short time, (depending on how long the transmitter was keyed) the battery voltage reaches 14.5 V and the pulsing begins again. The charger is now fully automatic, maintaining the battery in a charged condition and adjusting to varying load conditions.

The great thing about this charging system is that during transmit the majority of the required 2 to 3 A is taken from the battery. When you switch back to receive, the charger is able to supply the 220 mA needed to run the receiver and deliver up to 280 mA to the battery to replenish what was used during transmit. This means that the power source need only supply the average energy used over time, rather than being required to supply the peak energy needed by the transmitter. (You don't need to carry a heavy 3 A regulated power supply with your K2.) As long as you don't transmit more than about 9% of the time, this system should be able to power a K2 indefinitely.

Have you ever noticed that sometimes when your handheld radio has a low battery and you drop it into its charger you hear hum on the received signals? This charger's power supply is well filtered to ensure that there is no ripple or ac hum to get into the K2 under low battery voltage conditions.

CIRCUIT DESCRIPTION

The charger schematic is shown in **Fig 7.67**; the unit is dubbed the PCR12-500A, short for Pulsed-Charge Regulator for 12 V SLA batteries with maximum bulk charge rates of 500 mA. U1, an LM317 three-terminal voltage regulator, is used as a current limiter, voltage regulator and charge-control switch. A 15 V Zener diode (D2) sets U1 to deliver a no-load output of 16.2 V. R3 sets U1 to limit the charging current to 500 mA. When Q1 is turned on by the LM555 timer (U2), the ADJ pin of U1 is pulled to ground, lowering its output voltage to 1.2 V. D4 effectively disconnects the battery by preventing battery current from flowing back into U1. A Schottky diode is used at D4 because of its low voltage drop (0.4 V).

An LM358 (U4A) operates as a voltage comparator. U5, an LM336, provides a 2.5 V reference to the positive input (pin 3) of U4. R11, R12 and R13 function as a voltage divider to supply a portion of the battery voltage

to pin 2 of U4A. R13 is adjusted so that when the battery terminal voltage reaches 14.5 V, the negative input of U4A rises slightly above the 2.5 V reference and its output switches from +12 V to 0 V. When this happens, the 1 M Ω resistor (R7) causes the reference voltage to drop a little and provide some hysteresis. The battery voltage must now drop to approximately 13.8 V before U4A turns back on.

U4B is a voltage follower. It pulls the trigger input (pin 2) of U2 to 0 V, causing its output to go to 12 V. U4B's output remains at 12 V until C5 has charged through R6 (approximately four seconds) and the trigger has been released by U4A sensing the battery dropping to 13.8 V or less. While the output of U2 is at 12 V, emitter/base current for Q1 flows via R5 and Q1's collector pulls U1's ADJ pin to ground, turning off the charging current.

The output of U2 also provides either +12 V or 0 V to the bicolor LED, D3. R14 and R15 form a voltage divider to provide a reference voltage to D3 such that D3 glows red when U2's output is +12 V and green when U2's output is at 0 V. When ac power is applied but U1 is switched off and not supplying current to the battery, D3 glows red. When U1 is on and supplying current to the battery, D3 is green. As the battery reaches full charge, D3 blinks green at about a four-second rate. As the battery charge increases, the on time of the green LED decreases and the off time increases. A fully charged battery may show green pulses as short as a half-second and the time between pulses may be 60 seconds or more.

T1, D1, C1 and C2 form a standard full-wave-bridge power supply providing an unregulated 20 V dc at 500 mA. U3, an LM78L12 three-terminal regulator, provides a regulated 12 V source for the control circuits.

Note that the mounting tab on U1 is not at ground potential. U1 should be mounted to a heat sink with suitable electrically insulated but thermally conductive mounting hardware to avoid short circuits. Suitable mounting hardware is included with the PC board.

OTHER BULK-CHARGE RATES

The maximum bulk-charge rate is set by the value of R3 in the series regulator circuit. The formula used to determine the value of this resistor is $R (\Omega) = 1200 / I (\text{mA})$. T1 must be capable of supplying the bulk charge current and U1 must be rated to handle this current. The LM317T used here is rated for a maximum current of 1.5 A, provided it has a heat sink sufficiently large enough to dissipate the generated heat. If you increase the bulk-charge rate, you'll definitely need to increase the size of the on-board heat sink. Mounting U1 directly to the housing (be sure to use an insulator) may be a good option.

source variable from 12 to 15 V dc. A convenient means of obtaining this test voltage is to connect two 9 V transistor-radio batteries in series to supply 18 V as shown in Fig 7.69. Connect a 1 k Ω resistor (R2) in series with a 1 k Ω potentiometer (R1) and connect this series load across the series batteries with the fixed-value resistor to the negative lead. The voltage at the pot arm should now be adjustable from 9 to 18 V. During the following procedure, be sure to adjust the voltage with the test supply connected to the charger at 12 V because the charger loads the test-voltage supply and causes the voltage to drop a little when it's connected.

Remove the jumper at J1 and apply ac line voltage to the unit at J3. Turn R13 fully counterclockwise. D3 should glow green. Connect the test voltage to J2 and adjust R1 of Fig 7.68 for an output of 14.5 V. Slowly adjust R13 clockwise until D3 glows red. To test the circuit, wait at least four seconds, then gradually reduce the test voltage until D3 turns green. At that point, the test voltage should be approximately 13.8 V. Slowly increase the test voltage again until D3 turns red. The test voltage should now read 14.5 V. If it is not exactly 14.5 V, make a minor adjustment to R13 and try again. The aim of this adjustment is to have D3 glow red just as the test voltage reaches 14.5 V.

To test the timer functioning, remove the test voltage from J2 and set it for about 15 V. Momentarily apply the test voltage to J2. D3 should turn red for approximately four seconds, then turn green. The regulator is now calibrated and ready for operation. Remove the test voltage and ac power and install the jumper at J1.

The prototype used an 8 \times 3 \times 2.75-inch LMB Perf137 box (Digi-Key L171-ND) to house the charger. An alternative enclosure is the Bud CU482A Convertabox, which measures 8 \times 4 \times 2 inches (available from Mouser). If you use the Convertabox, be sure to add some ventilation holes directly above the board-mounted heat sink. The LMB Perf box comes with a ventilated cover. If you are inclined to do some metal work, you could build your own enclosure using aluminum angle stock and sheet and probably reduce the size to perhaps 8 \times 3 \times 2 inches. If you use a PC-board-mounted power transformer, watch out for potential shorts between the transformer pins (especially the 120 V ac-line pins) and the case. If you use a metal enclosure, connect the safety ground (green) wire of the ac-line cord directly to the case.

OPERATION

It is very important that this charger be connected directly to the SLA battery with no diodes, resistors or other electronics in between the two. The charger works by reading the battery voltage, so any voltage drop across

Fig 7.68 — Complete SLA charger PC board.

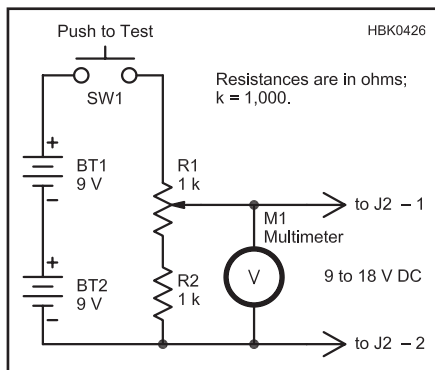

Fig 7.69 — Test voltage source for the battery charger.

an external series component results in an incorrect reading and improper charging. For example, the Elecraft K2 has internal diodes in the power-input circuit, so it's necessary to add a charging jack to the transceiver that provides a direct connection to the battery. Now the K2 can be left connected to the charger at all times and be assured that its internal battery is fully charged and ready to go at a moment's notice.

7.16.9 Simple Adjustable Tracking Power Supply

This project by Bryant Julstrom, KC0ZNG, was originally published in the Spring 2014 issue of the QRP ARCI *QRP Quarterly*. A PDF version of the original article, including all figures, is available on this book's CD-ROM.

The typical experimenter's bench power supply provides an adjustable positive voltage of up to 25 V at up to 1 A of current. This suffices for many circuits and projects, but others require positive and negative voltages of equal magnitude. Op-amp circuits, for example, often require ± 15 V.

THE CIRCUIT

The circuit is implemented using two

garden-variety ICs, an LM317 positive regulator and an LM337 negative regulator, both in TO-220 packages. (Note that the orientation of the input-common-output connections are different between the two regulators!) The input voltages of the circuit are limited only by the maximum inputs of the two regulators, ± 40 V. (An alternate implementation based on the LT1033 tracking regulator is shown in the CD-ROM version of the article.) A voltmeter is switched between either of the supply's outputs and common.

Input power to the tracking regulator is supplied by a power transformer with a center-tapped secondary. The peak secondary output voltage on each side of the center-tap should be several volts higher than the maximum supply output at full load. See this chapter's section on power supply ripple to determine the minimum required filter capacitance.

In the author's case, the heaviest transformer available provided only 26 V CT (center-tapped) and the input to the regulator of ± 13 V was too low. One possible solution would be to use two identical transformers with their primary windings in parallel and their secondaries in series with the connection between secondaries serving as the center-tap.

Since 24 to 28 V CT is a common secondary voltage range, however, the author chose to use the available transformer and back-to-back half-wave voltage doublers, one on either side of the secondary winding's center tap, to provide about ± 26 V to the tracking regulator. This halves the current that can be drawn from the transformer, but if the transformer secondary is rated at 2 A, the resulting maximum output current of 1 A in each leg of the supply is sufficient for a wide range of projects.

Fig 7.70 shows the circuit of the tracking power supply. The author used 1N5402 rectifiers in the voltage doublers because they were available, but any 100 V diode rated at 3 A or more of average forward current will work. The two 2.2 μ F capacitors should be solid tantalum types.

R4, a front-panel potentiometer, is used for voltage adjustment. R6, a 200 Ω trimmer

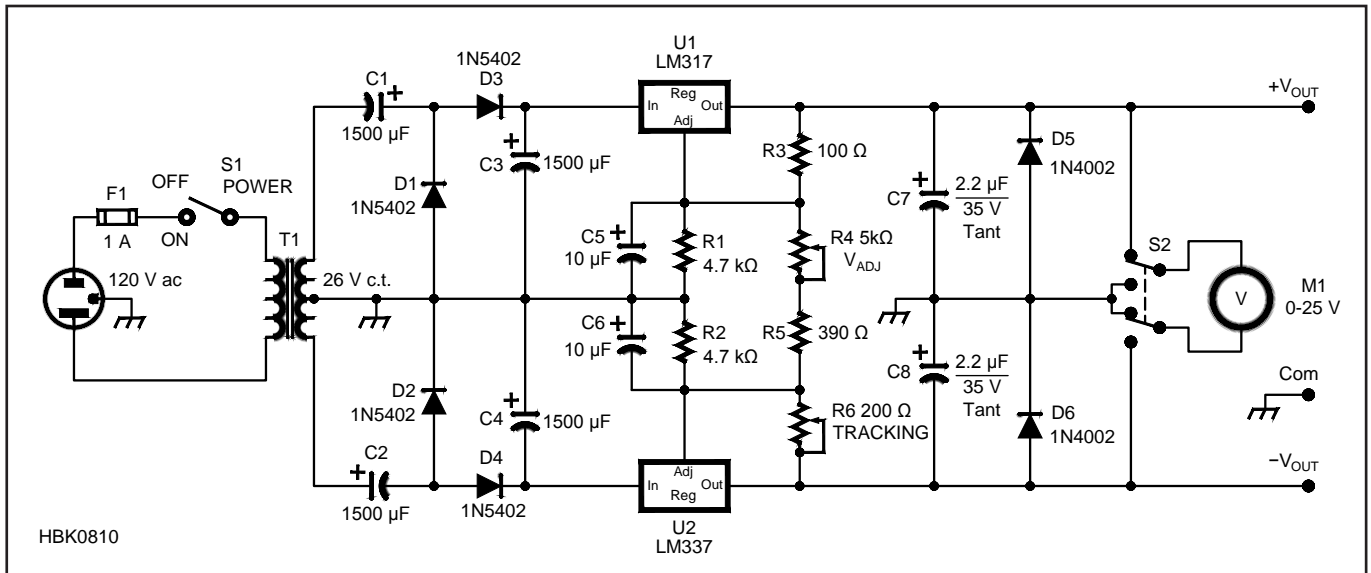

Fig 7.70 — Schematic of the adjustable tracking power supply. Regulators are mounted to the enclosure, which serves as a heat sink. Resistors are 1/4 W film, 5% tolerance unless noted otherwise.

C1-C4 — 1500 µF, 50 V electrolytic.
 C5, C6 — 10 µF, 50 V electrolytic.
 C7, C8 — 2.2 µF, 35 V, solid tantalum.
 D1-D4 — 1N5402 or equivalent.
 D5, D6 — 1N4002 or equivalent.
 F1 — 250 V, 1 A ac fuse and fuse holder.

M1 — 0-25 V voltmeter or equivalent.
 R1, R2 — 4.7 kΩ.
 R3 — 100 Ω.
 R4 — 5 kΩ, panel-mount potentiometer.
 R5 — 390 Ω.
 R6 — 200 Ω trimmer potentiometer.
 S1 — SPST toggle switch.

S2 — DPDT miniature toggle switch.
 T1 — 26 V CT at 2 A secondary or equivalent (see text).
 U1 — LM317 adjustable positive voltage regulator.
 U2 — LM337 adjustable negative voltage regulator.

potentiometer, provides for fine tracking adjustment. The 390 Ω resistor (R5) sets the regulator's minimum outputs at about ±3.6 V for reasons described below.

CONSTRUCTION

As constructed, the front panel holds three binding posts (positive output, negative output, and common), two miniature toggle switches (on/off and voltmeter switching), the voltage-adjustment potentiometer and its knob, and a voltmeter. Note that the common connection of the power supply is usually left floating from the enclosure ground which must be connected to the "third-wire" ac safety ground. If desired, a binding post connected to the enclosure can be added so that a jumper can be used to connect the power supply common to the ac safety ground.

The voltmeter used by the author is a three-digit LED unit from Marlin P. Jones (www.mpja.com; part number 30217 ME with blue digits, also available in green and red). The meter is powered by the voltage it measures, as long as the voltage is at least 3.6 V as determined by R5 as explained previously. An analog meter or a digital meter with a separate power supply would allow lower minimum output voltages. One could augment the supply's measurements with current metering or with simultaneous measurements of both outputs.

The enclosure holds the power transformer

and two circuit boards. The two voltage doublers occupy one circuit board and the tracking regulator the other. The circuit is simple enough that perforated board ("Perf-board") was used with point-to-point wiring.

The LM317 and LM337 are mounted at the edge of the regulator board and attached to the back panel, which serves as a heat sink, using mica insulators, nylon bolts, and a thin coating of heat sink compound. The rear panel also holds a snap-in IEC three-wire ac line connector. (Photographs of the finished power supply are provided in the CD-ROM version of the article.)

ADJUSTMENT AND PERFORMANCE

The only internal adjustment in the supply is the tracking potentiometer (R6), which must be set so that the two voltages track each other accurately. This is touchy, but the two voltages can be made to match within 0.1 V throughout the supply's range. The completed supply provides closely matched positive and negative voltages from ±3.6 V to about ±23 V, and a maximum current of 1 A in each leg.

The tracking adjustment and the front-panel voltage adjustment (R4) are delicate. In both cases, multi-turn potentiometers would be much easier to set. The tracking control could also be replaced with a series resistor and a smaller-value potentiometer to make adjustment less sensitive.

7.16.10 Overvoltage Protection for AC Generators

When using portable generators, there is always a possibility of damage to expensive equipment as a result of generator failure, especially from overvoltage. If the generator supplying power to this equipment puts out too much voltage, you run the risk of burning up power supplies or other electronic components. This project, by Jerry Paquette, WB8IOW, addresses the problem of increased voltage (not lower voltage) or surges and spikes lasting for a few microseconds.

Using a portable generator overvoltage protection circuit and ground-fault circuit interrupter (GFCI) as shown in Fig 7.71 is good insurance. This overvoltage protection device must be used in conjunction with a GFCI at each station! (More information on GFCIs may be found in the **Safety** chapter.)

CIRCUIT DESCRIPTION

Refer to Fig 7.71 for this description. R1 places an intentional fault on the load side of the GFCI. With the value resistor used, the fault is limited to 10 mA. (The normal tripping threshold of a GFCI is 5 mA. This current forces the GFCI to trip in just a few milliseconds. This circuit will not function at all without the use of a GFCI. A GFCI must be used at each station. If a single GFCI were used at the generator, rather than one at

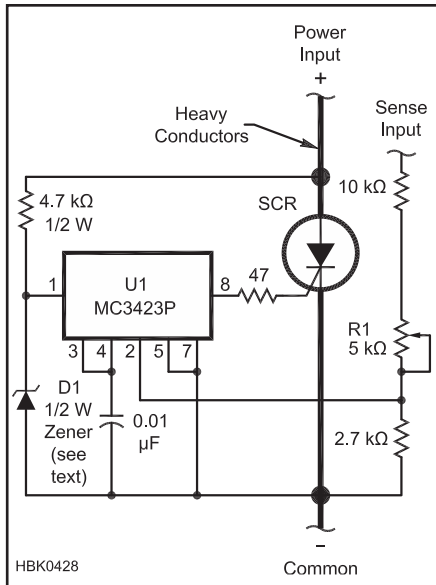

Fig 7.72 — Schematic of the over-voltage crowbar circuit. Unless otherwise specified, resistors are ¼ W, 5% tolerance. A PC board is available from FAR Circuits (www.farcircuits.net).

SCR — C38M stud-mount (TO-65 package).

U1 — MC3423P or NTE7172 voltage protection circuit, 8-pin DIP.

D1 — Zener diode, ½ W (see text).

R1 — 5 kΩ, PC board mount trimmer potentiometer.

4.5-40 V. Use a Zener diode with a voltage rating a few volts below that of the crowbar circuit positive-to-negative power input voltage. For example, if the crowbar is connected to a 12 V supply output, D1 voltage should be 6 to 9 V. The exact value is not critical.

U1 contains a 2.5 V reference and two comparators. When the voltage at pin 2 (sense terminal) reaches 2.5 V, the output voltage (pin 8) changes from the negative input voltage to the positive input voltage. This drives the gate of the SCR through the 47 Ω resistor. The trip voltage is set by the resistive divider across the + and - inputs:

$$V_{\text{trip}} = 2.5 \left(1 + \frac{10 \text{ k}\Omega + R}{2.7 \text{ k}\Omega} \right)$$

The application notes for the MC3423 recommend that the resistance from the sense input to the negative input be less than 10 kΩ for minimum drift, suggesting the value of 2.7 kΩ. The value of 10 kΩ for the fixed portion of the adjustable resistance is selected for $V_{\text{trip}} = 15 \text{ V}$ at the midpoint of the 5 kΩ potentiometer (R1) travel. For other trip voltages, the fixed resistor value should be the closest standard value to

$$R_{\text{fixed}} = 2.7 \text{ k}\Omega \left(\frac{V_{\text{trip}}}{2.5} - 1 \right) - 2.5 \text{ k}\Omega$$

assuming the potentiometer value remains at 5 kΩ.

When the SCR turns on, it short-circuits the inputs, causing any protective fuses or circuit breakers to open. The SCR will stay on until the current through drops below the “keep alive” threshold, at which point the SCR turns off. The SCR will stay on even if the input voltage to U1 drops below 4.5 V.

If the crowbar circuit fires due to RFI, an additional 0.01 μF capacitor should be connected from pin 2 of U1 to common and another across the D1.

More information may be found in the MC3423 datasheet and “Semiconductor Consideration for DC Power Supply Voltage Protector Circuits,” ON Semi AN004E/D, both available from ON Semiconductor.

Additional Projects and Information

Additional power source projects and supporting files are included on the *Handbook* CD-ROM.

Modulation

Radio amateurs use a wide variety of modulation types to convey information. This chapter, written by Alan Bloom, N1AL, explores analog, digital and image modulation techniques, as well as impairments that affect our ability to communicate. A glossary of terms and suggestions for additional reading round out the chapter.

8.1 Introduction

The purpose of Amateur Radio transmissions is to send information via radio. The one possible exception to that is a beacon station that transmits an unmodulated carrier for propagation testing. In that case the only information being sent is, “Am I transmitting or not?” One can think of it as a single data bit with two states, *on* or *off*. However, in reality even a beacon station or test transmission must periodically identify with the station call sign, so we can say that modulation is an essential ingredient of Amateur Radio.

To represent the information being sent, the radio signal must periodically change its state in some way that can be detected by the receiver. In the early days of radio, the only way to do that was on-off keying using Morse code. By alternating the on and off states with the proper sequence and rhythm, a pair of highly-skilled operators can exchange textual data at rates up to perhaps 60 WPM. Later, engineers figured out how to amplify the signal from a microphone and use it to vary the power of the radio signal continuously. Thus was born amplitude modulation, which allowed transmitting voices at full speaking speeds, that is, up to about 200 WPM. That led to analog modes such as television with even faster information rates. Today’s digital radio systems are capable of transferring tens of megabits of information per second, equivalent to tens of millions of words per minute.

Modulation is but one component of any transmission mode. For example AM voice and NTSC television (the analog US system) both use amplitude modulation, but the transmission protocol and type of information sent are very different. Digital modes also are generally defined not only by the modulation but also by multiple layers of protocol and data coding. Of the three components of a mode (modulation, protocol and information), this chapter will concentrate on the first. The **Digital Modes** chapter covers digital transmission protocols and the **Digital Communications** supplement on the *Handbook* CD covers the practical aspects of operating the various digital modes.

EMISSION DESIGNATORS

We tend to think of a radio signal as being “on” a particular frequency. In reality, any modulated signal occupies a band of frequencies. The bandwidth depends on the type of modulation and the data rate. A Morse code signal can be sent within a bandwidth of a couple hundred Hz at 60 WPM, or less at lower speeds. An AM voice signal requires about 6 kHz. For high-fidelity music, more bandwidth is needed; in the United States, an FM broadcast signal occupies a 200-kHz channel. Television signals need about 6 MHz, while 802.11n, the latest generation of “WiFi” wireless LAN, uses up to 40 MHz for data transmission.

The International Telecommunication Union (ITU) has specified a system for designating radio emissions based on the bandwidth, modulation type and information to be transmitted. The emission designator begins with the bandwidth, expressed as a maximum of five numerals and one letter. The letter occupies the position of the decimal point and represents the unit of bandwidth, as follows: H = hertz, K = kilohertz, M = megahertz and G = gigahertz. The bandwidth is followed by three to five emission classification symbols, as defined in the sidebar, “Emission Classifications.” The first three symbols are mandatory; the fourth and fifth symbols are supplemental. These designators are found in Appendix 1 of the ITU Radio Regulations, ITU-R Recommendation SM.1138 and in the FCC rules §2.201.

For example, the designator for a CW signal might be 150H0A1A, which means 150 Hz

Emission Classifications

Emissions are designated according to their classification and their necessary bandwidth. A minimum of three symbols is used to describe the basic characteristics of radio waves. Emissions are classified and symbolized according to the following characteristics:

- I. First symbol—Type of modulation of the main carrier
- II. Second symbol—Nature of signal(s) modulating the main carrier
- III. Third symbol—Type of information to be transmitted
- Note: A fourth and fifth symbol are provided for in the ITU Radio Regulations. Use of the fourth and fifth symbol is optional.
- IV. Details of signal(s)
- V. Nature of multiplexing

First symbol—type of modulation of the main carrier

- (1) Emission of an unmodulated carrier N
- (2) Emission in which the main carrier is amplitude-modulated (including cases where subcarriers are angle-modulated):
 - Double sideband A
 - Single sideband, full carrier H
 - Single sideband, reduced or variable level carrier R
 - Single sideband, suppressed carrier J
 - Independent sidebands B
 - Vestigial sideband C
- (3) Emission in which the main carrier is angle-modulated:
 - Frequency modulation F
 - Phase modulation G

Note: Whenever frequency modulation (F) is indicated, phase modulation (G) is also acceptable.
- (4) Emission in which the main carrier is amplitude and angle-modulated either simultaneously or in a pre-established sequence D
- (5) Emission of pulses¹
 - Sequence of unmodulated pulses P
 - A sequence of pulses:
 - Modulated in amplitude K
 - Modulated in width/duration L
 - Modulated in position/phase M
 - In which the carrier is angle-modulated during the period of the pulse Q
 - Which is a combination of the foregoing or is produced by other means V
- (6) Cases not covered above, in which an emission consists of the main carrier modulated, either simultaneously or in a pre-established sequence in a combination of two or more of the following modes: amplitude, angle, pulse W
- (7) Cases not otherwise covered X

Second symbol—nature of signal(s) modulating the main carrier

- (1) No modulating signal 0
- (2) A single channel containing quantized or digital information without the use of a modulating subcarrier, excluding time-division multiplex 1
- (3) A single channel containing quantized or digital information with the use of a modulating subcarrier, excluding time-division multiplex 2
- (4) A single channel containing analog information .. 3
- (5) Two or more channels containing quantized or digital information 7

- (6) Two or more channels containing analog information 8
- (7) Composite system with one or more channels containing quantized or digital information, together with one or more channels containing analog information 9
- (8) Cases not otherwise covered X

Third symbol—type of information to be transmitted²

- (1) No information transmitted N
- (2) Telegraphy, for aural reception A
- (3) Telegraphy, for automatic reception B
- (4) Facsimile C
- (5) Data transmission, telemetry, telecommand D
- (6) Telephony (including sound broadcasting) E
- (7) Television (video) F
- (8) Combination of the above W
- (9) Cases not otherwise covered X

Where the fourth or fifth symbol is used it shall be used as indicated below. Where the fourth or the fifth symbol is not used this should be indicated by a dash where each symbol would otherwise appear.

Fourth symbol—Details of signal(s)

- (1) Two-condition code with elements of differing numbers and/or durations A
- (2) Two-condition code with elements of the same number and duration without error-correction B
- (3) Two-condition code with elements of the same number and duration with error-correction C
- (4) Four-condition code in which each condition represents a signal element (of one or more bits) D
- (5) Multi-condition code in which each condition represents a signal element (of one or more bits) E
- (6) Multi-condition code in which each condition or combination of conditions represents a character F
- (7) Sound of broadcasting quality (monophonic) G
- (8) Sound of broadcasting quality (stereophonic or quadraphonic) H
- (9) Sound of commercial quality (excluding categories given in (10) and (11) below J
- (10) Sound of commercial quality with frequency inversion or band-splitting K
- (11) Sound of commercial quality with separate frequency-modulated signals to control the level of demodulated signal L
- (12) Monochrome M
- (13) Color N
- (14) Combination of the above W
- (15) Cases not otherwise covered X

Fifth symbol—Nature of multiplexing

- (1) None N
- (2) Code-division multiplex³ C
- (3) Frequency-division multiplex F
- (4) Time-division multiplex T
- (5) Combination of frequency-division and time-division multiplex W
- (6) Other types of multiplexing X

¹ Emissions where the main carrier is directly modulated by a signal which has been coded into quantized form (eg, pulse code modulation) should be designated under (2) or (3).

² In this context the word "information" does not include information of a constant unvarying nature such as is provided by standard frequency emissions, continuous wave and pulse radars, etc.

³ This includes bandwidth expansion techniques.

bandwidth, double sideband, digital information without subcarrier, and telegraphy for aural reception. SSB would be 2K5J3E, or 2.5 kHz bandwidth, single sideband with suppressed carrier, analog information, and telephony. The designator for a PSK31 digital signal is 60H0J2B, which means 60 Hz bandwidth, single sideband with suppressed

carrier, digital information using a modulating subcarrier, and telegraphy for automatic reception.

Authorized modulation modes for Amateur Radio operators depend on frequency, license class, and geographical location, as specified in the FCC regulations §97.305. Technical standards for amateur emissions are speci-

fied in §97.307. Among other things, they require that no amateur station transmission shall occupy more bandwidth than necessary for the information rate and emission type being transmitted, in accordance with good amateur practice. We will discuss the necessary bandwidth for each type of modulation as it is covered in the following sections.

8.2 Analog Modulation

While the newer digital modes are all the rage today, traditional analog modulation is still quite popular on the amateur bands. There are many reasons for that, some technical and some not. Analog equipment tends to be simpler; no computer is required. For example, a low-power CW transceiver is easy to construct and simple to understand. CW and SSB are both narrowband modes with spectral efficiency that is quite competitive with their digital equivalents. While heated arguments have been made about the relative power efficiency of analog vs digital modes, it is clear that in the hands of skilled operators CW and SSB are at least in the same ballpark with, if perhaps not better than, many digital modes.

When copying under difficult conditions, the human brain is capable of higher-level signal processing that is difficult to duplicate on a computer. For example, in a DX pileup, an operator may realize that the signal he wants is the weak one and mentally filter out all the stronger stations based on signal strength alone. Other aspects of the signal may be used for filtering as well, such as the operator's accent (on voice) or "fist" (on CW), propagation effects, the operator's speed and operating pattern, CW hum and chirp, and other factors. Different portions of the other station's call sign may be copied

at different times and stitched together in the operator's brain. Missing portions of a transmission can be filled in based on context. Many operators enjoy the challenge of using their ears and brain to decipher a weak signal, an aspect of operating that is lost with the digital modes.

8.2.1 Amplitude-Modulated Analog Signals

Of the various properties of a signal that can be modulated to transmit voice information, amplitude was the first to be used. Not only are modulation and demodulation of AM signals simple in concept, but they are

simple to implement as well. Since the RF output voltage of a class-C amplifier is approximately proportional to the power supply voltage, an AM modulator needs only to vary the power supply voltage in step with the audio signal, as shown in **Fig 8.1**.

To prevent overmodulation and the resulting distortion, the modulating signal should not try to reduce the power supply voltage to less than zero volts or more than twice the average voltage. The *modulation index* of an AM signal is the ratio of the peak modulation to those limits. The resulting RF signal might look like the waveform in **Fig 8.2C**.

Note that the shape of the envelope of the modulated RF signal matches the shape of the modulating signal. That suggests a possible demodulation method. A diode detector puts out a signal proportional to the envelope of the RF signal, recovering the original modulation. See **Fig 8.3**. The capacitor should be large enough that it filters out most of the RF ripple but not so large that it attenuates the higher audio frequencies.

So far we have been discussing signals as a function of time — all the graphs have time as the horizontal axis. It is equally valid

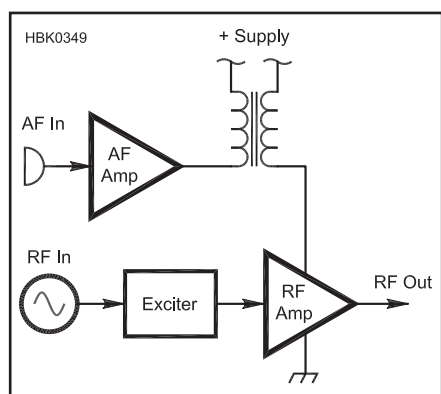

Fig 8.1 — An AM modulator. With a vacuum-tube RF power amplifier this method is known as *plate modulation* since the modulated power supply voltage is applied to the vacuum tube plate.

Fig 8.2 — Graphical representation of amplitude modulation. In the unmodulated carrier (A) each RF cycle has the same amplitude. When the modulating signal (B) is applied, the RF amplitude is increased or decreased according to the amplitude of the modulating signal (C). A modulation index of approximately 75% is shown. With 100% modulation the RF power would just reach zero on negative peaks of the modulating signal.

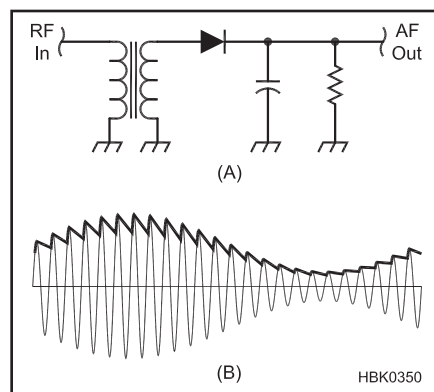

Fig 8.3 — A simple diode-type AM detector, also known as an *envelope detector* (A). The demodulated output waveform has the same shape as the envelope of the RF signal (B). In (B) the thin line is the RF signal modulated with a sine wave and the darker line is the demodulated audio frequency with some residual RF ripple.

Fig 8.4 — A 10-MHz carrier that is AM-modulated by a 1-kHz sine wave.

to look in the frequency domain. It turns out that the modulation spectrum consists of a pair of sidebands above and below the RF carrier. **Fig 8.4** shows a 10-MHz signal modulated with a 1-kHz sine wave. The upper sideband is a single frequency at 10 MHz + 1 kHz = 10.001 MHz. The spectrum of the lower sideband is inverted, so it is at

10 MHz – 1 kHz = 9.999 MHz.

To see why that happens, refer to **Fig 8.5**. Simply adding the first three sine waves shown, representing a carrier and upper and lower sidebands, results in the 100%-modulated AM waveform at the bottom. Note that each sideband has half the amplitude of the carrier, which corresponds to one-quarter the power or –6 dB. Each sideband in an AM signal that is 100% modulated with a sine wave is therefore –6 dB with respect to the carrier.

If a more complex modulating signal is used, each frequency component of the modulation f_m appears at $f_c + f_m$ and $f_c - f_m$, where f_c is the carrier frequency. An AM modulator is really nothing more than a type of mixer that generates new output frequencies at the sum and difference of the carrier and modulation frequencies. The upper sideband is simply a frequency-shifted version of the modulation spectrum and the lower sideband is both frequency-shifted and inverted. For communications purposes, the audio frequency response typically extends up to about 2.5-3 kHz, resulting in a 5-6 kHz RF bandwidth.

One problem with AM is that if the amplitude of the carrier becomes attenuated for

Fig 8.5 — At A is an unmodulated carrier. If the upper (B) and lower (C) sidebands are added together a double-sideband suppressed carrier (DSBSC) signal results (D). If each sideband has half the amplitude of the carrier, then the combination of the carrier with the two sidebands results in a 100%-modulated AM signal (E). Whenever the two sidebands are out of phase with the carrier, the three signals sum to zero. Whenever the two sidebands are in phase with the carrier, the resulting signal has twice the amplitude of the unmodulated carrier.

any reason, then the modulation is distorted, especially the negative-going portion near the 100%-modulation (zero power) point. This can happen due to a propagation phenomenon called *selective fading*. It occurs when the signal arrives simultaneously at the receive antenna via two or more paths, such as ground wave and sky wave. If the difference in the distance of the two paths is an odd number of half-wavelengths, then the two signals are out of phase. If the amplitudes are nearly the same, they cancel and a deep fade results. Since wavelength depends on frequency, the fading is frequency-selective. On the lower-frequency amateur bands it is possible for an AM carrier to be faded while the two sidebands are still audible.

A solution is to regenerate the carrier in the receiver. Since the carrier itself carries no information about the modulation, it is not necessary for demodulation. The transmitted signal may be a standard full-carrier AM signal or the carrier may be suppressed, resulting in *double sideband, suppressed carrier* (DSBSC). An AM detector that regenerates the carrier from the signal is known as a *synchronous detector*. Often the regenerated carrier oscillator is part of a phase-locked loop (PLL) that locks onto the incoming carrier. See **Fig 8.6**. Synchronous detectors not only reduce the effects of selective fading but also are usually more linear than diode detectors so they have less distortion. Some commercial short-wave broadcasts include a reduced, but not suppressed, carrier (DSBRC) to allow operation with PLL-type synchronous detectors.

Since the advent of single sideband in the 1960s, full-carrier double-sideband AM has become something of a niche activity in Amateur Radio. It does retain several advantages however. We have already mentioned the simplicity of the circuitry. Another advantage is that, because of the presence of the

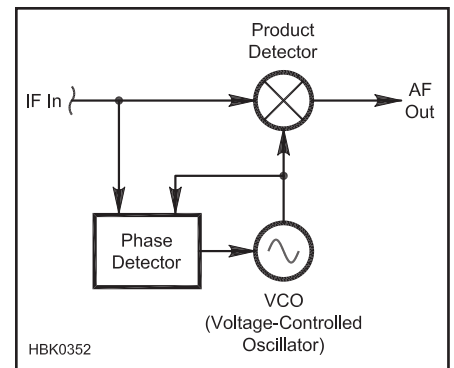

Fig 8.6 — Block diagram of a synchronous detector. The voltage-controlled oscillator (VCO) is part of a phase-locked loop that locks the oscillator to the carrier frequency of the incoming AM or DSBRC signal.

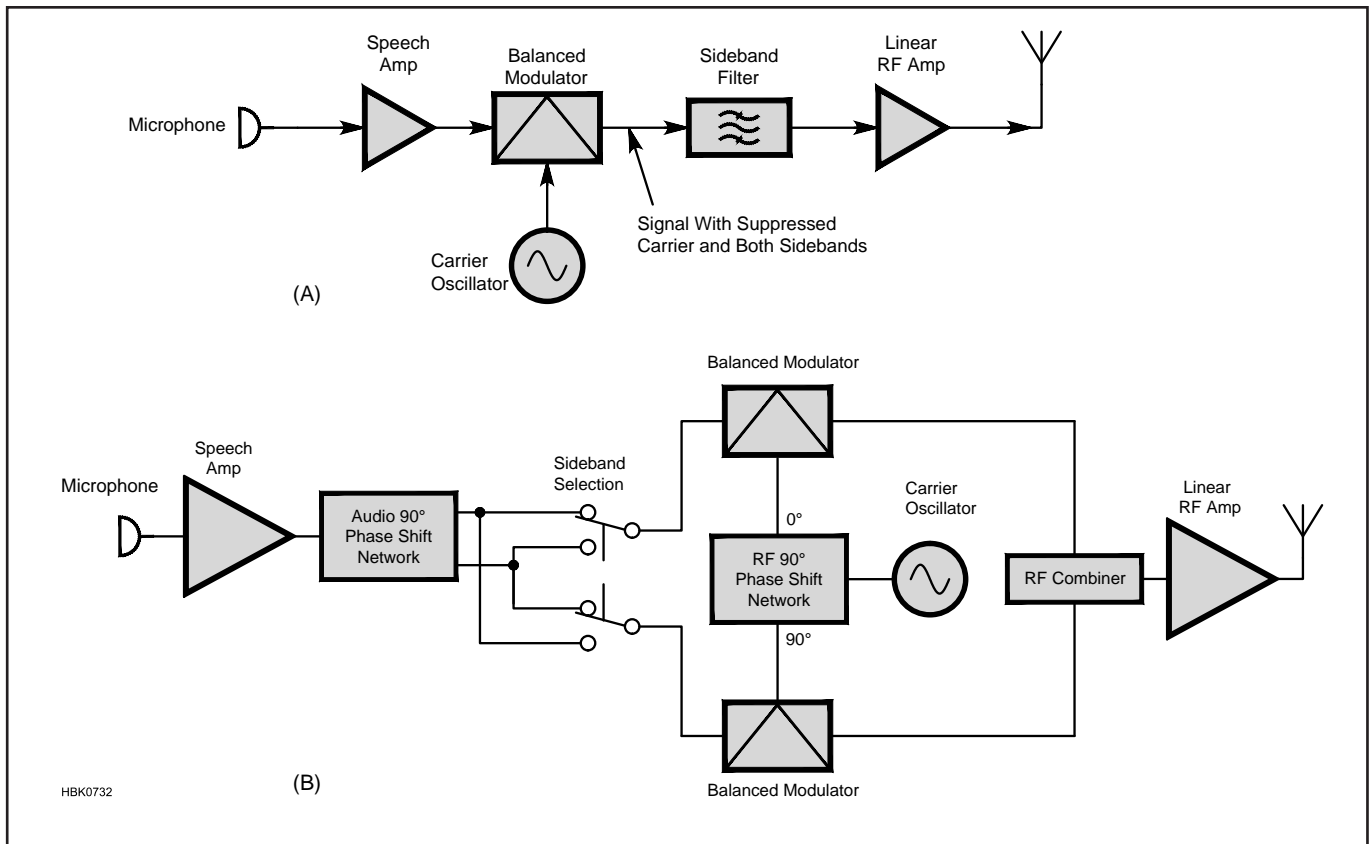

Fig 8.7 — Block diagram of a filter-type (A) and a phasing-type (B) SSB generator.

carrier, the automatic gain control system in the receiver remains engaged at all times, ensuring a constant audio level. Unlike with SSB, there is no rush of noise during every pause in speech. Also tuning is less critical than with SSB. There is no “Donald Duck” sound if the receiver is slightly mistuned. Finally, the audio quality of an AM signal is usually better than that of SSB because of the lack of a crystal filter in the transmit path and the wider filter in the receiver.

SINGLE SIDEBAND

As we have seen, since the carrier itself contains no modulation, it does not need to be transmitted, which saves at least 67% of the transmitted power. In addition, since the two sidebands carry identical information, one of them may be eliminated as well, saving half the bandwidth. The result is *single sideband, suppressed carrier* (SSBSC), which is commonly referred to simply as “SSB.” If the lower sideband is eliminated, the result is called *upper sideband* (USB). If the upper sideband is eliminated, you’re left with *lower sideband* (LSB). The bandwidth is a little less than half that of an equivalent AM signal. A typical SSB transmitter might have an overall audio response from 300 Hz to 2.8 kHz, resulting in 2.5 kHz bandwidth.

As with an AM synchronous detector, the

carrier is regenerated in the receiver but since only one sideband is present, the synchronous detector’s phase-locked loop is not possible. Instead, the detector uses a free-running *beat-frequency oscillator* (BFO). The detector itself is called a *product detector* because its output is the mathematical product of the BFO and the SSB signal. The BFO must be tuned to the same frequency as the suppressed carrier to prevent distortion of the recovered audio. In a superheterodyne receiver, that is done by carefully tuning the local oscillator (the main tuning dial) such that after conversion to the intermediate frequency, the suppressed carrier aligns with the BFO frequency.

In the transmitter, the SSB modulator must suppress both the carrier and the unwanted sideband. Carrier suppression is normally accomplished with a *balanced modulator*, a type of mixer whose output contains the sum and difference frequencies of the two input signals (the modulating signal and the carrier) but not the input signals themselves. There are several ways to eliminate the unwanted sideband, but the most common, shown in **Fig 8.7A**, is to pass the output of the balanced mixer through a crystal filter that passes the wanted sideband while filtering out the unwanted one. This is convenient in a transceiver since the same filter can be used in the receiver

by means of a transmit-receive switch.

Another method to generate single sideband is called the *phasing method*. See Fig 8.7B. Using trigonometry, it can be shown mathematically that the sum of the signals from two balanced modulators, each fed with audio signals and RF carriers that are 90° out of phase, consists of one sideband only. The other sideband is suppressed. The output can be switched between LSB and USB simply by reversing the polarity of one of the inputs, which changes the phase by 180°. The phasing method eliminates the need for an expensive crystal filter following the modulator or, in the case of a transceiver, the need to switch the crystal filter between the transmitter and receiver sections. In addition, the audio quality is generally better because it eliminates the poor phase dispersion that is characteristic of most crystal filters. In the old days, designing and building an audio phase-shift network that accurately maintained a 90° differential over a decade-wide frequency band (300 Hz to 3000 Hz) was rather complicated. With modern DSP techniques, the task is much easier.

Compared to most other analog modulation modes, SSB has excellent power efficiency because the transmitted power is proportional to the modulating signal and no power at all is transmitted during pauses in speech. Another advantage is that the lack of a carrier results

in less interference to other stations. Back in the days when AM ruled the HF amateur voice bands, operators had to put up with a cacophony of heterodynes emanating from their headphones. SSB transceivers also are well-suited for the narrowband digital modes. Because an SSB transceiver simply frequency-translates the baseband audio signal to RF in the transmitter and back to audio again in the receiver, digital modulation may be generated and detected at audio frequencies using the sound card in a personal computer.

8.2.2 Angle-Modulated Analog Signals

Angle modulation varies the phase angle of an RF signal in response to the modulating signal. In this context, “phase” means the phase of the modulated RF sine wave with respect to the unmodulated carrier. Phase modulation is one type of angle modulation, but so is frequency modulation because any change in frequency results in a change in phase. For example, the way to smoothly ramp the phase from one value to another is to change the frequency and wait. If the frequency is changed by +1 Hz, then after 1 second the phase will have changed by +360°. After 2 seconds, the phase will have changed by +720°, and so on. Change the frequency

in the other direction and the phase moves in the opposite direction as well. With sine-wave modulation, the frequency and phase both vary in a sinusoidal fashion. See Fig 8.8.

Since any change in frequency results in a change in phase and vice versa, *frequency modulation* (FM) and *phase modulation* (PM) are fundamentally the same. The only difference is the audio frequency response. An FM transmitter with 6 dB/octave pre-emphasis of the modulating signal is indistinguishable from a PM transmitter. A PM transmitter with 6 dB/octave de-emphasis is indistinguishable from an FM transmitter. The reverse happens at the receiver. A frequency detector followed by a 6 dB/octave de-emphasis network acts like a phase detector. It is interesting to note that most VHF and UHF amateur “FM” transceivers should really be called “PM” transceivers due to the pre-emphasis and de-emphasis networks used in the transmitters and receivers respectively.

The term *frequency deviation* means the amount the RF frequency deviates from the center (carrier) frequency with a given modulating signal. The instantaneous deviation of an FM signal is proportional to the instantaneous amplitude of the modulating signal. The instantaneous deviation of a PM signal is proportional to the instantaneous *rate of change* of the modulating signal.

Since the rate of change of a sine wave is proportional to its frequency as well as its amplitude, the deviation of a PM signal is proportional to both the amplitude and the frequency of the modulating signal.

Most FM and PM transmitters include some kind of audio compressor before the modulator to limit the maximum deviation. Common usage of the term *deviation* is that it refers to the maximum peak deviation allowed by the audio compressor. If the frequency swings a maximum of 5 kHz above the center frequency and 5 kHz below the center frequency, we say the deviation is 5 kHz. The *modulation index* is the ratio of the peak deviation to the highest audio frequency. The *deviation ratio* is the ratio of maximum permitted peak deviation to the maximum permitted modulating frequency.

FCC regulations limit the modulation index at the highest modulating frequency to a maximum of 1.0 for frequencies below 29 MHz. If the audio is low-pass filtered to 3 kHz, then the deviation may be no more than 3 kHz. For that reason, FM transmitters for frequencies below 29 MHz are usually set for 3 kHz deviation while FM transmitters at higher frequencies are typically set for about 5 kHz deviation. The term *narrowband FM* generally refers to deviation of no more than 3 kHz and *wideband FM*

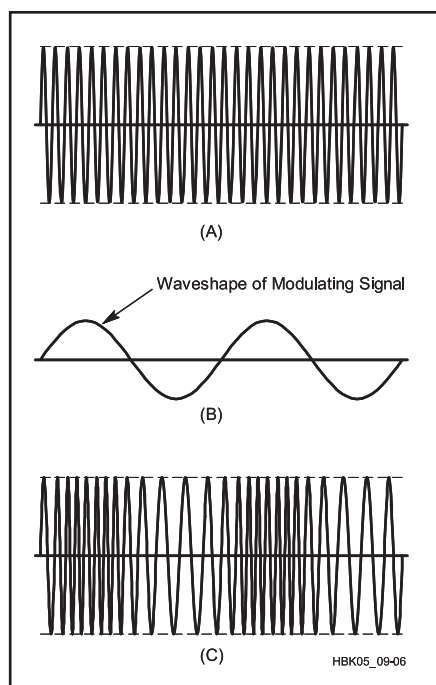

Fig 8.8 — Graphical representation of frequency modulation. In the unmodulated carrier (A) each RF cycle occupies the same amount of time. When the modulating signal (B) is applied, the radio frequency is increased or decreased according to the amplitude and polarity of the modulating signal (C).

Fig 8.9 — Amplitude of the FM carrier and the first nine sidebands versus modulation index. This is a graphical representation of mathematical functions developed by F. W. Bessel. Note that the carrier completely disappears at modulation indices of 2.405 and 5.52.

refers to deviation greater than 3 kHz.

Unlike amplitude modulation, angle modulation is nonlinear. Recall that with amplitude modulation, the shape of the RF spectrum is the same as that of the modulation spectrum, single-sided with SSB and double-sided with DSB. That is not true with angle modulation. A double-sideband AM signal with audio band-limited to 3 kHz has 6 kHz RF bandwidth. It is easy to see that an FM transmitter with the same audio characteristics but with, say, 5 kHz deviation must have a bandwidth of at least 10 kHz. And it is even worse than that. While you might think that the bandwidth equals twice the deviation, in reality the transmitted spectrum theoretically extends to infinity, although it does become vanishingly small beyond a certain point. As a rule of thumb, approximately 98% of the spectral energy is contained within the bandwidth defined by *Carson's rule*:

$$BW = 2(f_d + f_m) \quad (1)$$

where

f_d = the peak deviation, and

f_m = the highest modulating frequency.

For example, if the deviation is 5 kHz and the audio is limited to 3 kHz, the bandwidth is approximately $2(5 + 3) = 16$ kHz.

With sine-wave modulation, the RF frequency spectrum from an angle-modulated transmitter consists of the carrier and a series of sideband pairs, each spaced by the frequency of the modulation. For example, with 3 kHz sine-wave modulation, the spectrum includes tones at ± 3 kHz, ± 6 kHz, ± 9 kHz and so on with respect to the carrier. When the modulation index is much less than 1.0, only the first sideband pair is significant, and the spectrum looks similar to that of an AM signal (although the phases of the sidebands are different). As the modulation index is increased, more and more sidebands appear within the bandwidth predicted by Carson's rule. Unlike with AM, the carrier amplitude also changes with deviation and

Fig 8.10 — A plot of post-detection signal-to-noise ratio (S/N) versus input carrier-to-noise ratio (C/N) for an FM detector at various modulation indices, m . For each modulation index the deviation is also noted assuming a maximum modulating frequency of 3 kHz. For comparison, the performance of an SSB product detector is also shown.

actually disappears altogether for certain modulation indices. Because the amplitude of an angle-modulated signal does not vary with modulation, the total power of the carrier and all sidebands is constant.

The amplitudes of the carrier and the various sidebands are described by a series of mathematical equations called Bessel functions, which are illustrated graphically in **Fig 8.9**. Note that the carrier disappears when the modulation index equals 2.405 and 5.52. That fact can be used to set the deviation of an FM transmitter. For example, to set 5 kHz deviation, connect the microphone input to a sine-wave generator set for a frequency of $5 / 2.405 = 2.079$ kHz, listen to the carrier on

a narrowband receiver, and adjust the deviation until the carrier disappears.

Since the amplitude carries no information, FM receivers are designed to be as insensitive to amplitude variations as possible. Because noise tends to be mostly AM in nature, that results in a quieter demodulated signal. Typically the receiver includes a *limiter*, which is a very high-gain amplifier that causes the signal to clip, removing any amplitude variations, before being applied to the detector. Unlike with AM, as an FM signal gets stronger the volume of the demodulated audio stays the same, but the noise is reduced. Receiver sensitivity is often specified by how much the noise is suppressed for a certain input signal level. For example, if a $0.25 \mu\text{V}$ signal causes the noise to be reduced by 20 dB, then we say the receiver sensitivity is “ $0.25 \mu\text{V}$ for 20 dB of quieting.”

The limiter also causes a phenomenon known as *capture effect*. If more than one signal is present at the same time, the limiter tends to reduce the weaker signal relative to the stronger one. We say that the stronger signal “captures” the receiver. The effect is very useful in reducing on-channel interference.

The suppression of both noise and interference is greater the wider the deviation. FM signals with wider deviation do take up more bandwidth and actually have a poorer signal-to-noise (S/N) ratio at the detector output for weak signals but have better S/N ratio and interference rejection for signal levels above a certain threshold. See **Fig 8.10**.

In addition to the noise and interference-reduction advantage, angle-modulated signals share with full-carrier AM the advantages of non-critical frequency accuracy and the continuous presence of a signal, which eases the task of the automatic gain control system in the receiver. In addition, since the signal is constant-amplitude, the transmitter does not need a linear amplifier. Class-C amplifiers may be used, which have greater power efficiency.

8.3 Digital Modulation

The first digital modulation used in Amateur Radio was on-off keying using Morse code. However, the term “digital” is commonly understood to refer to modes where the sending and receiving is done by machine. By that definition, the first popular amateur digital mode (called radioteletypewriter, or RTTY) used frequency-shift keying with

all the coding and decoding done by mechanical teleprinters. You still hear RTTY on the bands today, although most operators are using computers these days rather than Teletype machines. More-modern digital modes use more efficient modulation formats as well as error detection and correction to ensure reliable communications. Data can be sent

much more rapidly than with Morse code or voice, with less effort, and with fewer errors. In some systems, stations operate unattended 24 hours per day, transferring data with little or no operator intervention. For point-to-point transmission of large quantities of text or other data, these modern digital modes are the obvious choice.

8.3.1 Amplitude-Modulated Digital Signals

We start this section by discussing *on-off keying* (OOK), which is a special case of *amplitude-shift keying* (ASK) and is normally sent using Morse code. For historical reasons dating from the days of spark transmitters, amateurs often refer to this as *continuous wave* (CW) even though the signal is actually keyed on and off. While most amateurs think of CW as being an analog mode, we include it here because it has technical characteristics that are more similar to other digital modes than to analog.

You can think of OOK as being the same as analog AM that is modulated with a two-level signal that switches between full power and zero power. For example, imagine that the modulation is a 10 Hz square wave, equivalent to sending a series of dits at 24 WPM. A square wave may be decomposed into a sine wave of the same frequency and a theoretically infinite succession of odd harmonics. Recall that the lower and upper sidebands of an AM signal are simply the inverted and non-inverted spectra of the baseband modulation. The RF spectrum therefore contains sidebands at the carrier frequency ± 10 Hz, ± 30 Hz, ± 50 Hz, and so on to plus and minus infinity. This phenomenon is called *key clicks*. Stations listening on nearby frequencies hear a click upon every key closure and opening.

To prevent interference to other stations, the modulation must be low-pass filtered, which slows down the transition times between the on and off states. See **Fig 8.11**. If the transitions are too fast, then excessive key clicks occur. If the transitions are too slow, then at high speeds the previous transition may not have finished before the next one starts, which makes the signal sound mushy and hard to read. Traditionally, filtering was done with a simple resistor-capacitor low-pass filter on the keying line, but using a transition with a raised-cosine shape allows faster transition times without excessive key clicks. Some modern transceivers use DSP techniques to generate such a controlled transition shape.

The optimum transition time, and thus bandwidth, depends on keying speed. It also depends on propagation conditions. When the signal is fading, the transitions must be sharper to allow good copy. **Fig 8.12** gives recommended keying characteristics based on sending speed and propagation. As a compromise, many transmitters use a 5 ms rise and fall time. That limits the bandwidth to approximately 150 Hz while allowing good copy up to 60 WPM on non-fading channels and 35 WPM on fading channels, which covers most requirements.

With any digital system, the number of

Fig 8.11 — A filtered CW keying waveform. The on-off transitions of the RF envelope should be as smooth as possible while transitioning as quickly as possible. The shape of the RF Output waveform is nearly optimum in that respect.

Fig 8.12 — Keying speed vs rise and fall times vs bandwidth for fading and non-fading communications circuits. For example, to optimize transmitter timing for 20 WPM on a non-fading circuit, draw a vertical line from the WPM axis to the $K = 3$ line. From there draw a horizontal line to the rise/fall axis (approximately 15 ms). Draw a vertical line from where the horizontal line crosses the bandwidth line and see that the bandwidth is about 50 Hz.

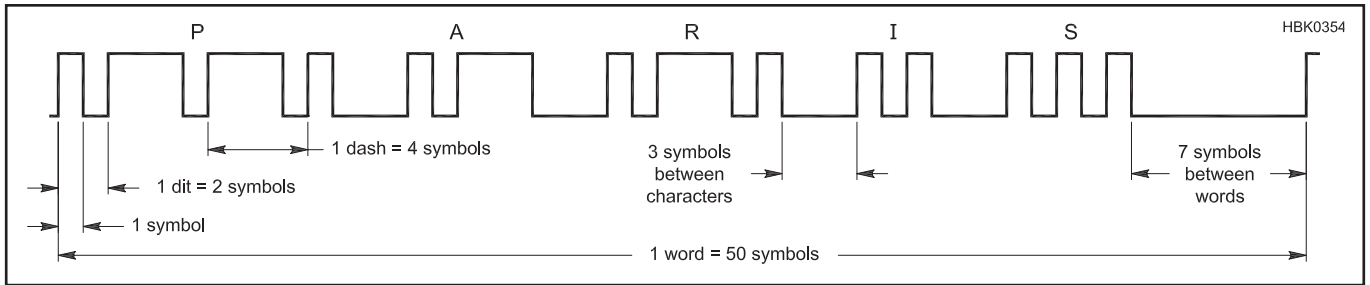

Fig 8.13 — CW timing of the word **PARIS**, which happens to have a length equal to the standard 50 symbols per word. By programming it multiple times into a memory keyer, the speed may be calibrated simply by counting the number of times the word is completed in one minute.

changes of state per second is called the *baud rate* or the *symbol rate*, measured in *bauds* or *symbols per second*. Sending a single Morse code dit requires two equal-length states, or symbols: *on* for the length of the dit and *off* for the space between dits. Thus, a string of dits sent at a rate of 10 dits per second has a symbol rate of 20 bauds.

Refer to **Fig 8.13**. A Morse code dash is on for three times the length of a dit. Including one symbol for the off time, the total time to send a dash is four symbols, twice the time to send a dit. For example, at a baud rate of 20 bauds, there are 10 dits per second or 5 dashes per second. The spacing between characters within a word is three symbols, two more than the normal space between dits and dashes. The spacing between words is seven symbols.

For purposes of computing sending speed, a standard word is considered to have five characters, plus the inter-word spacing. On average, that results in 50 symbols per word. From that, the speed in words per minute may be computed from the baud rate:

$$\text{WPM} = \frac{60 \text{ (sec / min)}}{50 \text{ (symbols / word)}} \times \text{bauds} \quad (2)$$

$$= 1.2 \times \text{bauds} = 2.4 \times \text{dits / sec}$$

Characters in Morse code do not all have the same length. Longer codes are used for characters that are used less frequently while the shortest codes are reserved for the most common characters. For example, the most common letter in the English language, E, is sent as a single dit. In that way, the average character length is reduced, resulting in a faster sending speed for a given baud rate. Such a variable-length code is known as *varicode*, a technique that has been copied in some modern digital modes.

PULSE MODULATION

Another type of digital amplitude modulation comes under the general category of *pulse modulation*. The RF signal is broken up into a series of pulses, which are usually equally-spaced in time and separated by peri-

Fig 8.14 — Three types of pulse-code modulation. A sine-wave modulating signal (A) is shown at the top. Pulse-amplitude modulation (B) varies the amplitude of the pulses, pulse-width modulation (C) varies the pulse width, and pulse-position modulation (D) varies the pulse position, proportional to the modulating signal. The tic marks show the nominal pulse times. The RF signal is created by an AM modulator using (B), (C) or (D) as the modulating signal.

ods of no signal. We will discuss three types of pulse modulation, PAM, PWM and PPM.

Pulse-amplitude modulation (PAM) consists of a series of pulses of varying amplitude that correspond directly to the amplitude of the modulating signal. See **Fig 8.14B**. The

pulses can be positive or negative, depending on the polarity of the signal. The modulating signal can be recovered simply by low-pass filtering the pulse train. The effect of the negative pulses is to reverse the polarity of the RF signal. The result is very similar to a

double-sideband, suppressed-carrier signal that is rapidly turned on and off at the pulse rate of the PAM. In other words, the DSBSC signal is periodically sampled at a certain pulse repetition rate.

For the signal to be properly represented, its highest modulating frequency must be less than the *Nyquist frequency*, which is one-half the sample rate. That condition, known as the *Nyquist criterion*, applies not only to PAM but to any digital modulation technique.

There are two variations of PAM that should be mentioned. *Natural sampling* does not hold the amplitude of each pulse constant throughout the pulse as shown in Fig 8.14B, but rather follows the shape of the analog modulation. The *single-polarity method* adds a fixed offset, or pedestal, to the modulating signal before the PAM modulator. As long as the pedestal is greater than or equal to the peak negative modulation, then the RF phase never changes and the signal is equivalent to sampled full-carrier AM rather than DSBSC.

PAM is rarely used on the amateur bands because it increases the transmitted bandwidth and adds circuit complexity with no improvement in signal-to-noise ratio for most types of noise and interference. The concept is useful, however, because PAM is similar to the signal generated by the sample-and-hold circuit that is used at the input to an analog-to-digital converter (ADC). An ADC is used in virtually every digital transmitter to convert the analog voice signal to a digital signal suitable for digital signal processing.

Pulse-width modulation (PWM) is a series of pulses whose width varies in proportion to the amplitude of the modulating signal. Fig 8.14C shows the pulses centered on the sample times, but in some systems the sample times may correspond to the leading or trailing pulse edges. With either method, the modulating signal can be recovered by low-pass filtering the pulse train and passing it through a coupling capacitor to remove the DC component.

Pulse-position modulation (PPM), Fig 8.14D, varies the position, or phase, of the pulses in proportion to the amplitude of the modulating signal. With both PWM and PPM, the peak amplitude of the signal is constant. That allows the receiver to be designed to be insensitive to amplitude variations, which can result in a better post-detection signal-to-noise ratio, in a manner similar to analog angle modulation.

8.3.2 Angle-Modulated Digital Signals

Just as with analog modulation, angle-modulated digital signals have constant amplitude and vary the phase and frequency to represent the modulating signal. They share some of the same advantages as their ana-

log counterparts. The receiver can be made relatively insensitive to amplitude noise and on-channel interference. The constant-amplitude signal simplifies the job of the receiver's automatic-gain-control system. The transmitter does not require a linear amplifier, so a more-efficient class-C amplifier may be used. However digital angle modulation also shares analog's nonlinearity so that the bandwidth is not as well-constrained as it is with linear modulation systems.

Frequency-shift keying (FSK) was the first digital angle-modulated format to come into common use. FSK can be thought of as being the same as analog FM that is modulated with a binary (two-level) signal that causes the RF signal to switch between two frequencies. It can also be thought of as equivalent to two on-off-keyed (OOK) signals on two nearby frequencies that are keyed in such a way that whenever one is on the other is off. Just as with OOK, if the transitions between states are instantaneous, then excessive bandwidth occurs — causing interference on nearby channels similar to key clicks. For that reason, the modulating signal must be low-pass filtered to slow down the speed at which the RF signal moves from one frequency to the other.

Although FSK is normally transmitted as a true constant-amplitude signal with only the frequency changing between symbols, it does not have to be received that way. The receiver can treat the signal as two OOK signals and demodulate each one separately. This is an advantage when HF propagation conditions exhibit selective fading — even if one frequency fades out completely the receiver can continue to copy the other, a form of *frequency diversity*. To take advantage of it, wide shift (850 Hz) must normally be used. With narrow-shift FSK (170 Hz), the two tones are generally too close to exhibit selective fading.

As previously discussed, selective fading is caused by the signal arriving at the receiver antenna by two or more paths simultaneously. The same phenomenon can cause another signal impairment known as *inter-symbol interference*. See Fig 8.15. If the difference in the two path lengths is great enough, then

the signal from one path may arrive delayed by one entire symbol time with respect to the other. The receiver sees two copies of the signal that are time-shifted by one symbol. In effect, the signal interferes with itself. One solution is to slow down the baud rate so that the symbols do not overlap. It is for this reason that symbol rates employed on HF are usually no more than 50 to 100 bauds.

Multi-level FSK (MFSK) is one method to reduce the symbol rate. Unlike with conventional binary FSK, more than two shift frequencies are allowed. For example, with eight frequencies, each symbol can have eight possible states. Since three bits are required to represent eight states, three bits are transmitted per symbol. That means you get three times the data rate without increasing the baud rate. The disadvantage is a reduced signal to noise and signal to interference ratio. If the maximum deviation is the same, then the frequencies are seven times closer with 8FSK than with binary FSK and the receiver is theoretically seven times (16.9 dB) more susceptible to noise and interference. However the IF limiter stage removes most amplitude variations before the signal arrives at the FSK detector, so the actual increase in susceptibility is less for signal levels above a certain threshold.

With any type of FSK, you can theoretically make the shift as narrow as you like. The main disadvantage is that the receiver becomes more susceptible to noise and interference, as explained above. In addition, the bandwidth is not reduced as much as you might expect. Just as with analog FM, you still get sidebands whose extent depends on the symbol rate, no matter how small the deviation.

Minimum-shift keying (MSK) is FSK with a deviation that is at the minimum practical level, taking bandwidth and signal-to-noise ratio into account. That turns out to be a frequency shift from the center frequency of 0.25 times the baud rate or, using the common definition of frequency shift, a difference between the two tones of 0.5 times the baud rate. If, on a given symbol, the frequency is shifted to the upper tone, then the phase of the RF signal will change by 0.25 cycles, or 90°, during the symbol period. If the lower tone is selected, the phase shift is -90°. Thus, MSK may be regarded as either FSK with a frequency shift of 0.5 times the symbol rate, or as *differential phase-shift keying* (DPSK) with a phase shift of ±90°. The binary data cause the phase to change by either +90 or -90° from one symbol to the next.

Gaussian minimum-shift keying (GMSK) refers to MSK where the modulating signal has been filtered with a low-pass filter that has a Gaussian frequency response. As mentioned before, with any type of angle modulation the spectrum of the modulation is not duplicated at RF, but spreads out into an increased band-

Fig 8.15 — Multipath propagation can cause inter-symbol interference (ISI). At the symbol decision points, which is where the receiver decoder samples the signal, the path 2 data is often opposing the data on path 1.

width. For that reason, there is no point in using a modulation filter with a sharp cutoff since the RF spectrum will be wider anyway. It turns out that a Gaussian filter, with its gradual transition from passband to stopband, has the optimum shape for an angle-modulated digital system. However, a Gaussian filter also has a gradual transition from symbol-to-symbol in the time domain as well. The transition is not totally completed by the time of the next symbol, which means that there is some inter-symbol interference in the transmitted signal, even in the absence of propagation impairments. With the proper choice of filter bandwidth, however, the ISI is small enough not to seriously affect performance.

Binary phase-shift keying (BPSK), often referred to simply as phase-shift keying (PSK), is included in this section because the name suggests that it is true constant-amplitude angle modulation. It is possible to implement it that way. An example is MSK which, as described above, can be considered to be differential BPSK with a $\pm 90^\circ$ phase shift. However the term BPSK is normally understood to refer to phase-shift keying with a 180° phase difference between symbols. To transition from one state to the other, the modulation filter smoothly reduces the amplitude to zero where the polarity reverses (phase changes 180°) before smoothly ramping up to full amplitude again. For that reason,

BPSK as usually implemented really should not be considered to be PSK, but rather a form of amplitude-shift keying (ASK) with two modulation amplitudes, +1 and -1. Unlike true angle modulation, it is linear so that the spectrum of the modulation filter is duplicated at RF. The transmitter must use a linear amplifier to prevent distortion and excessive bandwidth similar to the splatter that results from an over-driven SSB transmitter.

8.3.3 Quadrature Modulation

Quadrature modulation encodes digital signals using a combination of amplitude and phase modulation. With two types of modulation to work with, it is possible to cram more data bits into each modulation symbol, which allows more throughput for a given bandwidth. Modulation formats in use today have up to 8 or more bits per symbol which would be impractical for ASK, FSK or PSK alone.

Since quadrature-modulated symbols are defined by both amplitude and phase, the most common way to represent symbol states is with a polar plot, called a *constellation diagram*. See Fig 8.16, which shows a *four-level quadrature amplitude modulation* (4-QAM) signal, often referred to simply as QAM. The distance of each state from the origin represents the amplitude. The phase angle with

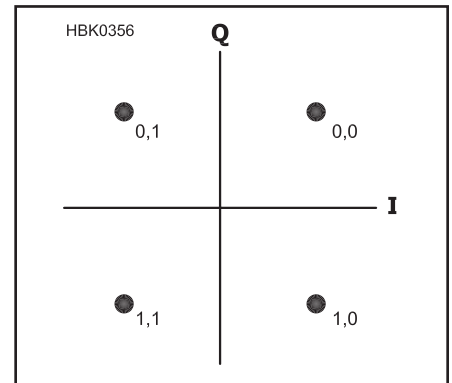

Fig 8.16 — Constellation diagram of a 4-QAM signal, also known as QPSK. The four symbol locations all have the same amplitude and have phase angles of 45° , 135° , -135° and -45° . 4-QAM is a two-bits-per-symbol format. The four symbols are selected by the four possible states of the two data bits, which can be assigned in any order. With the assignment shown, the Q value depends only on the first bit and the I value depends only on the second, an arrangement that can simplify symbol encoding.

respect to the +I axis represents the phase. The four states shown have phase angles of $+45^\circ$, $+135^\circ$, -45° and -135° . Normally, the receiver has no absolute phase information and can only detect phase differences between

Digital TV Modulation

DTV operates on the same 6 MHz-wide channels used for analog TV. However, instead of each channel slot carrying an analog NTSC television signal (visual carrier, color subcarrier and aural carrier), the channel slot carries an 8-VSB digitally modulated signal. The 6 MHz-wide over-the-air channel slots themselves didn't change, just the signals carried in them! So, channel 2 is still 54-60 MHz, channel 3 is 60-66 MHz, and so forth, up to channel 51. Channels 2-6 have largely been abandoned in the US as stations moved to broadcast digital TV on UHF channels. UHF channels 52-69 will be reallocated to other uses.

The designation "8-VSB" refers to 8-level vestigial sideband modulation. This is similar to 256-QAM, which means 256-state *quadrature amplitude modulation* — the 256 "states" are 256 combinations of signal phase and amplitude values that represent the 256 different transmitted symbols — a digital format used in cable TV networks (64-QAM is also used by cable companies). In the case of 8-VSB, the "8" refers to the eight-level baseband DTV signal that amplitude modulates an IF signal. For more info about 8-VSB modulation, see the online article, "What Exactly Is 8-VSB Anyway?" by David Sparano at www.arri.org/files/file/Technology/TV_Channels/8_Bit_VSB.pdf and other references at www.arri.org/tv-channels-air-catv.

Digitally modulated signals used to transport video — whether 8-VSB for over-the-air or 64-QAM or 256-QAM in cable networks — are noise-like signals over their 6 MHz bandwidth. If a digital TV signal interferes with analog radio communications such as FM or SSB, the effect is similar to degraded signal-to-noise ratio. Indeed, a digital TV signal can be thought of as a 6 MHz wide "pile of noise." On a spectrum analyzer, it looks like a "haystack" as shown in Fig 8.A Of course, the IF bandwidth

of the amateur receiver is quite narrow relative to the 6 MHz-wide digital TV channel, so the actual noise level seen by the receiver (assuming no overload or IMD problems) will in part be determined by the receiver's IF bandwidth. Still, the effect on the receiver is what amounts to an elevated noise floor, similar to the effects of wide-spectrum broadband noise.

Fig 8.A — The spectrum of three analog NTSC TV channels (left of center) and three QAM signals (right of center). The digital channel power of the QAM "haystacks" is about 6 dB below the analog visual carrier PEP.

Fig 8.17 — Constellation diagram of a 256-QAM signal. Since an 8-bit number has 256 possible states, each symbol represents 8 bits of data.

the states. For that reason, we could just as easily have drawn the four states directly on the I and Q axes, at 0° , $+90^\circ$, 180° and -90° . Note that each of the four states has the same amplitude, differing only in phase. For that reason 4-QAM is often referred to as *quadrature phase-shift keying* (QPSK), in the same manner that two-level ASK is normally referred to as BPSK.

Since 4-QAM has four possible states, there are two data bits per symbol. However QAM is not limited to four states. **Fig 8.17** illustrates a 256-QAM signal. It takes 8 bits to represent 256 states, so 256-QAM packs 8 data bits into each symbol. The disadvantage of using lots of states is that the effect of noise and interference is worse at the receiver. Since, for the same peak power, the states of a 256-QAM signal are 15 times closer together than with 4-QAM, the receiver's decoder has to determine each symbol's location to 15 times greater accuracy. That means the ratio of peak power to noise and interference must be $20 \log(15) = 23.5$ dB greater for accurate decoding. That is why QAM with a large number of states is normally not used on the HF bands where fading, noise and interference are common. A more common application is digital cable television where the coaxial-cable transmission channel is much cleaner. For example, the European DVB-C standard provides for 16-QAM through 256-QAM, depending on bandwidth and data rate.

There are at least two ways to generate a QAM signal. One is to combine a phase modulator and an amplitude modulator. The phase modulator places the symbol location at the correct phase angle and the amplitude modulator adjusts the amplitude so the symbol is the correct distance from the origin. That method is seldom used, both because

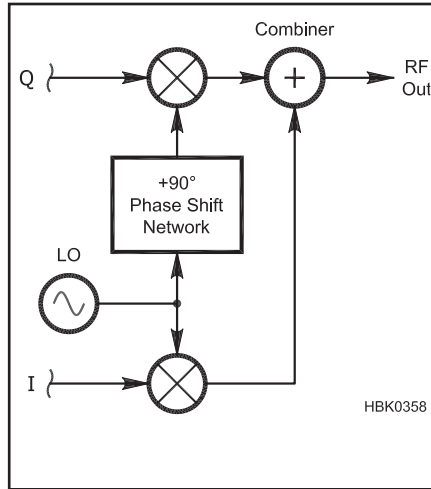

Fig 8.18 — Block diagram of an I/Q modulator. Note the similarity to Fig 8.7. By connecting an audio 90° phase-shift network to the I and Q inputs, an I/Q modulator can generate an analog SSB signal by the phasing method.

of the circuit complexity and because the nonlinear phase modulator makes the signal difficult to filter so as to limit the bandwidth.

A much more common method of generating QAM is with an *I/Q modulator*. See **Fig 8.18**. By using two modulators (mixers) fed with RF sine waves in quadrature (90° out of phase with each other), any amplitude and phase may be obtained by varying the amplitudes of the two modulation inputs. The input labeled I (for in-phase) moves the symbol location horizontally in the constellation diagram and the one labeled Q (for quadrature) moves it vertically. For example, to obtain an amplitude of I and a phase angle of -45° , set I to $+0.707$ and set Q to -0.707 .

It is possible to generate virtually any type of modulation using an I/Q modulator. For example, to generate BPSK or on-off keying, simply disconnect the Q input and apply the modulation to I. For angle modulation, such as FM or PM, a waveform generator applies a varying signal to I and Q in such a manner to cause the symbol to rotate at constant amplitude with the correct phase and frequency (rotation rate). Even a multi-carrier signal may be generated with a single I/Q modulator by applying the sum of a number of signals, each representing one carrier, to the I and Q inputs. The phase of each signal rotates at a rate equal to the frequency offset of its carrier from the center.

One problem with QAM is that whenever the signal trajectory between two symbol states passes through the origin, the signal amplitude momentarily goes to zero. That imposes stringent linearity requirements on the RF power amplifier, since many amplifiers exhibit their worst linearity near zero

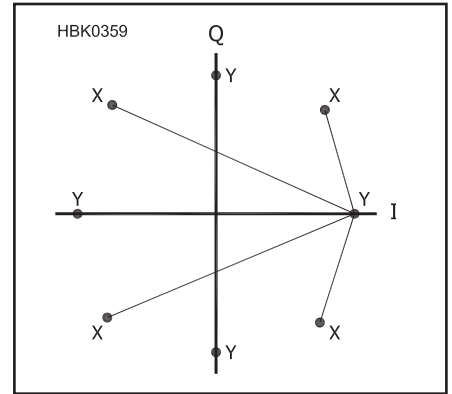

Fig 8.19 — Constellation diagram of a $\pi/4$ DQPSK signal. There are eight possible symbol locations. If the current symbol location is at one of the four positions labeled "X" then the next symbol will be at one of the four locations labeled "Y" and vice versa. That guarantees that no possible symbol trajectories (the lines between symbol locations) can ever pass through the origin.

power. One solution is *offset QPSK* (OQPSK) modulation. In this case, the symbol transitions of the I and Q channels are offset by half a symbol. That is, for each symbol, the I channel changes state first then the Q channel changes half a symbol time later. That allows the symbol trajectory to sidestep around the origin, allowing use of a higher-efficiency or lower-cost power amplifier that has worse linearity.

Another solution to the zero-crossing problem is called *PI over 4 differential QPSK* ($\pi/4$ DQPSK). See **Fig 8.19**. This is actually a form of 8-PSK, where the eight symbol locations are located every 45° around a constant-amplitude circle. On any given symbol, however, only four of the symbol locations are used. The symbol location always changes by an odd multiple of 45° ($\pi/4$ radians). If the current symbol is located on the I or Q axis, then on the next symbol only the four non-axis locations are available and vice versa. As with OQPSK, that avoids transitions that pass through the origin.

Another advantage of $\pi/4$ DQPSK which is shared with other types of differential modulation is that absolute phase doesn't matter. The information is encoded only in the *difference* in the phase of successive symbols. That greatly simplifies the job of the receiver's demodulator.

The block diagram of an I/Q demodulator looks like an I/Q modulator drawn backward. See **Fig 8.20**. If the local oscillator is not tuned to exactly the same frequency as the one in the transmitter (after downconversion to the IF, assuming a superhet receiver) then the demodulated signal will rotate in the I/Q plane at a rate equal to the frequency error.

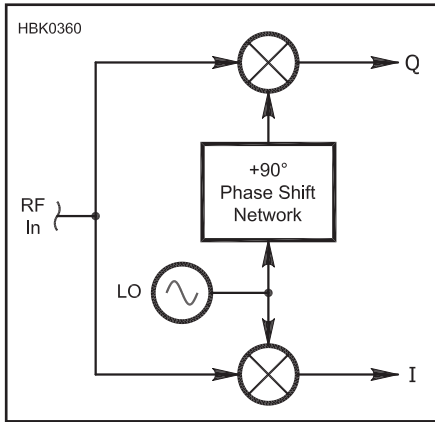

Fig 8.20 — Block diagram of an I/Q demodulator.

Most receivers include a *carrier-recovery* circuit, which phase-locks the local oscillator to the average frequency of the incoming signal to obtain stable demodulation. While that corrects the frequency error, it does not

correct the phase, which must be accounted for in some other manner such as by using differential modulation or some kind of symbol-recovery mechanism.

8.3.4 Multi-carrier Modulation

An effective method to fit more data bits into each symbol is to use more than one separately-modulated signal at a time, each on its own carrier frequency spaced an appropriate distance from the frequencies of the other carriers. An example is multi-carrier FSK. This is not to be confused with MFSK which also uses multiple frequencies, but only one at a time. With multi-carrier FSK, each carrier is present continuously and is frequency-shifted in response to a separate data stream. The total data rate equals the data rate of one carrier times the number of carriers. A disadvantage of multi-carrier FSK is that the resulting signal is no longer constant-amplitude—a linear amplifier must be used. In general, multi-carrier signals us-

ing any modulation type on each carrier tend to have high peak-to-average power ratios.

In the presence of selective fading, one or more of the carriers may disappear while the others are still present. An advantage of multi-carrier modulation is that error-correcting coding can use the unaffected carriers to reconstruct the missing data. Also, since each carrier signal is relatively narrowband, propagation conditions are essentially constant within that bandwidth. That makes it easier for the receiver to correct for other frequency-selective propagation impairments such as phase distortion. If a single-carrier signal of the same total bandwidth had been used instead, the receiver would need an adaptive equalizer to correct for the amplitude and phase variations across the transmission channel.

By using multiple carriers each with multiple-bit-per-symbol modulation it is possible to obtain quite high data rates while maintaining the low symbol rates that are required to combat the effects of multi-path

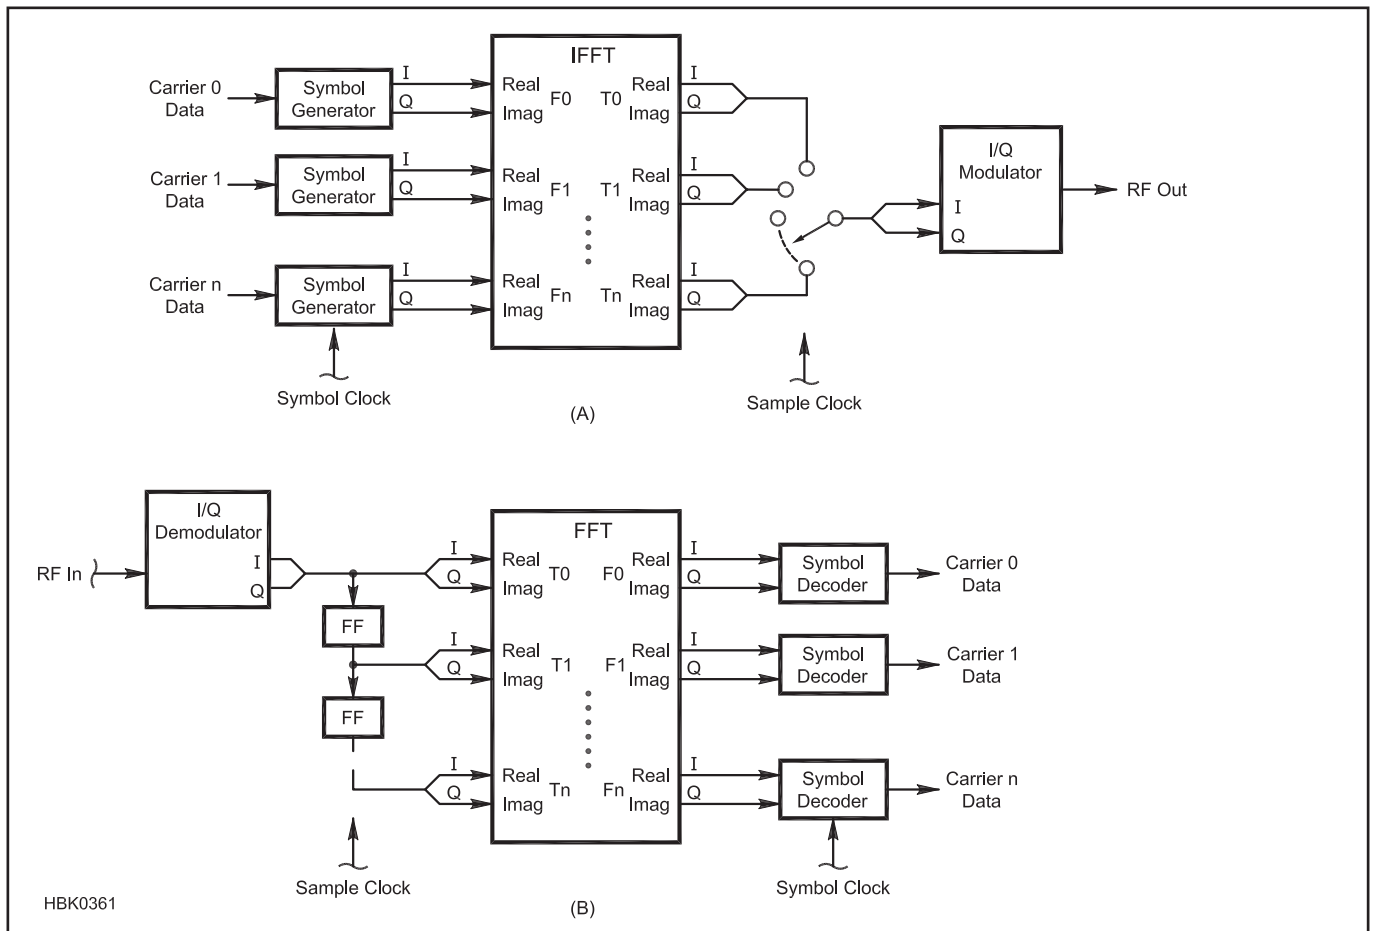

Fig 8.21 — Block diagram of an OFDM modulator (A) and demodulator (B) using the FFT/IFFT technique. The number of carriers is n , and the sample rate is n times the symbol rate. Once per symbol, all the symbol generators in the modulator are loaded with new data and the inverse fast-Fourier transform (IFFT) generates n output samples, which are selected in succession by the switch. In the demodulator, n samples are stored in a shift register (string of flip-flops) for each symbol, then the FFT generates one “frequency” output for each carrier frequency. From the amplitude and phase of each frequency, the symbol decoders can determine the symbol locations and thus the data.

propagation on the HF bands. For example, PACTOR-III achieves a raw data rate of 3600 bits per second with a 100-baud symbol rate using 18 carriers with DQPSK. (100 bauds \times 2 bits/symbol \times 18 carriers = 3600 bits per second.) Similarly, Clover-2000 modulation gets 3000 bits per second with a 62.5-baud symbol rate using eight carriers of 16-DPSK combined with 4-level DASK. (62.5 bauds \times (4+2) bits/symbol \times 8 carriers = 3000 bits per second.) Decoding is rather fragile using these complex modulation techniques, so PACTOR and Clover include means to automatically switch to simpler, more-robust modulation types as propagation conditions deteriorate.

What is the minimum carrier spacing that can be used without excessive interference between signals on adjacent frequencies? The answer depends on the symbol rate and the filtering. It turns out that it is easy to design the filtering to be insensitive to interference on frequencies that are spaced at integer multiples of the symbol rate. (See the following section on filtering and bandwidth.) For that reason, it is common to use a carrier spacing equal to the symbol rate. The carriers are said to be *orthogonal* to each other since each theoretically has zero correlation with the others.

Orthogonal frequency-division multiplexing (OFDM), sometimes called *coded OFDM* (COFDM), refers to the multiplexing of multiple data streams onto a series of such orthogonal carriers. The term usually implies a system with a large number of carriers. In that case, an efficient decoding method is to use a DSP algorithm called the *fast Fourier transform* (FFT). The FFT is the software equivalent of a hardware spectrum analyzer. It gathers a series of samples of a signal taken at regular time intervals and outputs another series of samples representing the frequency spectrum of the signal. See **Fig 8.21B**. If the length of the series of input samples equals one symbol time and if the sample rate is selected properly, then each frequency sample of the FFT output corresponds to one carrier. Each frequency sample is a complex number (containing a “real” and “imaginary” part) that represents the amplitude and phase of one of the carriers during that symbol period. Knowing the amplitude and phase of a carrier is all the information required to determine the symbol location in the I/Q diagram and thus decode the data. At the transmitter end of the circuit, an *inverse FFT* (IFFT) can be used to encode the data, that is, to convert the amplitudes and phases of each of the carriers into a series of I and Q time samples to send to the I/Q modulator. See **Fig 8.21A**.

One advantage of OFDM is high spectral efficiency. The carriers are spaced as closely as theoretically possible and, because of the

narrow bandwidth of each carrier, the overall spectrum is very square in shape with a sharp drop-off at the passband edges. One disadvantage is that the receiver must be tuned very accurately to the transmitter’s frequency to avoid loss of orthogonality, which causes cross-talk between the carriers.

8.3.5 AFSK and Other Audio-Based Modulation

Audio frequency-shift keying (AFSK) is the generation of radio-frequency FSK using an audio-frequency FSK signal fed into the microphone input of an SSB transmitter. Assume the SSB transmitter is tuned to 14.000 MHz, USB. If the audio signal consists of a sine wave that shifts between 2125 Hz and 2295 Hz (170-Hz frequency shift), then the RF signal is a sine wave shifting between 14.002125 and 14.002295 MHz. The frequency shift and spectral characteristics are theoretically unchanged, other than being translated 14 MHz upward in frequency. The RF signal should be indistinguishable from one generated by varying the frequency of an RF oscillator directly.

This technique works not only for FSK but also for nearly any modulation type with a bandwidth narrow enough to fit within the passband of an SSB transmitter and receiver. The most common non-voice analog modulation type to use this technique on the amateur bands is *slow-scan television* (SSTV), which uses frequency modulation for the video signal. In addition, nearly all narrowband digital signals today are generated in this manner. The audio is generated and received either from a dedicated hardware modulator/demodulator (modem) or using the sound card that is found in virtually all personal computers.

Whatever the method, it is important to ensure that unwanted interference is not caused by audio distortion or by insufficient suppression of the carrier and unwanted sideband. For example, with the AFSK tone frequencies mentioned above, 2125 and 2295 Hz, the tone harmonics cause no trouble because they fall outside of the transmitter’s passband. However, some AFSK modems use 1275 and 1445 Hz (to accommodate 850-Hz shift without changing the 1275-Hz mark frequency). In that case, the second harmonics at 2550 and 2890 Hz must be suppressed since those frequencies are not well-attenuated by the transmitter. With non-constant-envelope modulation types such as QPSK or the various multi-carrier modes, it is important to set the amplitude of the audio input to the SSB transmitter below the level that activates the transmitter’s automatic level control (ALC). That is because the ALC circuit itself generates distortion of signals within the bandwidth of its feedback loop.

8.3.6 Spread Spectrum

A *spread-spectrum* (SS) system is one that intentionally increases the bandwidth of a digital signal beyond that normally required by means of a special spreading code that is independent of the data sequence. There are several reasons for spreading the spectrum in that way.

Spread spectrum was first used in military systems, where the purpose was to encrypt the transmissions to make it harder for the enemy to intercept or jam them. Amateurs are not allowed to encrypt transmissions for the purpose of concealing the information, but reducing interference, intentional or otherwise, is an obvious benefit. The signal is normally spread in such a fashion that it appears like random noise to a receiver not designed to receive it, so other users of the band may not even be aware that an SS signal is present.

Another advantage to spreading the spectrum is that it can make frequency accuracy less critical. In addition, the wide bandwidth means that expensive narrow-bandwidth filters are not required in the receiver. It also provides a measure of frequency diversity. If certain frequencies are unusable because of interference or selective fading, the signal can often be reconstructed using information in the rest of the bandwidth.

There are several ways to spread the spectrum — we will cover the two most common methods below — but they all share certain characteristics. Imagine that the unspread signal occupies a 10 kHz bandwidth and it is spread by a factor of 100. The resulting SS signal is 1000 kHz (1 MHz) wide. Each 10-kHz channel contains 1/100 of the total signal power, or -20 dB. That means that any narrowband stations using one of those 10-kHz channels experience a 20 dB reduction in interference, but also are more likely to be interfered with because of the 100-times greater bandwidth of the SS station’s emissions.

How is the spread-spectrum station affected by interference from narrowband stations? In effect, the SS receiver attenuates the signal received on each 10 kHz channel by 20 dB in order to obtain a full-power signal when all 100 channels are added together. That means that the interference from a narrowband station is reduced by 20 dB but, again, the interference is more likely to occur because of the 100-times greater bandwidth of the SS station’s receiver.

How is the spread-spectrum station affected by interference from another SS station on the same frequency? It turns out that if the other station is using a different orthogonal spreading code then, once again, the interference reduction is 20 dB for 100-times spreading. That means that many SS stations can share the same channel without interference as long as they are all received at roughly the same signal level. Commercial mobile-tele-

phone SS networks use an elaborate system of power control with real-time feedback to ensure that the signals from all the mobile stations arrive at the base station at approximately the same level.

That scheme works well in a one-to-many (base station to mobile stations) system architecture but would be much more difficult to implement in a typical amateur many-to-many arrangement because of the different distances and thus path losses between each pair of stations in the network. On the HF bands it is not uncommon to see differences in signal levels of 80 to 90 dB or more. (For example, the difference between S1 and 40 dB over S9 is 88 dB, assuming 6 dB per S-unit.) A spread spectrum signal at S9 + 40 dB with a spreading ratio of 100 times would interfere with any other signals below about S9 + 20 dB. It works the same in the other direction as well. The SS signal would experience interference from any other stations that are more than 20 dB louder than the desired signal.

Normally, increasing the bandwidth of a transmission degrades the signal-to-noise (S/N) ratio at the receiver. A 100-times greater bandwidth contains 100 times as much noise, which causes a 20 dB reduction in S/N ratio. However SS receivers benefit from a phenomenon known as *processing gain*. Just as the receiver is insensitive to other SS signals with different orthogonal spreading codes, so it is insensitive to random noise. The improvement in S/N ratio due to processing gain is:

$$\text{Processing Gain} = 10 \times \log \left(\frac{\text{spread bandwidth}}{\text{unspread bandwidth}} \right) \text{ dB} \quad (3)$$

That is exactly equal to the reduction in

S/N ratio due to the increased bandwidth. The net result is that an SS signal has neither an advantage nor a disadvantage in signal-to-noise ratio compared to the unspread version of the same signal. When someone states that, because of processing gain, an SS receiver can receive signals that are below the noise level (signals that have a negative S/N ratio), that is a true statement. However, it does not imply better S/N performance than could be obtained if the signal were not spread.

FREQUENCY HOPPING SPREAD SPECTRUM

One simple way to spread the spectrum of a narrowband signal is to repetitively sweep it across the frequency range of the wider spectrum, either continuously or in a series of steps at discrete frequencies. That technique, called *chirp modulation*, can be considered a special case of *frequency-hopping spread spectrum* (FHSS), in which the narrowband signal covers the expanded spectrum by rapidly hopping back and forth from frequency to frequency in a pseudo-random manner. On average, each frequency is used the same percentage of time so that the average spectrum is flat across the bandwidth of the FHSS signal. See Fig 8.22.

If the receiver hops in step with the transmitter, using the same pseudo-random sequence synchronized to the one in the transmitter, then the transmitter and receiver are always tuned to the same frequency and the receiver's detector sees a continuous, non-hopped narrowband signal which can be demodulated in the normal way. We say that the signal has been *de-spread*, that is, returned to its normal narrowband form. Synchronization between the receiver and transmitter is one of the challenges in an FHSS system. If the timing of the two sequences

Fig 8.22 — Power versus frequency for a frequency-hopping spread spectrum signal. Emissions jump around to discrete frequencies in pseudo-random fashion. Normally the spacing of the frequencies is approximately equal to the bandwidth of the unspread signal so that the average spectrum is approximately flat.

differs by even one hop, then the receiver is always tuned to the wrong frequency, unless the same frequency happens to occur twice in succession in the pseudo-random sequence. Any signal with an unsynchronized sequence, or with a different sequence, is reduced in amplitude by the processing gain.

There are two types of FHSS based on the rate at which the frequency hops take place. *Slow-frequency hopping* refers to a hop rate slower than the baud rate. Several symbols are sent per hop. With *fast-frequency hopping*, the hop rate is faster than the baud rate. Several hops occur during each symbol. The term *chirp* refers to the shortest-duration modulation state in the system. For slow-frequency hopping, that is the baud rate. For fast-frequency hopping it is the hop rate. Fast-frequency hopping can be useful in reducing the effects of multi-path propagation. If the hop period is less than the typical time delay of secondary propagation paths, then those signals are uncorrelated to the main path and are attenuated by the processing gain.

A diagram of a frequency-hopping spread spectrum system is shown in Fig 8.23. In

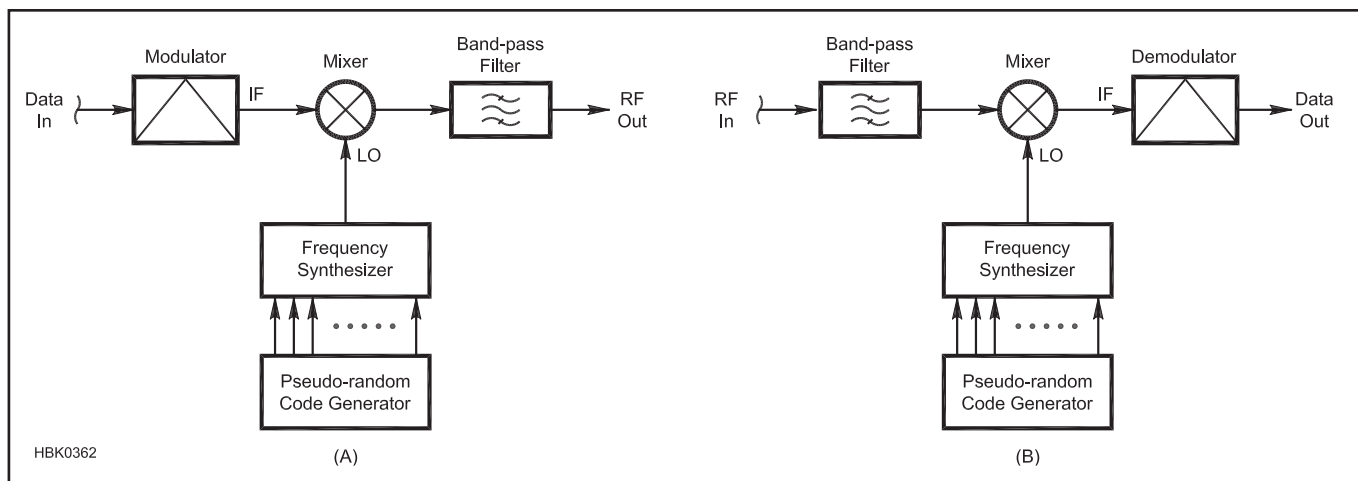

Fig 8.23 — Block diagram of an FHSS transmitter (A) and receiver (B). The receiver may be thought of as a conventional superhether with a local oscillator (LO) that is continually hopping its frequency in response to a pseudo-random code generator. The transmitter has a similar architecture to up-convert a conventionally-modulated intermediate frequency (IF) to a frequency-hopped radio frequency (RF).

both the transmitter and the receiver, a pseudo-random code generator controls a frequency synthesizer to hop between frequencies in the correct order. In this way, the narrowband signal is first spread by the transmitter, then sent over the radio channel, and finally de-spread at the receiver to obtain the original narrowband signal again. One issue with FHSS is that many synthesizers do not maintain phase coherence over successive frequency hops. That means the basic (non-spread) modulation must be a type that does not depend on phase information. That rules out PSK, QPSK and QAM. That is the reason that modulation types that do not depend on phase, such as FSK and MFSK with non-coherent detection, are frequently used as the base modulation type in FHSS systems.

DIRECT SEQUENCE SPREAD SPECTRUM

Whereas an FHSS system hops through a pseudo-random sequence of frequencies to spread the signal, a *direct-sequence spread spectrum* (DSSS) system applies the pseudo-random sequence directly to the data in order to spread the signal. See Fig 8.24. The binary data is considered to be in *polar* form, that is, the two possible states of each bit are represented by -1 and $+1$. The data bits are multiplied by a higher-bit-rate pseudo-random sequence, also in polar form, which chops the data into smaller time increments called *chips*. The ratio of the chip rate to the data's bit rate equals the ratio of the spread bandwidth to the unspread bandwidth, which is just the processing gain:

$$\text{Processing Gain} = 10 \times \log \left(\frac{\text{chip rate}}{\text{bit rate}} \right) \text{ dB} \quad (4)$$

Although it doesn't have to, DSSS nor-

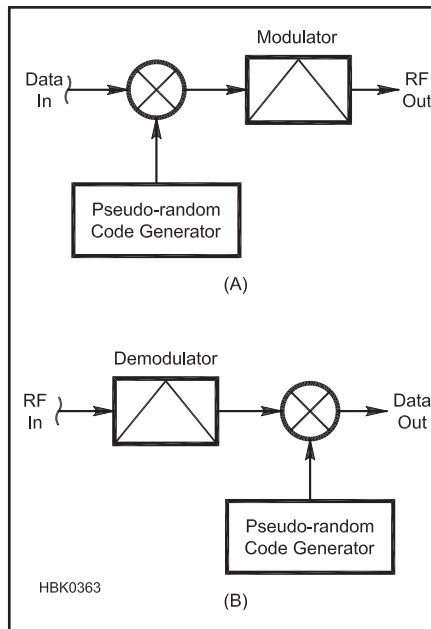

Fig 8.24 — Block diagram of a DSSS transmitter (A) and receiver (B). For BPSK modulation, the modulation has the same format as the bipolar data (± 1), so the modulator and demodulator could be moved to the other side of the multiplier if desired.

mally uses a one-bit-per-symbol modulation type such as BPSK. In that case, the modulator and demodulator in Fig 8.24 would consist simply of a mixer, which multiplies the RF local oscillator by the bipolar DSSS modulating signal. Since unfiltered BPSK is constant-envelope, a nonlinear class-C power amplifier may be used for high efficiency. The demodulator in the receiver would also be a mixer, which multiplies the RF signal by a local oscillator to regenerate the DSSS modulating signal. Not shown are additional

mixers and filters that would be used in a superheterodyne receiver to convert the received signal to an intermediate frequency before demodulation and decoding.

The unfiltered spectrum has the form of a sinc function. That shows up clearly in the spectrum of an actual DSSS signal in Fig 8.25A, which is plotted on a logarithmic scale calibrated in decibels. The humps in the response to the left and right (and additional ones not shown off scale) are not needed for communications and should be filtered out to avoid excessive occupied bandwidth. Fig 8.25B shows the DSSS signal in the presence of noise at the input to the receiver, and Fig 8.25C illustrates the improvement in signal-to-noise ratio of the de-spread narrowband signal.

CODE-DIVISION MULTIPLE ACCESS (CDMA)

As mentioned before, to receive an SS signal, the de-spreading sequence in the receiver must match the spreading sequence in the transmitter. The term *orthogonal* refers to two sequences that are coded in such a way that they are completely uncorrelated. The receiver's response to an orthogonal code is the same as to random noise, that is, it is suppressed by a factor equal to the processing gain. One can take advantage of this property to allow multiple SS stations to access the same frequency simultaneously, a technique known as *code-division multiple access* (CDMA). Each transmitter is assigned a different orthogonal code. A receiver can "tune in" any transmitter's signal by selecting the correct code for de-spreading.

If multiple stations want to be able to transmit simultaneously without using spread spectrum, they must resort to either *frequency-division multiple access* (FDMA), where each station transmits on a different frequency channel, or *time-division multiple*

Fig 8.25 — (A) The frequency spectrum of an actual unfiltered biphas-modulated spread spectrum signal as viewed on a spectrum analyzer. In this practical system, band-pass filtering is used to confine the spread spectrum signal to the amateur band. (B) At the receiver end of the line, the filtered spread spectrum signal is apparent only as a 10-dB hump in the noise floor. (C) The signal at the output of the receiver de-spreader. The original carrier — and any modulation components that accompany it — has been recovered. The peak carrier is about 45 dB above the noise floor — more than 30 dB above the hump shown at B. (These spectrograms were made at a sweep rate of 0.1 s/division and an analyzer bandwidth of 30 kHz; the horizontal scale is 1 MHz/division.)

access (TDMA), where each transmission is broken up into short time slots which are interleaved with the time slots of the other stations. Compared to TDMA, CDMA has the advantage that it does not require an external synchronization network to make sure that different stations' time slots do not overlap. Compared to both TDMA and FDMA, CDMA has the further advantage that it experiences a gradual degradation in performance as the number of stations on the channel increases. It is relatively easy to add new users to the system. Also CDMA has inherent resistance to interference due to multi-path propagation or intentional jamming. The primary disadvantages of CDMA are the relative complexity and the necessity for accurate power-level control to make sure that unwanted signals do not exceed the level that can be rejected through processing gain.

8.3.7 Filtering and Bandwidth of Digital Signals

We have already touched on this topic in previous sections, but let us now cover it a little more systematically. The bandwidth required by a digital signal depends on the filtering of the modulation, the symbol rate and the type of modulation. For linear modulation types such as OOK, BPSK, QPSK and QAM, the bandwidth depends only on the symbol rate and the modulation filter.

As an example, an unfiltered BPSK modulating signal with alternating ones and zeroes for data (10101010...) is a square wave at one-half the symbol rate. Like any square wave, its spectrum can be broken down into a series of sine waves at the fundamental frequency (symbol rate / 2) and all the odd harmonics. If the data consists of alternating pairs of ones and pairs of zeroes (11001100...) then we have a square wave at one-fourth the symbol rate and the spectrum is a series of sine waves at one-fourth the symbol rate and all its odd harmonics. Random data contains energy at all frequencies from zero to half the symbol rate and all the odd harmonics of those frequencies. The harmonics are not needed for proper demodulation of the signal, so they can be filtered out with a low-pass filter with a cutoff frequency of one-half the symbol rate.

With random data, the shape of the unfiltered spectrum is a sinc function,

$$\text{sinc}(f / f_s) = \frac{\sin(\pi f / f_s)}{\pi f / f_s} \quad (5)$$

where f_s is the symbol rate. See Fig 8.26. Note that the response is zero (minus infinity dB) whenever f is an integer multiple of the symbol rate. That is why multi-carrier modulation generally uses a carrier spacing equal to the symbol rate.

Fig 8.26 — The sinc function, which is the spectrum of an unfiltered BPSK modulating signal with random data, plotted with a linear vertical scale. The center (zero) point corresponds to the RF carrier frequency. To see what the double-sided RF spectrum looks like on a logarithmic (dB) scale, see Fig 8.25A.

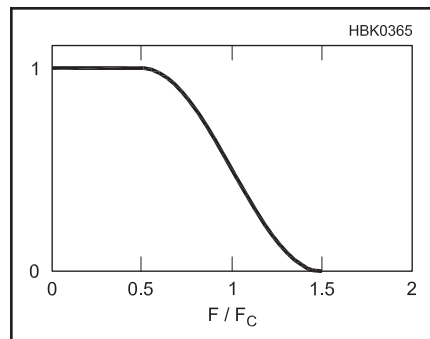

Fig 8.27 — Amplitude versus frequency for a 0.5-alpha, raised-cosine filter. The vertical scale is linear, not logarithmic as would be seen on a spectrum analyzer. The amplitude is 0.5 (-6 dB) at the cutoff frequency, F_c . The amplitude is 1.0 for frequencies less than $F_c \times (1 - \alpha)$ and is 0.0 for frequencies above $F_c \times (1 + \alpha)$.

The previous discussion applies to the baseband signal, before it modulates the RF carrier. BPSK is a double-sideband-type modulation so the baseband spectrum appears above and below the RF carrier frequency, doubling the bandwidth to $2 \times (\text{symbol rate} / 2) = \text{symbol rate}$. In reality, since no practical filter has an infinitely-sharp cutoff, the occupied bandwidth of a BPSK signal must be somewhat greater than the symbol rate. That is also true for all other double-sideband linear modulation types, such as OOK and the various forms of QPSK and QAM.

If the low-pass filtering is not done properly, it may slow down the transition between symbols to the point where one symbol starts to run into another, causing *inter-symbol interference* (ISI). A type of filter that avoids that problem is called a *Nyquist filter*. It ensures that each symbol's contribution to the

modulating signal passes through zero at the center of all other symbols, so that no ISI occurs. The most common type of Nyquist filter is the *raised-cosine* filter, so-called because the frequency response (plotted on a linear scale) in the passband-to-stopband transition region follows a raised-cosine curve. See Fig 8.27. The sharpness of the frequency cutoff is specified by a parameter called *alpha*. If alpha is 1.0, then the transition from passband to stopband is very gradual — it starts to roll off right at zero hertz and finally reaches zero response at two times the nominal cutoff frequency. An alpha of 0.0 specifies an ideal “brick-wall” filter that transitions instantaneously from full response to zero right at the cutoff frequency. Values in the range of 0.3 to 0.5 are common in communications systems.

Unfortunately, if any additional filter is placed before or after the Nyquist filter it destroys the anti-ISI property. In order to allow filtering in both the transmitter and the receiver many systems effectively place half the Nyquist filter in each place. Because the frequency response of each filter is the square root of the response of a Nyquist filter, they are called *root-Nyquist* filters. The *root-raised-cosine* filter is an example. While a Nyquist or root-Nyquist response theoretically could be approximated with an analog filter, they are almost always implemented as digital filters. More information on digital filters appears in the **DSP and Software Radio Design** chapter.

As mentioned before, filtering is more difficult with angle modulation because it is nonlinear. The RF spectrum is not a linear transposition of the baseband spectrum as it is with linear modes and Nyquist filtering doesn't work. Old-fashioned RTTY transmitters traditionally just used an R-C low-pass filter to slow down the transitions between mark and space. While that does not limit the bandwidth to the minimum value possible, the baud rate is low enough that the resulting bandwidth is acceptable anyway. In more modern systems, there is a tradeoff between making the filter bandwidth as narrow as possible for interference reduction and widening the bandwidth to reduce inter-symbol interference. For example, the GSM (Global System for Mobile communications) standard, used for some cellular telephone systems, uses minimum-shift keying and a Gaussian filter with a BT (bandwidth symbol-time product) of 0.3. A 0.3 Gaussian filter has a 0.3 ratio of 3-dB bandwidth to baud rate, which results in a small but acceptable amount of ISI and a moderate amount of adjacent-channel interference.

CHANNEL CAPACITY

It is possible to increase the quantity of error-free data that can be transmitted over a communications channel by using an er-

ror-correcting code. That involves adding additional error-correction bits to the transmitted data. The more bits that are added, the greater the errors that can be corrected. However, the extra bits increase the data rate, which requires additional bandwidth, which increases the amount of noise. For that reason, as you add more and more error-correction bits, requiring more and more bandwidth, you eventually reach a point of limited additional return. In the 1940s, Claude Shannon worked out a formula (called the *Shannon-Hartley theorem*) for the maximum capacity possible over a communications channel, assuming a theoretically-perfect error-correction code:

$$C = B \log_2 \left(1 + \frac{S}{N} \right) \text{ bits/s} \quad (6)$$

where

- C = the net channel capacity, not including error-correcting bits,
- B = the bandwidth in Hz, and
- S/N = the signal-to-noise ratio, expressed as a power ratio.

Note that as B increases, N increases in the same proportion. **Fig 8.28** is a plot of channel capacity versus bandwidth based on the formula. As bandwidth is increased, channel capacity increases rapidly until the point where the S/N ratio drops to unity (labeled Bandwidth = 1 in the graph) after which channel capacity increases much more slowly.

Fig 8.28 — Plot of channel capacity versus bandwidth, calculated by the Shannon-Hartley theorem. The S/N ratio has been selected to be unity at Bandwidth = 1.

8.4 Image Modulation

The following section covers the modulation aspects of amateur television and facsimile communications. More detailed information on protocols and operating standards can be found in the **Image Communications** supplement on the *Handbook CD*.

8.4.1 Fast-Scan Television

Amateur fast-scan television (ATV) is a wideband mode used in the amateur bands above 420 MHz. It is called “fast scan” to differentiate it from slow-scan TV.

The most popular ATV mode is based on NTSC, the same technical standard used by commercial analog television stations in the United States before most switched to digital TV in 2009. **Fig 8.29** shows the spectrum of an NTSC analog TV channel. It’s basically a full-carrier, double-sideband AM signal, with filtering to partially remove the lower sideband. The partially-filtered *vestigial sideband* (VSB) extends 1.25 MHz below the carrier frequency. The channel is 6 MHz wide to accommodate the composite video and two subcarriers, one at 3.58 MHz for the color burst and the other an FM-modulated signal at 4.5 MHz for the sound. For simplicity, amateur stations often transmit unfiltered full-DSB AM, but the normally-removed portion of the lower sideband is unused by the TV receiver. Since less than 5% of the video energy appears more than 1 MHz below the carrier, little of the transmitter power is wasted. If needed, to reduce interference to other band users, a VSB filter in the antenna line can attenuate the lower sideband color and sound subcarrier frequencies by 20-30 dB.

The video signal includes pulses to synchronize the vertical and horizontal scan oscillators in the receiver. See **Fig 8.30**. The

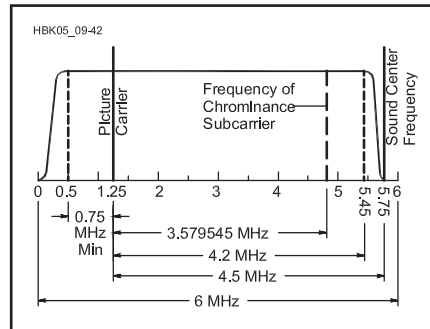

Fig 8.29 — An analog NTSC 6-MHz video channel with the video carrier 1.25 MHz up from the lower edge. The color subcarrier is at 3.58 MHz and the sound subcarrier at 4.5 MHz above the video subcarrier.

sync pulses and the “front porch” and “back porch” areas that bracket them are “blacker than black” so that the signal is blanked during retrace. The video-to-sync ratio must remain constant throughout all of the linear amplifiers in the transmit chain as the video level from the camera changes. To maintain the sync tips at 100% of peak power, the modulator usually contains a clamp circuit that also acts as a sync stretcher to compensate for amplifier gain compression.

Given NTSC’s 525 horizontal lines and its 30 frames per second scan rate, the resulting horizontal resolution bandwidth is 80 lines per MHz. Therefore, with the typical TV set’s 3-dB rolloff at 3 MHz (primarily in the IF filter), up to 240 vertical black lines can be

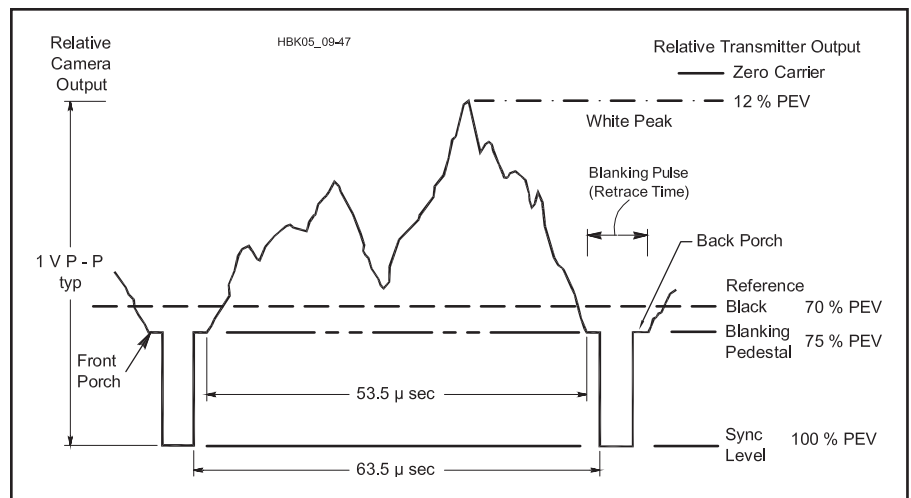

Fig 8.30 — An ATV waveform, showing the relative camera output as well as the transmitter output RF power during one horizontal line scan for black-and-white TV. (A color camera would generate a “burst” of 8 cycles at 3.58 MHz on the back porch of the blanking pedestal.) Note that “black” corresponds to a higher transmitter power than “white.”

seen, corresponding to 480 pixels per line. Color bandwidth in a TV set is less than that, resulting in up to 100 color lines. (Lines of resolution should not be confused with the number of horizontal scan lines per frame.)

The PAL analog TV system in Europe used frequency modulation rather than AM. As described previously, FM achieves superior noise and interference suppression for signal levels above a certain threshold, although AM seems to work better for receiver signal levels below about 5 μV . FM ATV in the United States typically uses 4 MHz deviation with NTSC video and a 5.5-MHz sound subcarrier set to 15 dB below the video level. Using Carson's rule, the occupied bandwidth comes out to just under 20 MHz. Most available FM ATV equipment is made for the 1.2, 2.4 and 10.25-GHz bands.

Digital fast-scan TV has been explored by amateurs in Europe and the US using the commercial DVB-S satellite digital video broadcasting standard. It uses MPEG2 audio and video data compression and QPSK modulation with symbol rates up to 20 Mbauds. Much of work has been on the 23 cm band since inexpensive set-top boxes are available that cover that frequency range.

In the United States and some other countries, commercial over-the-air digital television uses a modulation type called *8-level vestigial sideband* (8-VSB), which is basically 8-level amplitude-shift keying with the lower sideband filtered out. The eight levels result in three bits per symbol, resulting in approximately 32 Mbits/second raw data rate with a 10.76 Mbaud symbol rate. The net data rate with error correction and other overhead is 19.39 Mbits/second. The DTV signal fits into the same 6 MHz channel as analog TV.

8.4.2 Facsimile

Amateur *facsimile* (fax) is a method for sending high-resolution still pictures by radio. Standard 120-line-per-minute fax uses a frequency-modulated tone between 1500 Hz (black) and 2300 Hz (white), which may be sent and received as an audio signal via any voice transmitter and receiver. Commercially, fax has been used for many years to send newspaper photos over the landline and to receive weather images from satellites.

The resolution of typical fax images greatly exceeds what can be obtained using SSTV or even conventional television. Typical images are made up of 480 to 1600 scanning lines, compared to the 240 lines in a typical SSTV image. This high resolution is achieved by slowing down the rate at which the lines are transmitted, resulting in image transmission times typically in the range of 4 to 13 minutes. For color, transmission times are longer since the image is sent three times to include the red, green and blue components.

Besides the increased resolution, the main difference with SSTV is that many fax systems use no sync pulses. Instead, they rely on the extreme accuracy of external time bases at both the transmitting and receiving ends of the circuit to maintain precise synchronization.

Modern personal computers have virtually eliminated bulky mechanical fax machines from most amateur installations. Now the incoming image can be stored in computer memory and viewed on a high-resolution computer graphics display. The use of a color display system makes it entirely practical to transmit color fax images when band conditions permit the increased transmission time.

8.4.3 Slow-Scan Television

Despite its name, so-called *slow-scan television* (SSTV) is actually a method for sending still images, like facsimile. The original monochrome analog SSTV format illustrated in **Fig 8.31** takes approximately 8 seconds to send one complete frame. The 1500 to 2300-Hz frequency-modulated audio tone resembles that of a fax signal, but is sent at a faster rate and includes pulses at 1200 Hz for synchronization.

Color may be sent using any of several methods. The first to be used was the *frame-sequential* method, in which each of the three primary colors (red, green and blue) is sent sequentially, as a complete frame. That has the disadvantage that you have to wait for the third frame to begin before colors start to become correct, and any noise or interference is three times more likely to corrupt the image and risks ruining the image registration (the overlay of the frames) and thus spoil the picture.

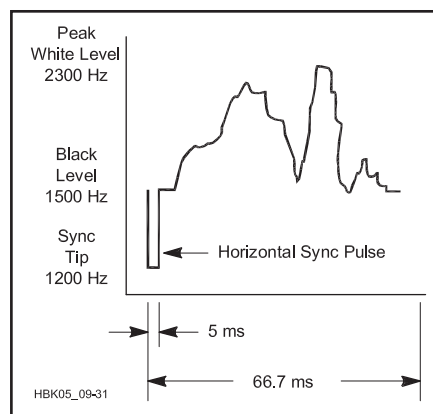

Fig 8.31 — The basic 8-second black and white transmission format developed by early SSTV experimenters. The sync pulses are “blacker than black” to blank the signal during retrace. A complete frame has 120 lines (8 seconds at 15 lines per second). Horizontal sync pulses occur at the beginning of every line; a 30-ms vertical sync pulse precedes each frame.

In the *line-sequential* method, each line is electronically scanned three times: once each for red, green and blue. Pictures scan down the screen in full color as they are received and registration problems are reduced. The Wraase SC-1 modes are examples of early line-sequential color transmission. They have a horizontal sync pulse for each of the color component scans. The major weakness of this method is that if the receiving system gets out of step, it doesn't know which scan represents which color.

Rather than sending color images with the usual RGB (red, green, blue) components, Robot Research decided to use luminance and chrominance signals for their 1200C modes. The first half or two thirds of each scan line contains the luminance information, which is a weighted average of the R, G and B components. The remainder of each line contains the chrominance signal with the color information. Existing black-and-white equipment could display the B&W-compatible image on the first part of each scan line and the rest would go off the edge of the screen. That compatibility was very beneficial when most people still had only B&W equipment.

The luminance-chrominance encoding makes more efficient use of the transmission time. A 120-line color image can be sent in 12 seconds, rather than the usual 24. Our eyes are more sensitive to details in changes of brightness than color, so the time is used more efficiently by devoting more time to luminance than chrominance. The NTSC and PAL broadcast standards also take advantage of this vision characteristic and use less bandwidth for the color part of the signal. For SSTV, luminance-chrominance encoding offers some benefits, but image quality suffers. It is acceptable for most natural images but looks bad for sharp, high-contrast edges, which are more and more common as images are altered via computer graphics. As a result, all newer modes have returned to RGB encoding.

The 1200C introduced another innovation, called *vertical interval signaling* (VIS). It encodes the transmission mode in the vertical sync interval. By using narrow FSK encoding around the sync frequency, compatibility is maintained. This new signal just looks like an extra-long vertical sync to older equipment.

The Martin and Scottie modes are essentially the same except for the timings. They have a single horizontal sync pulse for each set of RGB scans. Therefore, the receiving end can easily get back in step if synchronization is temporarily lost. Although they have horizontal sync, some implementations ignore them on receive. Instead, they rely on very accurate time bases at the transmitting and receiving stations to keep in step. The advantage of this “synchronous” strategy is

that missing or corrupted sync pulses won't disturb the received image. The disadvantage is that even slight timing inaccuracies produce slanted pictures.

In the late 1980s, yet another incompatible mode was introduced. The AVT mode is different from all the rest in that it has *no horizontal sync*. It relies on very accurate oscillators at the sending and receiving stations to maintain synchronization. If the beginning-of-frame sync is missed, it's all over. There is no way to determine where a scan line begins. However, it's much harder to miss the 5-s header than the 300-ms VIS code. Redundant information is encoded 32 times and a more powerful error-detection scheme

is used. It's only necessary to receive a small part of the AVT header in order to achieve synchronization. After this, noise can wipe out parts of the image, but image alignment and colors remain correct.

Digital images may be sent over Amateur Radio using any of the standard digital modulation formats that support binary file transfer. *Digital SSTV* (DSSTV) is one method of transmitting computer image files, such as JPEG or GIF, as described in an article by Ralph Taggart, WB8DQT, in the Feb 2004 issue of *QST*. This format phase-modulates a total of eight subcarriers (ranging from 590 to 2200 Hz) at intervals of 230 Hz. Each subcarrier has nine possible modulation states. This

signal modulation format is known as *redundant digital file transfer* (RDFT) developed by Barry Sanderson, KB9VAK.

Most digital SSTV transmission has switched to using Digital Radio Mondiale (DRM), derived from a system developed for shortwave digital voice broadcasting. The DRM digital SSTV signal occupies the bandwidth between 350 and 2750 Hz. As many as 57 subcarriers may be sent simultaneously, all at the same level. Three pilot carriers are sent at twice the level of the other subcarriers. The subcarriers are modulated using OFDM and QAM, which were described earlier in this chapter. DRM SSTV includes several methods of error correction.

8.5 Modulation Impairments

Most of the previous discussion of the various modulation types has assumed the modulation is perfect. With analog modulation, that means the audio or video modulating signal is perfectly reproduced in the RF waveform without distortion, spurious frequencies or other unwanted artifacts. With digital modulation, the symbol timing and the locations and trajectories in the I/Q constellation are perfectly accurate. In all cases, the RF power amplifier is perfectly linear, if so required by the modulation type, and it introduces no noise or other spurious signals close to the carrier frequency.

In the real world, of course, such perfection can never be achieved. Some modulation impairments are caused by the transmitting system, some by the transmission medium through which the signal propagates, and some in the receiving system. This section will concentrate on impairments caused by the circuitry in the transmitter and, to some extent, in the receiver. Signal impairments due to propagation are covered in detail in the **Propagation of Radio Signals** chapter.

8.5.1 Intermodulation Distortion

To minimize distortion of the modulation, each stage in the signal chain must be linear, from the microphone or modem, through all the intermediate amplifiers and processors, to the modulator itself. For the linear modulation types, all the amplifiers and other stages between the modulator and the antenna must be linear as well.

If the modulation consists of a single sine wave, then nonlinearity causes only harmonic distortion, which produces new frequencies at integer multiples of the sine-wave frequency. If multiple frequencies are present in the modulation, however, then *intermodulation*

distortion (IMD) products are produced. IMD occurs when a nonlinear amplifier or other device acts as a mixer, producing sum and difference frequencies of all the pairs of frequencies and their harmonics. For example if two frequencies, F_1 and $F_2 > F_1$, are present, then IMD will cause spurious frequencies to appear at $F_1 + F_2$, $F_2 - F_1$, $2F_1$, $2F_2$, $2F_1 - F_2$, $2F_2 - F_1$, $2F_2 - 2F_1$, $3F_1$, $3F_2$, and so on. *Odd-order* products are those that include the original frequencies an odd number of times, such as $3F_1$, $2F_1 + F_2$, $3F_1 - 2F_2$, and so on. *Even-order* products contain an even number of the original frequencies, such as $2F_2$, $F_1 + F_2$, $3F_1 + F_2$, and so on. If more than two frequencies are present in the undistorted modulation, then the number of unwanted frequencies increases exponentially.

Although intermodulation distortion that occurs before modulation is fundamentally the same as IMD that occurs after the modulator (at the intermediate or radio frequency), the effects are quite different. Consider two frequency components of a modulating signal at, for example, 1000 Hz and 1200 Hz that modulate an SSB transmitter tuned to 14.000 MHz, USB. The desired RF signal has components at 14.001 and 14.002 MHz. If the IMD occurs before modulation, then the $F_1 + F_2$ distortion product occurs at $1000 + 1200 = 2200$ Hz. Since that is well within the audio passband of the SSB transmitter, there is no way to filter it out so it shows up at 14.0022 MHz at the RF output. However, if the distortion had occurred after the modulator, the $F_1 + F_2$ product would be at $14.001 + 14.002 = 28.002$ MHz which is easily filtered out by the transmitter's low-pass filter.

That explains why RF speech processors work better than audio processors. A speech processor clips or limits the peak amplitude of the modulating signal to prevent over-modulation in the transmitter. However, the limit-

ing process typically produces considerable intermodulation distortion. If the limiter is located after the modulator rather than before it, then it is an RF signal being clipped, rather than audio. If the RF limiter is followed by a band-pass filter then many of the distortion products are removed, resulting in a less-distorted signal.

If the distortion is perfectly symmetrical (for example equal clipping of positive and negative peaks) then only odd-order products are produced. Most distortion is not symmetrical so that both even and odd-order products appear. However, the odd-order products are of particular interest when measuring the linearity of an RF power amplifier. The reason is that even-order products that occur after the modulator occur only near harmonics of the RF frequency where they are easy to filter out.

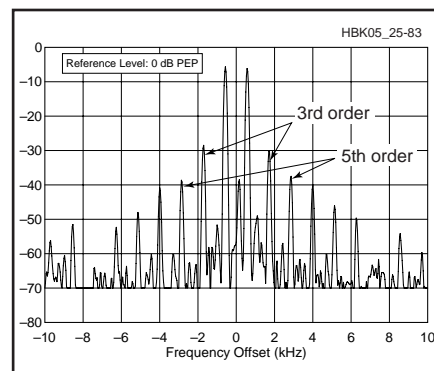

Fig 8.32 — Intermodulation products from an SSB transmitter. The two signals at the center are the desired frequencies. The frequencies of the third-order products are separated from the frequencies of the desired tones by the tone spacing. The fifth-order frequencies are separated by two times the tone spacing, and so on for higher-order products.

Odd-order products can fall within the desired channel, where they cause distortion of the modulation, or at nearby frequencies, where they cause interference to other stations.

The informal term for such IMD that interferes with other stations outside the desired channel is *splatter*. It becomes severe if the linear amplifier is over-driven, which causes clipping of the modulation envelope with the resulting odd-order IMD products.

The method commonly used to test the linearity of an SSB transmitter or RF power amplifier is the *two-tone test*. Two equal-amplitude audio-frequency tones are fed into the microphone input, the transmitter and/or amplifier is adjusted for the desired power level, and the output signal is observed on a spectrum analyzer. See **Fig 8.32**. The third-order products that occur near the desired signal are at $2F_1 - F_2$ and $2F_2 - F_1$. The fifth-order products occur at $3F_1 - 2F_2$ and $3F_2 - 2F_1$. If, for example, the two tones are spaced 1 kHz apart, then the two third-order products show up at 1 kHz above the high tone and 1 kHz below the low tone. The fifth-order products are at 2 kHz above and below the high and low tones respectively.

8.5.2 Transmitted Bandwidth

We have already discussed the necessary bandwidth for each of the various modulation types. The previous section explained how intermodulation distortion is one phenomenon that can cause unwanted emissions outside of the desired communications channel. Another is failing to properly low-pass filter the modulating signal to the minimum necessary bandwidth. That is especially a concern for linear modulation modes such as SSB, AM, OOK (CW), BPSK and QAM. For angle-modulated modes like FM and FSK, excessive bandwidth can result from simply setting the deviation too high.

There are other modulation impairments that cause emissions outside the desired bandwidth. For example, in an SSB transmitter, if the unwanted sideband is not sufficiently suppressed, the occupied bandwidth is up to twice as large as it should be. Also, an excessively strong suppressed carrier causes particularly-annoying heterodyne interference to stations tuned near that frequency. In some SSB modulators, there is an adjustment provided to optimize carrier suppression.

The carrier suppression may be degraded by a modulating signal that is too low in amplitude. For example, if the signal from the microphone to an SSB transmitter is one-tenth (-20 dB) of the proper amplitude, and if the gain of the RF amplifier stages is increased to compensate, then the carrier suppression is degraded by 20 dB.

The term *adjacent-channel power* (ACP) refers to the amount of transmitted power

that falls into an adjacent communications channel above or below the desired channel. Normally the unwanted out-of channel power is worse for the immediately-adjacent channels than for those that are two channels away, the so-called *alternate* channels. ACP is normally specified as a power ratio in dB. It is measured with a spectrum analyzer that can measure the total power within the desired channel and the total power in an adjacent channel, so that the dB difference can be calculated.

The *occupied bandwidth* is the bandwidth within which a specified percentage of the total power occurs. A common percentage used is 99%. For a properly-adjusted, low-distortion transmitting system, the occupied bandwidth is determined mainly by the modulation type and filtering and, in the case of digital modulation, the symbol rate. For example, the IS-54 TDMA format that has been used in some US digital cellular networks has about 30 kHz occupied bandwidth using 24.3-kilosymbols/sec, $\pi/4$ -DQPSK modulation with a 0.35-alpha root-raised-cosine filter. The GSM cellular standard requires about a 350-kHz occupied bandwidth for its 270.833-kilosymbols/sec, 0.3 Gaussian-filtered MSK signal.

8.5.3 Modulation Accuracy

For analog modes, modulation accuracy is mainly a question of maintaining the proper frequency response across the desired bandwidth with minimal distortion and unwanted signal artifacts. In-band artifacts like noise and spurious signals should not be a problem with any reasonably-well-designed system. Maintaining modulation peaks near 100% for AM signals or the proper deviation for FM signals is facilitated by an audio compressor. It can be either the type that uses a detector and an automatic-gain-control feedback loop to vary the gain in the modulation path or a clipper-type compressor that limits the peak amplitude and then filters the clipped signal to remove the harmonics and intermodulation products that result. SSB transmitters can also use audio speech compression to maintain the proper peak power level although, as explained previously, clipping of the signal before it reaches the modulator can cause unacceptable distortion unless special techniques are used.

For digital signals, there are a number of other possible sources of modulation inaccuracy. For modes that use Nyquist filtering, the cutoff frequency and filter shape must be accurate to ensure no inter-symbol interference (ISI). Fortunately, that is easy to do with digital filters. However any additional filtering in the signal path can degrade the ISI. For example, most HF digital modes use an analog SSB transceiver to up-convert the

signal from audio to RF for transmission and to down-convert from RF to audio again at the receiver end. The crystal filters used in the transmitter and receiver can significantly degrade group delay flatness, especially near the edges of the filter passband. That is why most HF digital modes use a bandwidth substantially less than a typical transceiver's passband and attempt to center the signal near the crystal filters' center frequency.

Distortion can also impair the proper decoding of digital signals, especially formats with closely-spaced symbols such as 256-QAM. Any "flat-topping" in the final amplifier causes the symbols at the outermost corners of the constellation to be closer together than they should be. The accuracy of the symbol clock is critical in formats like JT65 that integrate the detection process over a large number of symbols. Perhaps surprisingly, the clock rate on some inexpensive computer sound cards can be off on the order of a percent, which results in a similar error in symbol rate.

The modulation accuracy of an FSK signal is normally characterized by the frequency shift at the center of each symbol time, the point at which the receiver usually makes the decision of which symbol is being received. For other digital formats, the modulation accuracy is normally characterized by the amplitude and phase at the symbol decision points. Amplitude error is typically measured as a percentage of the largest symbol amplitude. The phase error is quoted in degrees. In both cases one can specify either the average RMS value or the peak error that was detected over the measurement period. Amplitude error is the most important consideration for modulation types such as BPSK where the

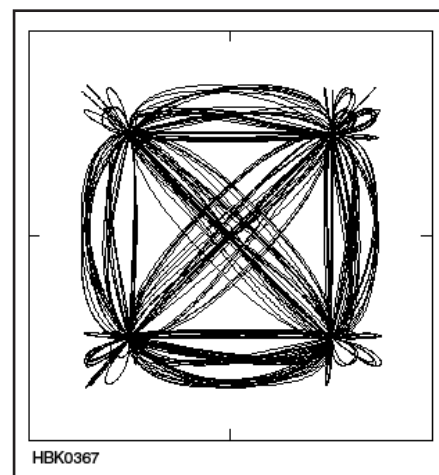

Fig 8.33 — Simulated I/Q constellation display of the trajectory of a QPSK signal over an extended period. A 0.5-alpha raised-cosine filter was used. Because it is a Nyquist filter, the trajectories pass exactly through each symbol location.

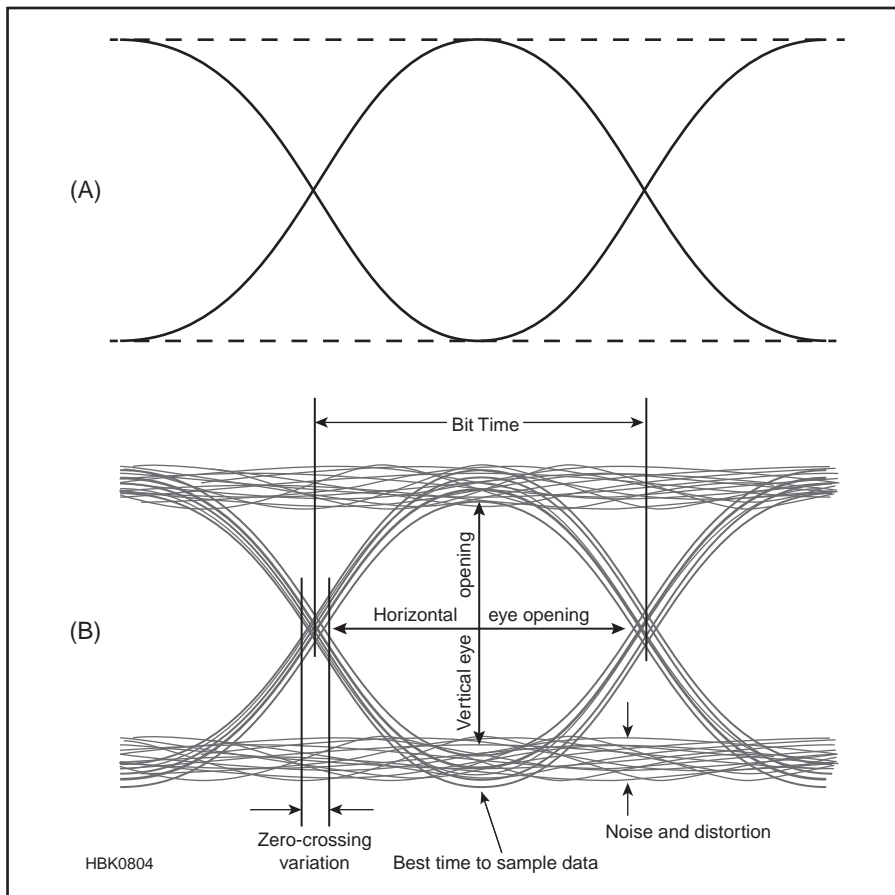

Fig 8.34 — The eye diagram is an oscilloscope-style diagram showing repeated samples of the digital signal as it transitions between points in the constellation. The eye diagram at A is for a perfect, undistorted signal. The eye diagram in B shows a signal with noise, distortion, and timing variations.

information is encoded as an amplitude. For a constant-envelope format like MSK, phase error is a more important metric.

For formats like QPSK and QAM, both amplitude and phase are important in determining symbol location. A measurement that includes both is called *error vector magnitude* (EVM). It is the RMS average distance between the ideal symbol location in the constellation diagram and the actual signal value at the symbol decision point, expressed as a percentage of either the RMS signal power or the maximum symbol amplitude. This is a measurement that requires specialized test equipment not generally available to home experimenters. However it is possible to estimate the effect on EVM of various design choices using computer simulations.

Previously, we have plotted constellation diagrams with the transitions between symbol locations indicated by straight lines. In an actual system, both the I and Q signals are low-pass filtered which makes the symbol transitions smoother, with no abrupt changes of direction at the symbol locations. **Fig 8.33** shows the actual symbol trajectories for a

QPSK signal using a 0.5-alpha raised-cosine filter with random data. Since a raised-cosine is a type of Nyquist filter, the trajectories pass exactly through each symbol location. This is what you would see if you connected the I and Q outputs from a QPSK baseband generator to the X (horizontal) and Y (vertical) inputs of an oscilloscope. It is also what you would see in a receiver at the input to the symbol detector after the carrier and clock-recovery circuits have stabilized the signal. If the symbol trajectories were not accurate, then the dark areas at the symbol points would be less distinct and more spread out. Such a constellation diagram is also a good troubleshooting tool for other purposes, for example to check for amplitude distortion or to see if a faulty symbol encoder is missing some symbols or placing them at the wrong location.

In a system where a root-Nyquist filter is used in both the transmitter and receiver to obtain a net Nyquist response, the transmitter output will not display sharply defined symbol locations as in the figure. In that case, the measuring instrument must supply the missing root-Nyquist filter that is normally

Fig 8.35 — Eye diagrams of the I and Q outputs of a QPSK generator (A) and a 16-QAM generator (B). The “eye” is the empty area between the symbol decision points, visible as the points where all the symbol trajectories come together. The bigger the “eye” the easier the signal is to decode.

in the receiver, in order to obtain a clean display. Professional modulation analyzers normally include a means of selecting the proper matching filter.

Another way to view modulation accuracy is with an *eye diagram*. See **Figs 8.34** and **8.35**. In this case the oscilloscope’s horizontal axis is driven by its internal sweep generator, triggered by the symbol clock. The two vertical channels of the oscilloscope are connected to the I and Q outputs of the baseband generator. The “eye” is the empty area at the center of the I and Q traces in between the symbol decision points, where all the traces come together. The eye should be as “open” as possible to make the job of the receiver’s symbol decoder as easy as possible. The oscilloscope would typically be set for infinite persistence, so that the worst-case excursions from the ideal symbol trajectory are recorded. QPSK has four symbol locations, one in each quadrant, such that I and Q each only have two possible values and there is only one “eye” for each. 16-QAM has 16 symbol locations with four possible locations for I and Q, which forms three “eyes.”

8.6 Modulation Glossary

GENERAL

AM — Amplitude modulation.

Angle modulation — Modulation of an RF carrier by varying the phase or frequency.

Emission designator — Official ITU code to specify the bandwidth and modulation type of a radio transmission.

Frequency diversity — The use of a wideband signal to compensate for selective fading. While one band of frequencies is faded, the data can be reconstructed from other frequencies that are not faded.

FM — Frequency modulation.

IMD — Intermodulation distortion. Unwanted frequencies that occur at the sum and difference of the desired frequencies and their harmonics.

ITU — International Telecommunications Union. An agency of the United Nations that coordinates and recommends technical standards for electronic communications.

Modulation — The periodic alteration of some parameter of a carrier wave in order to transmit information.

PM — Phase modulation.

Protocol — A formal set of rules and procedures for the exchange of information within a communications network.

Selective fading — A propagation phenomenon in which closely-spaced frequencies experience markedly different fading at the same time.

Telemetry — The use of telecommunication for automatically indicating or recording measurements at a distance from the measuring instrument.

Telephony — A form of telecommunication primarily intended for the exchange of information in the form of speech.

Telegraphy — A form of telecommunication in which the transmitted information is intended to be recorded on arrival as a graphic document; the transmitted information may sometimes be presented in an alternative form or may be stored for subsequent use.

Television — A form of telecommunication for the transmission of transient images of fixed or moving objects.

ANALOG MODULATION (INCLUDING IMAGE)

ATV — Amateur fast-scan television.

BFO — Beat frequency oscillator.

In an SSB or DSBSC receiver, the intermediate-frequency oscillator in the receiver that re-inserts the suppressed carrier.

Carson's rule — A rule of thumb to calculate FM bandwidth that says that 98% of the energy is typically contained within a bandwidth equal to two times the sum of the peak frequency deviation and the highest modulating frequency.

Capture effect — The tendency of the strongest signal to suppress other signals in an FM detector, which improves the signal-to-noise and signal-to-interference ratio.

Deviation ratio — The ratio of the maximum permitted peak deviation of an angle-modulated signal to the maximum permitted modulating frequency.

DSBSC — Double sideband, suppressed carrier. An AM signal in which the carrier has been removed but both sidebands remain.

Fax — Facsimile. The sending of still images by wire or by radio.

Frame — In television, one complete scanned image. On systems with interlaced scanning, there are two vertical scans per frame.

Frequency deviation — The amount the RF frequency of an angle-modulated signal deviates from the center (carrier) frequency in response to the modulating signal. The term is often understood to mean the maximum deviation available in a given system.

Limiting — A high-gain amplifier in an FM receiver that limits the peak amplitude of the signal in order to eliminate any AM component.

LSB — Lower sideband. An SSB signal with the upper sideband removed.

Martin — A series of analog SSTV formats, especially popular in Europe.

Modulation index (AM) — The ratio of the peak value of the modulation of an AM signal to the value that just causes the modulation envelope of the RF signal to reach zero on negative peaks and twice the average value on positive peaks.

Modulation index (FM) — The ratio of the peak deviation of an angle-modulated signal to the highest modulating frequency.

Narrowband FM — An FM signal with a modulation index less than or equal to 1.0.

NTSC — National Television System Committee. The analog television standard used in the US, Japan and several other countries.

PAL — Phase alteration line. The analog television standard used in many parts of Europe.

Phasing method — A method of generating an SSBSC signal that does not require a filter to remove the unwanted sideband.

Pixel — Picture element. The dots that make up images on a computer's monitor.

Product detector — A detector that multiplies a BFO signal with the received signal, typically SSB or DSBSC-modulated.

RGB — Red, green and blue. The three primary colors required to transmit a full-color image in many television and facsimile systems.

Scottie — A series of analog SSTV formats, especially popular in the US.

SSB — Single sideband. An AM signal in which one sideband has been removed. The term is usually understood to mean SSBSC.

SSBSC — Single sideband, suppressed carrier. An AM signal in which one sideband and the carrier have been removed.

SSTV — Slow scan TV, a system for sending and receiving still images.

Sync — Modulation pulses used in ATV and SSTV to synchronize the horizontal and/or vertical scanning.

Synchronous detector — A type of AM detector in which the carrier is regenerated in the receiver.

Two-tone test — A procedure for testing the IMD of an SSB transmitter. Two equal-amplitude tones are fed to the microphone input and the transmitter RF output is examined with a spectrum analyzer to determine the amplitudes of the IMD products.

USB — Upper sideband. An SSB signal with the lower sideband removed.

Vestigial sideband — The filtering of all but the bottom MHz or so of the lower sideband of an ATV or NTSC television signal.

VIS — Vertical interval signaling. Digital encoding of the transmission mode during the vertical sync interval of an SSTV frame.

Wideband FM — An FM signal with a modulation index greater than 1.0.

DIGITAL MODULATION

AFSK — Audio FSK. The use of an SSB transceiver to transmit and receive FSK using an audio-frequency modem.

ASK — Amplitude-shift keying. Digital amplitude modulation in which the

- amplitude depends on the modulating code.
- Baud rate** — The rate at which a digital signal transitions between symbol states. Symbol rate.
- Bauds** — Symbols per second. Unit of baud rate or symbol rate.
- Bit rate** — The total number of physically transferred bits per second over a communication link. Bit rate can be used interchangeably with **baud rate** only when each modulation transition carries exactly one bit of data.
- BPSK** — Binary PSK. PSK with only two possible states. The term is usually understood to mean a non-constant-envelope signal in which the two states differ by 180°.
- Chirp** — Incidental frequency modulation of a carrier as a result of oscillator instability during keying.
- CW** — Continuous wave. The term used for on-off keying using Morse code.
- Constellation diagram** — A diagram showing the constellation of possible symbol locations on a polar plot of modulation amplitude and phase.
- DBPSK** — Differential BPSK.
- Decision point** — The point, typically in the center of a symbol time, at which the receiver decides which symbol is being sent.
- Differential modulation** — A modulation technique that encodes the information in the difference between subsequent symbols, rather than in the symbols themselves.
- Equalization** — Correction for variations in amplitude and/or phase versus frequency across a communications channel.
- DQPSK** — Differential QPSK.
- Eye diagram** — An oscilloscope measurement of a digital modulating signal with the horizontal sweep synchronized to the symbol times. With Nyquist filtering, there should be a clear separation, or “eye”, in the trajectories at the symbol decision points.
- EVM** — Error vector magnitude. A measure of the RMS error in the symbol locations at the symbol decision points in the constellation plot of a digital signal.
- FFT** — Fast Fourier transform. The Fourier transform is a mathematical function that calculates the frequency spectrum of a signal. The FFT is a software algorithm that does the calculations very efficiently.
- FSK** — Frequency-shift keying. A form of digital frequency modulation in which the frequency deviation depends on the modulating data.
- GMSK** — Gaussian MSK. MSK with a Gaussian modulation filter.
- I/Q modulation** — Quadrature modulation implemented with an I/Q modulator, one that uses in-phase (I) and quadrature (Q) modulating signals to generate the zero-degree and 90° components of the RF signal.
- ISI** — Inter-symbol interference. Interference of a signal with itself, caused when energy from one symbol is delayed long enough to interfere with a subsequent symbol.
- MFSK** — Multi-level FSK. FSK with more than two states represented by different frequency deviations.
- Modem** — Modulator/demodulator. A device that generates and demodulates digital modulation signals, usually at audio frequencies. It connects between the data terminal (usually a computer) and the radio.
- MSK** — Minimum-shift keying. A form of FSK with a frequency shift equal to one-half the symbol rate.
- Nyquist criterion** — A principle that states that the sampling frequency must be greater than twice the highest frequency in the sampled signal.
- Nyquist frequency** — One-half the sampling frequency.
- OFDM** — Orthogonal frequency-division multiplexing. A transmission mode that uses multiple carriers, spaced such that modulation on each carrier is orthogonal with the others.
- OOK** — On-off keying. A type of ASK with only two states, on and off.
- OQPSK** — Offset QPSK. By offsetting in time the symbol transitions of the I and Q channels, symbol trajectories through the origin are eliminated.
- Orthogonal** — Refers to streams of data that are uncorrelated with each other such that there is no mutual interference.
- PAM** — Pulse amplitude modulation. A type of pulse modulation where the modulating signal is encoded in the pulse amplitude.
- $\pi/4$ DQPSK** — PI-over-four differential QPSK. A form of differential 8PSK in which the only allowed transitions are ± 45 and $\pm 135^\circ$, resulting in four allowed states per symbol.
- PPM** — Pulse position modulation. A type of pulse modulation where the modulating signal is encoded in the pulse position.
- PSK** — Phase-shift keying. A form of digital phase modulation in which the phase of the RF signal depends on the modulating code. The term often is understood to refer to BPSK.
- Pulse modulation** — The modulating signal is sampled at regular intervals to generate a series of modulation symbols in the form of pulses.
- PWM** — Pulse width modulation. A type of pulse modulation where the modulating signal is encoded in the pulse width.
- QAM** — Quadrature amplitude modulation. A digital modulation type in which both amplitude and phase are varied. The number that precedes it, for example 64QAM, is the number of different possible states of the amplitude and phase.
- QPSK** — PSK with four possible states. The term is usually understood to be equivalent to four-level QAM, in which the four states have the same amplitude and differ in phase by 90°.
- Quadrature modulation** — Refers to modulation using two RF carriers in phase quadrature, that is, 90° out of phase.
- Symbol rate** — The rate at which a digital signal transitions between different states. Baud rate.
- Varicode** — A coding method in which the length of each character code depends on its frequency of occurrence. It is used to optimize the ratio of characters per second to baud rate.

SPREAD SPECTRUM

- CDMA** — Code-division multiple access. A method of allowing several stations to use the same frequency band simultaneously by assigning each station a different orthogonal spreading code.
- Chip** — The shortest-duration modulation state in a SS system.
- De-spreading** — Conversion of an SS signal back to its narrowband equivalent by convolving it with the spreading code.
- DSSS** — Direct-sequence SS. Spreading of a signal by multiplying the data stream by a higher-rate pseudo-random digital sequence.
- FHSS** — Frequency-hopping SS. Spreading of a signal by means of pseudo-random frequency-hopping of the unspread signal.
- Processing gain** — The increase in signal-to-noise ratio that occurs when an SS signal is de-spread.
- SS** — Spread spectrum. A system that intentionally increases the bandwidth of a digital signal by means of a special spreading code.

FILTERING AND BANDWIDTH

- ACP** — Adjacent channel power. The amount of transmitted power that falls into a communications channel immediately adjacent to the desired one.

Oscillators and Synthesizers

RF signal paths all need to start somewhere. These starting places are oscillators — circuits that generate a periodic output signal without any input signal. In general, we use sinusoidal waveforms for communication signals, and square-wave outputs for digital signals (clocks). Ham operators care greatly about oscillator design. In a crowded band, a good oscillator is necessary for the receiver to resolve each of the signals present. Similarly, a good oscillator is needed for all transmitters so that our signals use only the amount of spectrum necessary for communication.

This chapter has been updated and rewritten for the 90th edition by Earl McCune, WA6SUH, from material originally written by David Stockton, GM4ZNX, and Frederick J. Telewski, WA7TZY. The sidebar on Phase-Locked Loops was contributed by Jerry DeHaven, WA0ACF. Dr Ulrich Rohde, N1UL, contributed material on oscillator designs along with articles on phase noise and oscillator design which may be found on the *Handbook* CD-ROM.

The sheer number of different oscillator circuits seen in the literature can be intimidating, but their great diversity is an illusion that evaporates once their underlying pattern is seen. Despite the number of combinations that are possible, a manageably small number of oscillator types will cover all but very special requirements. Look at an oscillator circuit and “read” it: What form of filter — resonator — does it use? What form of amplifier? How have the amplifier’s input and output been coupled into the filter? How is the filter tuned? These are simple, easily answered questions that put oscillator types into appropriate categories and make them understandable. The questions themselves make more sense when we understand the mechanics of oscillation, in which resonance plays a major role.

9.1 How Oscillators Work

Any oscillator is a fundamentally nonlinear device. Among other reasons, this circuit has an RF output even without any RF input. Any linear circuit can change the magnitude and phase shift on the signal only at its input.

9.1.1 Resonance

We are all familiar with pendulums. A weight (a mass in a gravitational field) hanging from some kind of string will swing back and forth with a very regular period. It has been known for millennia that this period does not change as long as the length of the string does not change, regardless of the amount of weight or how far it swings. Only a few centuries ago did Isaac Newton invent enough calculus to show why this is true. Yet even before Newton’s seminal work, people were comfortable enough with this very predictable swinging period that pendulums were adopted as the basis of clocks and timekeeping.

Newton showed that the pendulum works by continuously exchanging its energy between potential (height) and kinetic (moving) forms. The mass moves fastest when it has minimum height (all energy is kinetic), and stops moving (all energy is potential) when it has maximum height. Further, when the energy is all in one form, the ingredients are in place to assure that conversion to the other form will happen. At the bottom, when the mass is moving fastest, its momentum assures that it will keep moving. The string constrains that movement and forces it to rise. When the mass stops rising, the string pulls on it in a different direction from gravity, which is pulling it down. This assures that the mass will fall and pick up speed — and the cycle repeats.

An electrical equivalent is created by the combination of an inductor and a capacitance. The inductor stores energy in a magnetic field when there is a current (motion of charge) flowing through it. The capacitor stores energy in an electric field when there is a voltage (presence of charge) in it. Connect the two together and the charge in the capacitor (electric potential energy) forces a current to begin flowing through the inductor. When the charge in the capacitor is zero, the current in the inductor is maximum (magnetic energy) and the magnetic field forces the current to continue, which recharges the capacitor with the opposite polarity. Just like the pendulum, the combination of inductor and capacitor trade energy back and forth between two types. Because energy is being stored in this circuit, we call this a *tank circuit*.

The common features between a pendulum and an electrical tank circuit are shown in **Fig 9.1**. For the pendulum, the speed of the mass and the displacement (height) are both sinusoidal with time and offset in phase by 90 degrees. Similarly, the voltage and current in

Fig 9.1 — A resonator lies at the heart of every oscillatory mechanical and electrical system. A mechanical resonator (here, a pendulum) and an electrical resonator (here, a tuned circuit consisting of L and C in parallel) share the same mechanism: the regular movement of energy between two forms — potential and kinetic in the pendulum, electric and magnetic in the tuned circuit. Both of these resonators share another trait: Any oscillations induced in them eventually die out because of losses — in the pendulum, due to drag and friction; in the tuned circuit, due to the resistance, coupling to other circuits, and radiation. Note that the curves corresponding to the pendulum’s displacement vs velocity and the tuned circuit’s voltage vs current differ by one-quarter of a cycle, or 90°.

the LC tank circuit are sinusoidal and offset by 90 degrees.

Unfortunately, these oscillations do not continue forever. When you pull a pendulum aside and let it go, it will swing for a while and eventually stop. This is due to losses that take a little bit of energy away from the pendulum each time it swings. For a pendulum, one major loss mechanism is air drag: As the mass moves through the air, some energy is spent to move the air out of its way. There are losses from the string as well: Every time the string is bent, it warms up just a little bit. This also takes energy away from the pendulum. With these losses, the energy conversion is not complete between kinetic and potential forms, and each cycle of the oscillation is slightly smaller than the one before. We say that the oscillation is *damped*.

The electrical tank circuit works similarly. When an oscillation is started, say with a spark charging the capacitance as shown in **Fig 9.2A**, we see that this oscillation is also damped. The primary losses include resistance in the inductor and interactions of the electric and magnetic fields with other conductors. There is also direct radiation of electromagnetic fields — exactly what we want to happen for radio communication, but counts as an energy loss from the resonator.

It was not hard to figure out that a damped oscillation is not very useful for radio communication. We need our signals to last for a longer time so they can carry useful information. The first attempt to solve this problem was to repeatedly apply sparks to the tank circuit in a manner like that of Fig 9.2B. This still is not a continuous sine wave and it is very noisy because, among other things, the timing of the sparks is extremely difficult to hold in exact synchronization with the tank oscillation. There has to be a better way...

9.1.2 Maintained Resonance (CW: Continuous Waves)

What we need is a way to make up for the resonator losses, but only just enough to maintain the oscillation indefinitely. Invention of the escapement achieved this for the pendulum, and that’s what provides the distinctive “tick-tock” of a pendulum clock. Electrically we use an amplifier to do the same thing.

Fig 9.2 — Stimulating a resonance, 1880s style. Shock-exciting a gapped ring by a charged capacitor causes the ring to oscillate at its resonant frequency. The result is a damped wave, each successive alternation of which is weaker than its predecessor because of resonator losses. Repetitively stimulating the ring produces trains of damped waves, but oscillation is not continuous.

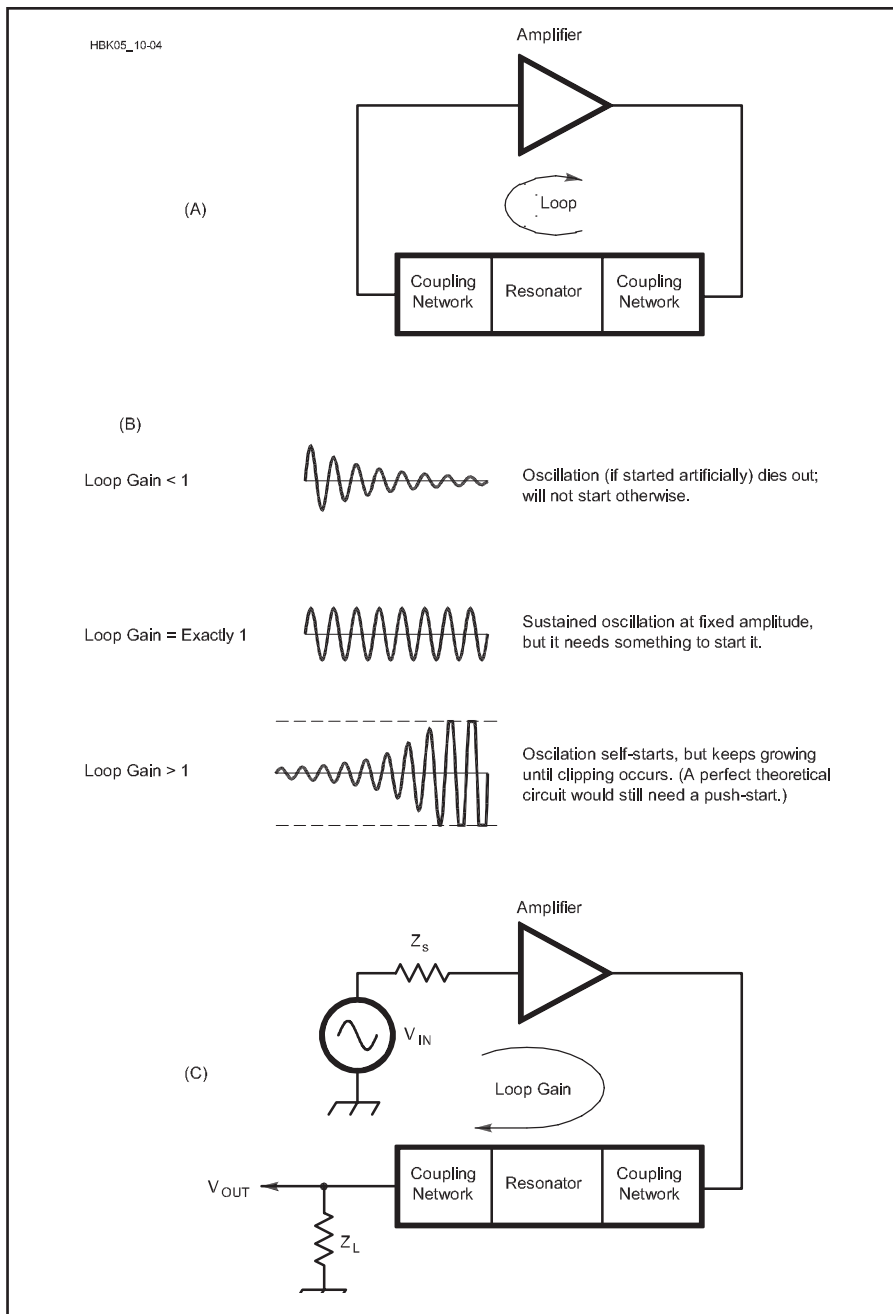

Fig 9.3 — A practical oscillator requires networks to couple power in and out of the resonator (A). At (B), we see the amount of loop gain determines whether the oscillations will die out (loop gain < 1), grow until the waveform is no longer a sine wave (>1), or sustain at a steady amplitude (=1). Breaking the loop, inserting a test signal and measuring the loop's overall gain allows us to determine whether the system can oscillate, sustain oscillation or clip (C).

By adding an amplifier to the tank circuit or resonator, we can take a small amount of the energy from the resonator, amplify it, and inject a part of the amplified tank signal back into the resonator. This process is shown in **Fig 9.3A**. Unlike in general amplifier design, here we are not interested in maximizing power transfer. Instead, we want to couple just enough energy into the resonator to overcome its losses, and to take only the minimum amount of energy out of the resonator

needed to generate the restoring energy. Thus Fig 9.3A shows coupling networks instead of matching networks. We end up with a loop: The amplifier input comes from the output of the resonator, and the amplifier output goes to the input of the resonator.

The trick to oscillator design is to get the coupling networks and the amplifier gain working together just right. What this means is shown in Fig 9.3B. If we want to get a sine wave output, we need to get the loop gain —

gain computed as the signal passes through the combination of amplifier, resonator, and both coupling networks — exactly equal to one, also called *unity*. If the loop gain is even slightly less than one, then not enough energy is supplied to overcome resonator losses and the damping still happens. If the loop gain is greater than one, then the magnitude of the sine wave will grow until the waveform is no longer sinusoidal.

There is more to making an oscillator work than getting the loop gain right. We also need to be sure that the energy from the amplifier output is applied to the resonator having the correct phase alignment with the oscillating signal in the resonator. Taken together these requirements are known as the *Barkhausen criteria*: to achieve oscillation the loop must 1) have a net zero phase shift (or some integer multiple of 360°) and 2) have a loop gain equal to one. Both of these are critically important. If either of these criteria is not met, the circuit will not oscillate.

How do we find out if we are meeting the Barkhausen criteria? We need to break the loop, usually at the input of the amplifier as shown in Fig 9.3C. We apply a signal slightly below the desired oscillation frequency, then sweep the frequency through and slightly past the desired oscillation frequency. During the sweep we monitor both the magnitude and phase response at the output of the resonator output coupling network. If everything is right, then at the desired frequency of oscillation the input and output signals will look exactly the same on an oscilloscope. If that doesn't happen, we have work to do.

Getting the phase response of the loop correct is usually the harder problem. Much of this difficulty comes from the many types of resonators that can be used, including:

- LC tank
- Quartz crystal (and other piezoelectric materials)
- Transmission line (stripline, microstrip, open-wire, coax, and so on)
- Microwave cavities, YIG spheres, dielectric resonators
- Surface-acoustic-wave (SAW) devices

Each of these also can be called a filter. It is true that any filter can also be used as a resonator in an oscillator. The more complicated phase responses of filters makes meeting both of the Barkhausen criteria more challenging, but certainly possible.

The phase response of the resonator is related to its Q (quality factor — see the **Electrical Fundamentals** chapter). If we have a parallel LC tank, then at frequencies well below resonance the tank looks inductive ($X_L \ll X_C$) and the current lags the voltage. At frequencies well above resonance the tank looks capacitive ($X_C \ll X_L$) so the current leads the voltage. In between, the phase shift of the current relative to the voltage depends on the actual frequency. The rapidity of the

Fig 9.4 — Phase shift through the resonator depends on resonator Q. The higher resonator Q, the more abruptly phase changes through the resonator as frequency changes.

phase shift with changing frequency is governed by resonator Q: the phase shift happens very rapidly when Q is high. This is shown in **Fig 9.4**. When the resonator Q is low then the phase changes much more slowly at different frequencies.

If we have a series resonator then the phase change profile is reversed (capacitive to inductive) but otherwise the shape is the same. There are an infinite number of combinations of L and C values that provide the same resonant frequency. If we are interested in high Q, for a series tank we want to select large inductor values and small capacitor values. For a high-Q parallel tank we want the opposite — large capacitor values and small inductor values. **Fig 9.5**, a modified version of the reactance vs frequency chart in the **Electrical Fundamentals** chapter, shows these regions for a resonant frequency of 10 MHz.

9.1.3 Oscillator Start-Up

Looking at **Fig 9.3B** we see that the oscillation will build up in magnitude only when the loop gain is greater than unity. Thus this is an important additional criterion for oscillator design. The loop gain must be slightly greater than unity for it to start oscillating. Otherwise we have the undesired condition in which there is no signal in the resonator, so we sample nothing from it and put nothing back into it.

Still we need one more thing — noise. Some kind of signal needs to be injected into the resonator for the oscillation to start building up. We are fortunate that all amplifiers have output noise when power is applied, even if there is no input signal. It is this noise that allows any oscillator to start. Amplifier noise initiates a resonant signal in the tank, and if loop gain is slightly greater than unity, more signal is fed back into the resonator than the resonator loses. The output signal builds up until something stops it.

Here we take advantage of an amplifier characteristic where gain is reduced as the output reaches some predefined value. This

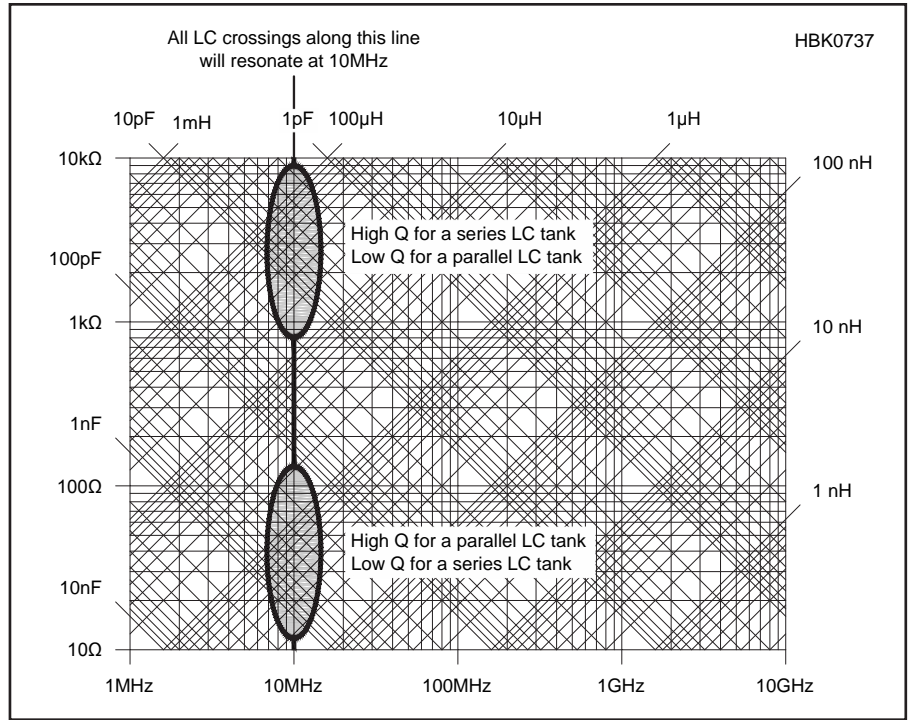

Fig 9.5 — There are an infinite number of combinations of L and C for a given resonant frequency. For a series-LC tank circuit, larger ratios of L to C result in higher values of Q and vice versa for parallel-LC tank circuits.

is referred to as *compression*: when the output signal gets large enough, the amplifier gain is reduced a little bit. When compression balances steady output amplitude with a loop gain of exactly unity, the oscillator has reached steady state operation and we are ready to go!

Why don't we have noise at the oscillator output instead of a sine wave? Because of the filtering action of the resonator, the filtered noise waveform appears mostly sinusoidal. The narrower the bandwidth of the resonator (the higher its Q), the more sinusoidal the waveform, but it actually consists of very well-filtered noise. It is impossible to get only a pure sine wave. Noise is inevitable, and tremendous efforts are spent in reducing this noise. This is discussed in section 9.2.

9.1.4 Negative Resistance Oscillators

It is possible to build an oscillator without using an amplifier. Recognizing that losses in the tank are represented by a resistor, if the loss resistor is canceled with a negative resistance then there will be no operating losses and the tank oscillation will continue without damping. This structure is shown in **Fig 9.6**.

Negative resistance devices definitely exist. Anything that draws lower current as the applied voltage increases exhibits negative resistance. Gunn diodes are classic examples and are widely used in microwave oscillators. Lower frequency devices include

tunnel diodes and lambda diodes. With this type of oscillator, the equivalent of having the loop gain slightly greater than unity at startup is for the negative resistance to be slightly more negative than the tank loss resistance is positive.

Amplitude limiting for this type of oscillator occurs when the signal amplitude increases enough to drive the negative resistance device to a less-negative value. All negative resistance devices listed here only exhibit their negative resistance over a finite range, so any signal approaching or exceeding this range will effectively reduce the negative resistance, as desired.

Fig 9.6 — The amplifier in an oscillator can be replaced by a device with negative resistance, such as a Gunn diode, and oscillation will still result.

9.2 Phase Noise

No oscillator output signal is perfect. Viewing an oscillator as a filtered-noise generator, as in the previous sections, is relatively modern. The older approach is to think of an oscillator making a pure sine wave with an added, unwanted noise signal. These are just different ways of visualizing the same thing. They are equally valid views which are used interchangeably, depending on which best makes some point clear.

For example, it is instructive to use the pure-sine-wave-plus-noise view to see relationships between AM noise and PM (phase) noise processes, shown in **Fig 9.7**. Adding Gaussian noise to a pure sine wave is usefully modeled using phasors as shown in Fig 9.7B. This generates both AM due to noise, and PM due to noise as shown in Fig 9.7C. Passing this signal through a limiter process, such as an amplifier in compression or through a switching mixer, leaves only the phase noise depicted in Fig 9.7D. Because it is so easy to remove AM noise but not phase noise, there is essentially no discussion about oscillator AM noise. Phase noise is the critical problem.

Phase modulation and frequency modulation are closely related. (See the **Modulation** chapter for a detailed description of each.) Phase is the integral of frequency, so phase modulation resembles frequency modulation, where the frequency deviation increases with increasing modulating frequency. Thus, there is no need to talk of “frequency noise” because phase noise already covers it.

A thorough analysis of oscillator phase noise is beyond the scope of this section. However, a detailed, state-of-the-art treatment by Dr Ulrich Rohde, NIUL, of free-running oscillators using nonlinear harmonic-balance techniques is presented as a supplement on the CD-ROM accompanying this book.

Because of the dynamic range required to measure phase noise, it is one of the most difficult measurements in all of electrical engineering. The sidebar “Transmitter Phase-Noise Measurement in the ARRL Lab” illustrates the lengths to which one must go to obtain repeatable, reliable measurements. An additional article on measuring receiver phase noise is included on the *Handbook* CD-ROM.

Fig 9.7 — At A, a vector (left) and phasor (right) diagram of an ideal oscillator with no noise. Added noise creates a region of uncertainty in the phasor’s length and position (B). AM noise varies the phasor’s length; PM noise varies the phasor’s relative angular position (C). Limiting a signal that contains both AM and PM noise strips off the AM and leaves the PM (D).

Transmitter Phase-Noise Measurement in the ARRL Lab

Here is a brief description of the technique used in the ARRL Lab to measure transmitter phase noise. The system consists of a phase noise test set with low-noise variable crystal oscillators for reference signals. The test set zero-beats the oscillator to the transmitter signal using phase detectors on both signals. As shown in **Fig 9.A1**, we use an attenuator after the transmitter to bring the signal down to a suitable level for the phase noise test set. The crystal oscillator output is low level, so it does not require attenuation.

The phase noise test set is an automated system run by a PC that steps through the test, setting parameters in the spectrum analyzers and reading the data back from them, in addition to performing system calibration measurements at the start of the test. The computer screen displays the transmitted phase-noise spectrum, which can be printed or saved to a file on the hard drive. To test the baseline phase noise of the system, two identical crystal oscillators are tested against each other. It is quite important to be sure that the phase noise of the reference source is lower than that of the signal under test.

A sample phase-noise plot for an amateur transceiver is shown in **Fig 9.A2**. It was produced with the test setup shown in Fig 9.A1. These plots do not necessarily reflect the phase-noise characteristics of all units of a particular model.

The reference level (the top horizontal line on the scale in the plot) represents 0 dBc/Hz. Because each vertical division represents 20 dB, the plot shows the noise level between 0 dBc/Hz (the top horizontal line) and -160 dBc/Hz (the bottom horizontal line). The horizontal scale is logarithmic, with one decade per division (the first division shows noise from 100 Hz

to 1000 Hz offset, whereas the last division shows noise from 100 kHz through 1 MHz offset).

What Do the Phase-Noise Plots Mean?

Although they are useful for comparing different radios, plots can also be used to calculate the amount of interference you may receive from a nearby

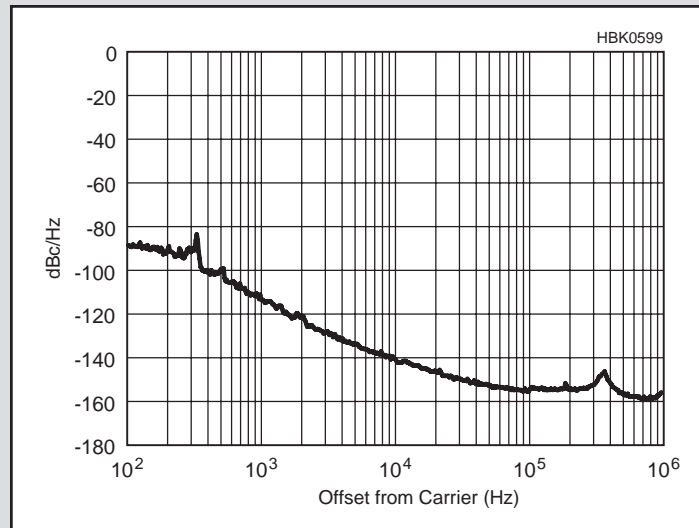

Fig 9.A2 — Sample phase noise plot for an amateur HF transceiver as published in Product Review in *QST*. This is the Elecraft K3.

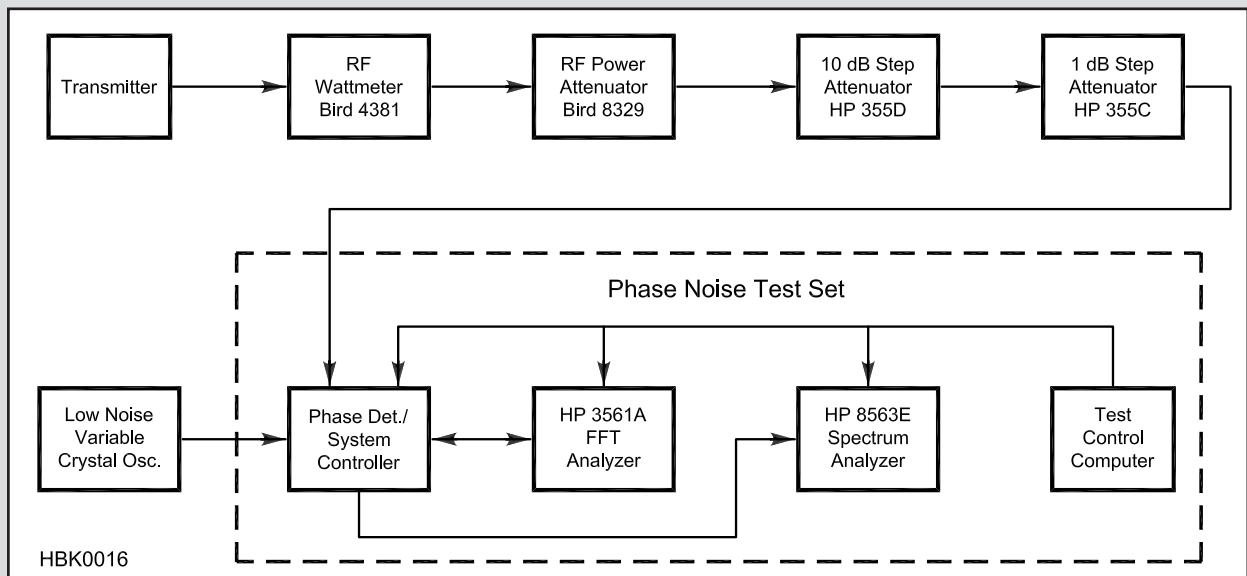

Fig 9.A1 — ARRL Lab phase-noise measurement setup.

transmitter with known phase-noise characteristics. An approximation is given by

$$A_{\text{QRM}} = \text{NL} + 10 \times \log(\text{BW})$$

where

- A_{QRM} = Interfering signal level, dBc
- NL = noise level on the receive frequency, dBc
- BW = receiver IF bandwidth, in Hz

For instance, if the noise level is -90 dBc/Hz and you are using a 2.5 kHz SSB filter, the approximate interfering signal will be -56 dBc. In other words, if the transmitted signal is 20 dB over S9, and each S unit is 6 dB, the interfering signal will be as strong as an S3 signal.

The measurements made in the ARRL Lab apply only to transmitted signals. It is reasonable to assume that the phase-noise characteristics of most transceivers are similar on transmit and receive because the same oscillators are generally used in local-oscillator (LO) chain.

In some cases, the receiver may have better phase noise characteristics than the transmitter. Why the possible difference? The most obvious reason is that circuits often perform less than optimally in strong RF fields, as anyone who has experienced RFI problems can tell you. A less obvious reason results from the way that many high-dynamic-range receivers work. To get good dynamic range, a sharp crystal filter called a *roofing filter* is often placed immediately after the first mixer in the receive line. This filter removes all but a small slice of spectrum for further signal processing. If the desired filtered signal is a product of mixing an incoming signal with a noisy oscillator, signals far away from the desired one can end up in this slice. Once this slice of spectrum is obtained, however, unwanted signals cannot be reintroduced, no matter how noisy the oscillators used in further signal processing. As a result, some oscillators in receivers don't affect phase noise.

The difference between this situation and that in transmitters is that crystal filters are seldom used for reduction of phase noise in transmitting because of the high cost involved. Equipment designers have enough trouble getting smooth, click-free break-in operation in transceivers without having to worry about switching crystal filters in and out of circuits at 40 WPM keying speeds! — Zack Lau, W1VT, and Michael Tracy, KC1SX

9.2.1 Effects of Phase Noise

Phase noise becomes a problem when it is more noticeable than other limitations. It degrades all signals, but whether it is important or not depends on the application. For voice signals it sounds like background “hiss” in headphones or speakers. It also limits the dynamic range of receivers with closely separated signals, or receiving signals with widely different input powers.

Phase noise became a significant problem for amateurs when the use of frequency synthesizers supplanted conventional LC VFOs in amateur equipment. For reasons discussed in the Synthesizers section of this chapter, it is a major task to develop a synthesizer that tunes in steps fine enough for use with SSB and CW operation while competing with the phase-noise performance of a reasonable-quality LC VFO. Many synthesizers fall far short of this target. Along with the problems with frequency synthesizers, phase noise always gets worse at higher frequencies. The trend toward general-coverage, up-converting architectures has required local oscillators to operate at higher and higher frequencies, making phase noise even more of a problem. Examples of phase noise and the problems it causes are detailed in the next two sections.

9.2.2 Reciprocal Mixing

All mixers are symmetrical, meaning that the output IF signal depends on the characteristics of both input signals: the local oscillator (LO) and the desired signal. A change to either signal shows up at the IF, where there is no way of knowing if the signal characteristics seen are from the input signal itself, or from the LO. We usually assume that the LO is very pure so only input signal modulations show up at the IF.

When there is phase noise on the LO signal, the situation changes. Noise on the LO transfers to *all* input signals at the mixer output as if it was originally present on each input signal and the LO was perfectly clean — the IF circuits can't tell the difference. This process is called *reciprocal mixing*, where noise on the LO appears as noise on the desired output signal. This is a serious limitation on a receiver's weak-signal ability.

How reciprocal mixing of LO phase noise can limit receiver dynamic range is shown in Fig 9.8. One possible scenario of band activity is shown as the set of input signals in Fig 9.8A. Fig 9.8B shows the phase noise profile for the LO of this receiver. Reciprocal mixing is illustrated in Fig 9.8C, showing that the LO phase noise is added to each of the signals in the band in proportion to its input power. The

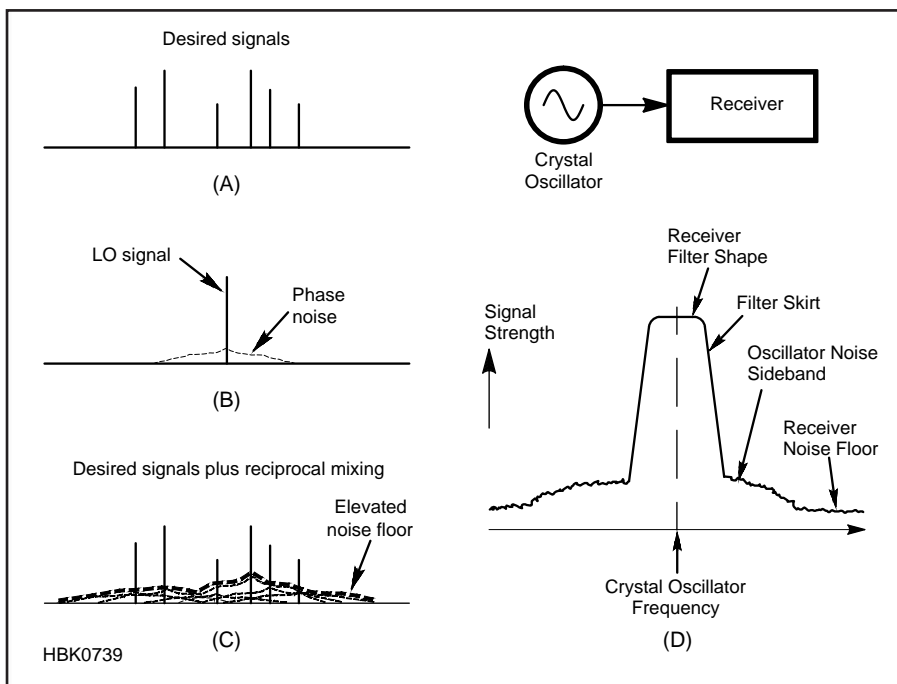

Fig 9.8 — A typical set of input signals is shown at A and an LO signal with phase noise at B. When the LO signal at B is mixed with the input signals at A, the result is a set of mixing products each having phase noise added, raising the noise floor across the band as shown at C. Phase noise in your receiver can be heard by tuning to a strong, clean crystal-oscillator signal as shown in D.

Fig 9.9 — A strong received signal can also cause such severe reciprocal mixing that desired signals are completely obscured by noise. If the signal is transmitted with phase noise from the transmitter LO, the effect is the same as noise covers the desired signals, sometimes across a very wide range of frequencies.

total noise seen by the receiver demodulator is the sum of all transferred phase noise profiles at the received frequency. This raises the apparent noise floor of the receiver.

Another receiver problem due to LO phase noise occurs if a very large signal appears in the receiver passband but at a frequency well removed from the desired signal. One example of this is shown in **Fig 9.9**. If the LO phase noise is excessive, then reciprocal mixing with this large signal can completely block the ability to demodulate the desired signals. Indeed, it is possible to make a wide swath of spectrum relatively useless. (If the strong signal is strong enough, it can result in *blocking* by causing a reduction of receiver gain. This is described in the **Receivers** and the **Test Equipment and Measurements** chapters.)

Reciprocal mixing in a receiver does not affect the operating ability of other stations. The solution is to reduce the phase noise on the receiver's LO.

9.2.3 A Phase Noise Demonstration

Healthy curiosity demands some form of

demonstration so the scale of a problem can be judged "by ear" before measurements are attempted. We need to be able to measure the noise of an oscillator alone (to aid in the development of quieter ones) and we also need to be able to measure the phase noise of the oscillators in a receiver (a transmitter can be treated as an oscillator). Conveniently, a receiver contains most of the functions needed to demonstrate its own phase noise.

Because reciprocal mixing adds the LO's sidebands to clean incoming signals, in the same proportion to the incoming carrier as they exist with respect to the LO carrier, all we need do is to apply a strong, clean signal wherever we want within the receiver's tuning range. This signal's generator must have lower phase noise than the radio being evaluated. A general-purpose signal generator is unlikely to be good enough; a crystal oscillator is needed.

It's appropriate to set the oscillator's signal level into the receiver to about that of a strong broadcast carrier, say S9 + 40 dB. Set the receiver's mode to SSB or CW and tune around the test signal, looking for an increasing noise floor (higher hiss level) as you tune closer toward the signal, as shown in **Fig 9.8D**. Switching in a narrow CW filter allows you to hear noise closer to the carrier than is possible with an SSB filter. This is also the technique used to measure a receiver's effective selectivity, and some equipment reviewers kindly publish their plots in this format. *QST* reviews, done by the ARRL Lab, often include the results of specific phase-noise measurements.

9.2.4 Transmitted Phase Noise

Phase noise on an LO used to generate a transmitted signal will also be amplified and transmitted along with the desired output signal. This obscures reception by raising the noise floor even for receivers with low phase noise because they also receive the noise from the transmitter. In this case, the phase noise is

generated externally to the receiver and must be removed at the transmitter.

If the transmitter is operating linearly, the strength of the transmitted noise is of the same proportion to transmitter output power as the phase noise is to the oscillator signal power. The noise may even extend well beyond the band in which the desired signal is transmitted unless the signal passes through narrow-band filtering that limits its bandwidth.

This transmitted noise is wasted power that is not useful for communication and unfortunately makes for a noisier band. If you are working a weak station and a nearby transmitter with a noisy oscillator comes on the air with a high power signal on a different frequency, it is possible that the output noise from this off-frequency transmitter may completely block your ability to continue working that weak station.

In bad cases, reception of nearby stations can be blocked over many tens of kilohertz above and below the frequency of the offending station. This is seen in **Fig 9.9**, where the offending signal and its associated noise are from a nearby transmitter. Frequencies close to that of the nearby transmitter are suddenly useless.

Transmitted phase noise can present serious problems for multi-station operation such as at Field Day or during emergency communications where several transmitters and receivers are in close proximity. This is a particular problem with transceivers that use early PLL-synthesized VFOs. If you are planning such an operation, be sure the level of transmitted phase noise is acceptable for the transceivers you plan on using.

At your receiver there is nothing you can do about transmitted phase noise. When there is noise power present at the same frequency as a weak (far) signal you are receiving, your receiver cannot separate them. The only solution is for the problem station to use a transmitter with a "cleaner" LO (less phase noise). This is a more serious problem than reciprocal mixing since this transmitted noise affects the ability of many other stations to use that band.

9.3 Oscillator Circuits and Construction

In this section we introduce some important oscillator circuits and provide well-tested guidelines on how to successfully build one. The following section presents a design example.

There are thousands of oscillator circuits, but just a few principal designs. One of the principal oscillator circuits is shown in Fig 9.10. An LC tank circuit is shown in Fig 9.10A. The usual single capacitance is replaced with two series capacitors having the same equivalent capacitance, C_{EQUIV} . The two capacitors act as an ac voltage divider, so that the voltage V_1 at the midpoint is less than the total ac voltage of the tank, V_{TANK} .

What happens when we try to force V_1 to be the same as V_{TANK} by adding an amplifier with unity voltage gain as shown in Fig 9.10B? The voltage division action of the capacitive divider does not change. If V_1 is forced to be equal to V_{TANK} by the amplifier, then V_{TANK} will become greater than before. But then V_1 will take on the new value of V_{TANK} and so forth. This is positive feedback and we have created an oscillator. Connecting an amplifier with low voltage gain to a split tank capacitance leads to the *Colpitts* group of oscillator designs.

It is certainly possible to “split” the inductor instead of the capacitor in a tank circuit and apply the same amplifier trick as before. This is shown in Fig 9.10C and describes the *Hartley* group of oscillators.

9.3.1 LC VFO Circuits

The LC oscillators used in radio equipment are usually designed to be variable frequency oscillators (VFOs). Tuning is achieved by either varying part of the capacitance of the resonator or, less commonly, by using a movable magnetic core to vary the inductance. Since the early days of radio, there has been a huge quest for the ideal, low-drift VFO. Amateurs and professionals have made immense efforts in this pursuit. A brief search of the literature reveals a large number of VFO designs, many accompanied by claims of high stability. The quest for stability has been solved by the development of low-cost frequency synthesizers, which give crystal-controlled stability. Synthesizers are generally noisier than a good VFO, so the VFO still has much to offer in terms of signal cleanliness, cost, and power consumption, making it attractive for homebrew construction. No single VFO circuit has any overwhelming advantage over any other — component quality, mechanical design and the care taken in assembly are much more important.

Fig 9.11 shows three popular oscillator circuits stripped of any non-essential components so they can be more easily compared. The original Colpitts circuit (Fig 9.11A) is now often referred to as the parallel-tuned

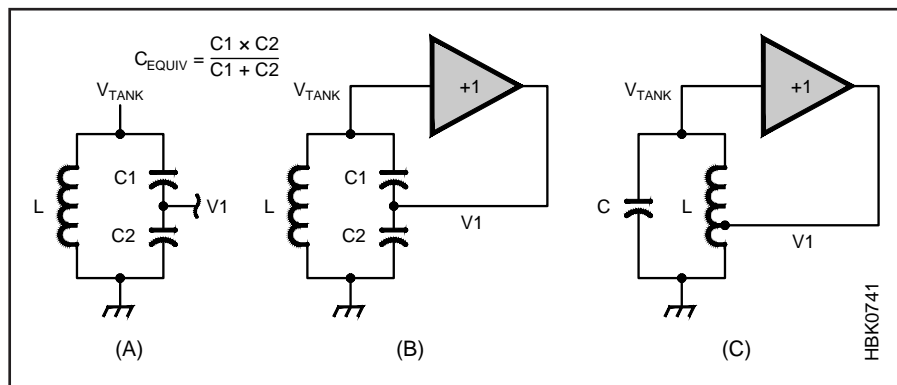

Fig 9.10 — The capacitor in an LC tank circuit (A) can be split into two capacitors with the same equivalent capacitance, C_{EQUIV} , so that the resonant frequency of the tank circuit is unchanged. (B) shows a unity-gain amplifier connected so that it forces $V_1 = V_{TANK}$, creating positive feedback and a Colpitts oscillator results. (C) shows the same technique applied to the tank circuit inductor, creating a Hartley oscillator.

Colpitts because its series-tuned derivative (Fig 9.11B) has become the most common. All three of these circuits use an amplifier with a voltage gain less than unity, but large current gain. The N-channel JFET source follower shown appears to be the most popular current choice.

PARALLEL-TUNED COLPITTS VFO

In the parallel-tuned Colpitts, C_3 and C_4 are large values, perhaps 10 times larger than typical values chosen for C_1 and C_2 to resonate L at the desired frequency. This means only a small fraction of the total tank voltage is applied to the FET gate, and the FET can be considered to be only lightly coupled into the tank. Equally important, the values of C_3 and C_4 must be much larger than the FET device internal capacitances to provide good stability for the output frequency. This keeps small variations in the FET capacitances from having a significant effect on oscillator operation.

The FET is driven by the sum of the voltages across C_3 and C_4 , while it drives the voltage across C_4 alone. This means that the tank operates as a resonant, voltage-step-up transformer compensating for the less-than-unity-voltage-gain amplifier. The resonant circuit consists of L , C_1 , C_2 , C_3 and C_4 . The resonant frequency can be calculated by using the standard formulas for capacitors in series and parallel to find the resultant capacitance effectively connected across the inductor, L , and then use the standard formula for LC resonance:

$$f = \frac{1}{2\pi\sqrt{LC}} \quad (9.1)$$

where

- f = frequency in hertz
- L = total inductance in henries
- C = total capacitance in farads.

Equation 9.1 holds for all cases. Its accuracy is dependent on the designer’s ability to account for all of the contributions to tank inductance and capacitance. There are several rules of thumb that help a VFO designer identify the various “stray” contributions to tank inductance and capacitance:

1. Wherever there is voltage, stray capacitance must be considered.
2. Wherever there is current, stray mutual inductance must be considered.
3. All currents form loops, creating inductance.

These “rules” will help point out where to look for contributions to inductance and capacitance. At frequencies below 10 MHz the actual components you see and touch tend to be all you need to consider. As the oscillator frequency increases, consideration of stray capacitance and stray inductance — reactance effects that are not associated directly with a visible component — becomes increasingly important. If the oscillator frequency is noticeably lower than what you predict from using Eq 9.1, it is almost certain that there are important stray reactances that you need to account for.

Getting back to the circuit of Fig 9.11A, for a wide tuning range C_2 must be kept small to reduce the swamping effect of C_3 and C_4 on the variable capacitor C_1 . (For more information on component selection, the chapters on oscillators in *Experimental Methods for RF Design and Introduction to Radio Frequency Design* listed in the References provide excellent material.) “Swamping” refers to a much larger value component reducing the effect of a small component connected to it.

A parallel-tuned Colpitts oscillator is the subject of the detailed paper “A Design Example for an Oscillator for Best Phase Noise and Good Output Power” by Dr Ulrich

* Reduce value and/or adjust feedback for reliable starting

** Use lowest value that allows reliable starting; 2.7 pF is

Rohde, N1UL, available on the CD-ROM accompanying this book. The paper shows the design process by which both noise and power can be optimized in a simple oscillator.

SERIES-TUNED COLPITTS VFO

The series-tuned Colpitts circuit works in much the same way. The difference is that the variable capacitor, C1, is positioned so that it is well-protected from being swamped by the large values of C3 and C4. In fact, small values of C3, C4 would act to limit the tuning range. Fixed capacitance, C2, is often added across C1 to allow the tuning range to be reduced to that required without interfering with C3 and C4, which set the amplifier coupling. The series-tuned Colpitts has a reputation for better stability than the parallel-tuned original. Note how C3 and C4 swamp the capacitances of the amplifier in both versions.

HARTLEY VFO

The Hartley oscillator of Fig 9.11C is similar to the parallel-tuned Colpitts, but the JFET amplifier source is connected to a tap on the tank inductance instead of the tank capacitance. A typical tap placement is 10% to 20% of the total turns up from the cold end of the inductor. (It's usual to refer to the lowest-signal-voltage end of an inductor as "cold" and the other, with the highest signal voltage as "hot".) C2 limits the tuning range as required.

C3 is reduced to the minimum value that allows reliable starting. This is necessary because the Hartley's lack of the Colpitts' capacitive divider would otherwise couple the FET's internal capacitances to the tank more strongly than in the Colpitts, potentially affecting the circuit's frequency stability.

VFO DESIGN NOTES

Generally, VFOs can be adapted to work at other frequencies (within the limits of the active device). To do so, compute an adjustment factor: f_{old} / f_{new} . Multiply the value of each frequency determining or feedback L or C by that factor. As frequency increases and amplifier gain drops, it may be required to increase feedback more than indicated by the factor.

In all three circuits, there is a 1 kΩ resistor in series with the source bias circuit. This resistor does a number of desirable things. It spoils (lowers) the Q of the inevitable low-frequency resonance of the choke with the tank tap circuit. It reduces tuning drift due to choke impedance and winding capacitance variations. It also protects against spurious oscillation at undesired frequencies due to internal choke resonances. Less obviously, it acts to stabilize the loop gain of the built-in AGC action of this oscillator. Stable operating conditions act to reduce frequency drift.

Fig 9.11 — The Colpitts (A), series-tuned Colpitts (B) and Hartley (C) oscillator circuits. Rules of thumb: C3 and C4 at A and B should be equal and valued such that their $X_C = 45 \Omega$ at the operating frequency; for C2 at A, $X_C = 100 \Omega$. For best stability, use C0G or NP0 units for all capacitors associated with the FETs' gates and sources. Depending on the FET chosen, the 1-kΩ source-bias-resistor value shown may require adjustment for reliable starting.

Some variations of these circuits may be found with added resistors providing a dc bias to stabilize the system quiescent current. More elaborate still are variations characterized by a constant-current source providing bias. This can be driven from a separate AGC detector system to give very tight level control. The gate-to-ground clamping diode (1N914 or similar) long used by radio amateurs as a means of avoiding gate-source conduction has been shown by Dr Ulrich Rohde, N1UL, to degrade oscillator phase-noise performance, and its use is virtually unknown in professional circles.

Fig 9.12 shows two more VFOs to illustrate the use of different devices. The vacuum-tube triode Hartley shown features permeability tuning, which has no sliding contact like that of a capacitor's rotor and can be made reasonably linear by artfully spacing the coil turns. The slow-motion drive can be done with a screw thread. The disadvantage is that special care is needed to avoid backlash and eccentric rotation of the core. If a non-rotating core is used, the slides have to be carefully designed

to prevent motion in unwanted directions. The Collins Radio Company made extensive use of tube-based permeability tuners, and a semiconductor version can still be found in a number of Ten-Tec radios.

Vacuum tubes cannot run as cool as competitive semiconductor circuits, so care is needed to keep the tank circuit away from the tube heat. In many amateur and commercial vacuum-tube oscillators, oscillation drives the tube into grid current at the positive peaks, causing rectification and producing a negative grid bias. The oscillator thus runs in Class C, in which the conduction angle reduces as the signal amplitude increases until the amplitude stabilizes. As in the FET circuits of Fig 9.11, better stability and phase-noise performance can be achieved in a vacuum-tube oscillator by moving its operating point out of true Class C — that is, by including a bypassed cathode-bias resistor (the resistance appropriate for Class A operation is a good starting value). Vacuum-tube radios are still maintained in operation and occasionally constructed for enjoyment but the

semiconductor long ago achieved dominance in VFOs.

Compared to the more frequently used JFET, bipolar transistors like the one used in Fig 9.12B are relatively uncommon in oscillators because their relatively low input and output impedances are more difficult to couple into a high-Q tank without loading it excessively. Bipolar devices do tend to give better sample-to-sample amplitude uniformity for a given oscillator circuit, because many of the bipolar transistor characteristics are due less to manufacturing than physics. This is not true for JFETs of any given type; JFETs tend to vary more in their characteristics because manufacturing variations directly affect their threshold or pinch-off voltage.

SQUEGGING

The effect called *squegging* (or *squeezing*) can be loosely defined as oscillation on more than one frequency at a time, but may also manifest itself as RF oscillation interrupted at an audio frequency rate, as in a super-regenerative detector. One form of squegging occurs when an oscillator is fed from a power supply with high source impedance. The power supply charges up the decoupling capacitor until oscillation starts. The oscillator draws current and pulls down the capacitor voltage until it has starved itself of power and oscillation stops. The oscillator stops drawing current and the decoupling capacitor then recharges until oscillation restarts. The process, the low-frequency cycling of which is a form of relaxation oscillation, repeats indefinitely. The oscillator output can clearly be seen to be pulse modulated with an oscilloscope.

Squegging can be a consequence of poor design in battery-powered radios. As the cells become exhausted, their internal resistance often rises and circuits that they power can begin to misbehave. In audio stages, such misbehavior may manifest itself in the “putt-putt” sound of the slow relaxation oscillation called “motorboating.”

9.3.2 RC VFO Circuits

Due to the requirements for physical length and area to create inductance, actual inductors cannot be reduced in size to the degree required for use in RF integrated circuits. Resistors and capacitors can be made very small, a fraction of a percent of the size of any inductor. Since size is money in RF integrated circuits, there is a great motivation to eliminate inductors. The problem is that any oscillator without an inductor must use resistors to develop the necessary phase shift, and resistors add loss and noise.

A 180° phase-shift network and an inverting amplifier can be used to make an oscillator with the required 360° of phase shift. A single-stage RC low-pass network cannot

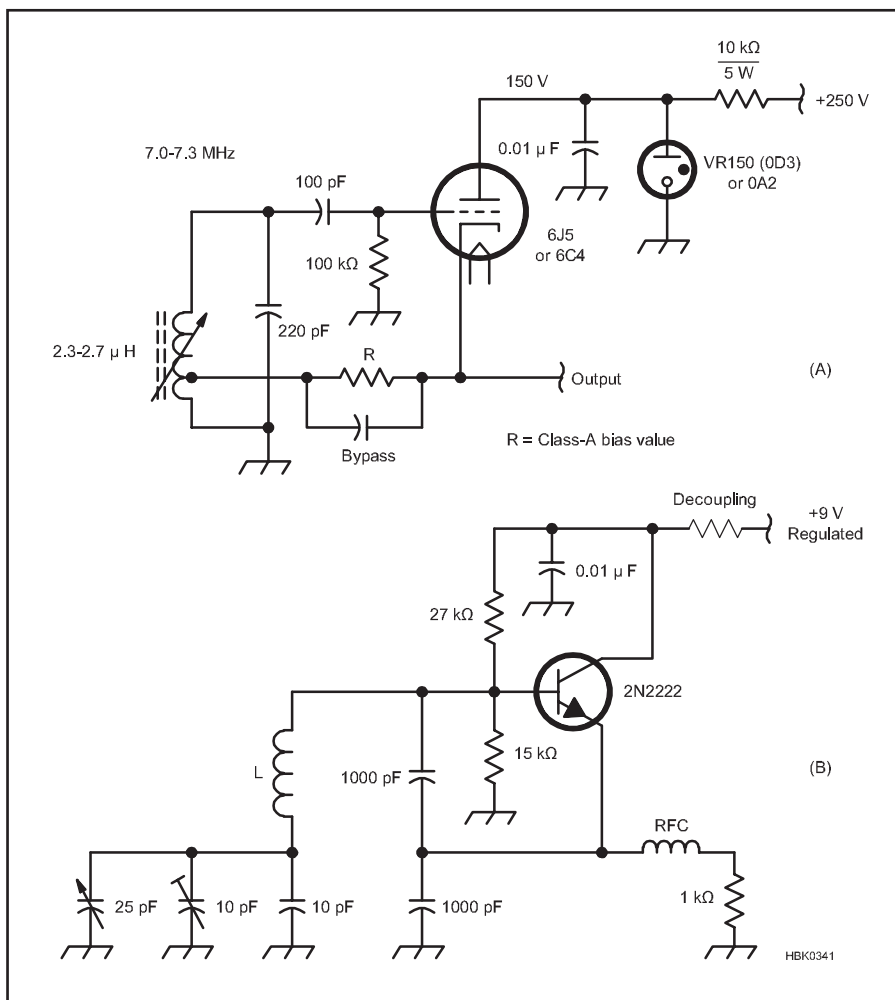

Fig 9.12 — Two additional oscillator examples: at A, a triode-tube Hartley; at B, a bipolar junction transistor in a series-tuned Colpitts.

produce more than 90° of phase shift and only approaches that as the signal becomes infinitely attenuated. Two stages can only approach 180° and then also with immense attenuation. A practical RC phase-shift oscillator requires three stages to produce 180° of phase shift without destroying the loop gain. **Fig 9.13A** shows the basic form of the phase-shift oscillator; Fig 9.13B is an example of a phase-shift oscillator commonly used in commercial transceivers as an audio sidetone oscillator.

An RC oscillator can be made extremely small and to tune over a huge bandwidth (1000:1 is common). Unfortunately, Q of the phase-shift circuit is less than one, giving very poor noise performance that's unsuitable even to the least-demanding RF application.

RC oscillators are common though in digital clock generators. A common example uses a Schmitt trigger inverter as shown in Fig 9.13C. (See the discussion of comparators in the **Analog Basics** chapter.) This oscillator alternately charges and discharges the capacitor through the feedback resistor. Oscillation is assured because the inverter has hysteresis: the threshold at which output switches high is lower than the threshold at which the output switches low. The voltage across the capacitor moves between these two switching thresholds. The tuning bandwidth is the ratio of the fixed feedback resistor value to its sum with the potentiometer at full value. The ratio can be as high as 1000:1.

9.3.3 Three High-Performance HF VFOs

THE N1UL MODIFIED VACKAR VFO

The oscillator circuit of **Fig 9.14A** is contributed by Dr Ulrich Rohde, N1UL. It is a modified Vackar design (see the sidebar) in which a small coupling capacitor (8 pF) and voltage divider capacitor (18 pF) isolate the resonator circuit (10 μH and 50 pF tuning capacitor) from the oscillator transistor.

The oscillator transistor is followed by a buffer stage to isolate the oscillator from the load. Because the coupling between the transistor base and the resonator is fixed and light, stability of the oscillator is high across a wide tuning range from 5.5 to 6.6 MHz. Either the inductor or capacitor may be varied to tune the oscillator, but a variable capacitor is recommended as more practical and gives better performance.

Because of the oscillator transistor's large capacitors from base to ground (220 pF) and collector to ground (680 pF), the various parameters of the oscillator transistor have little practical influence on circuit performance. The widely available 2N3904 performs well for both the oscillator and buffer transistors.

Practical resonator coil and the tuning capacitors will have a positive temperature

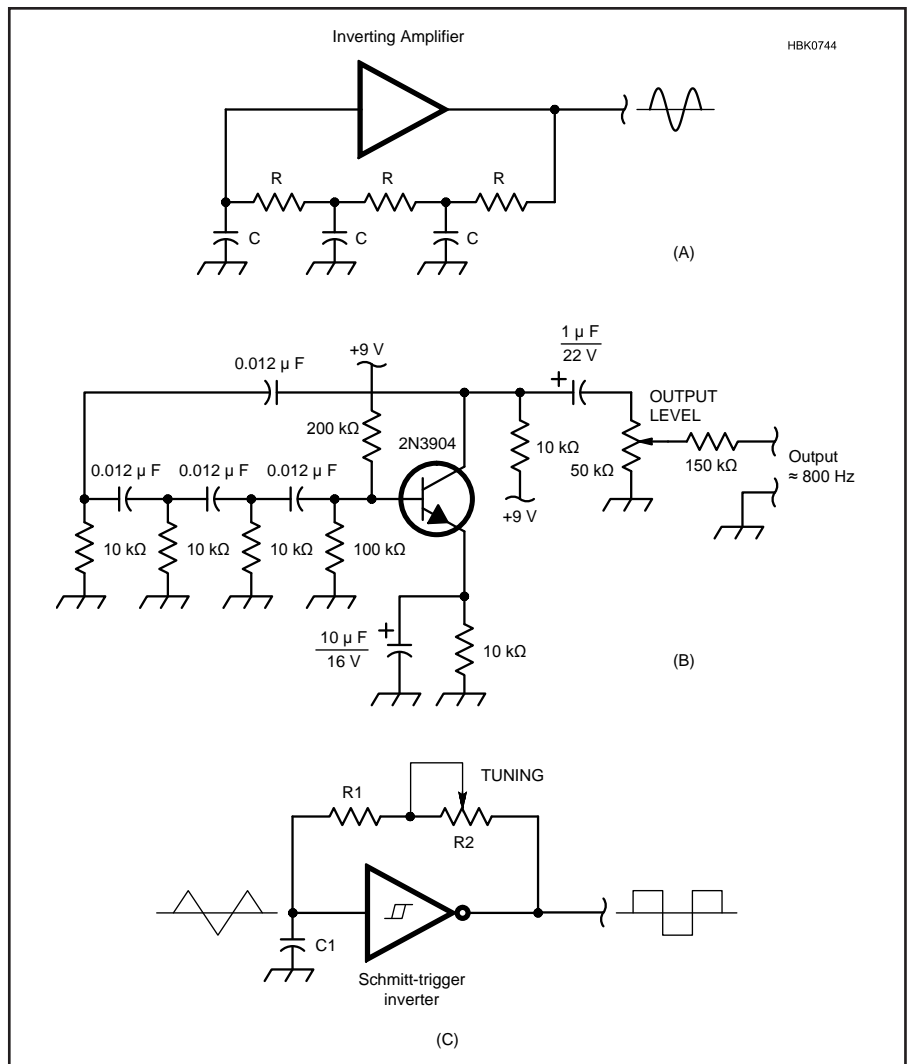

Fig 9.13 — In the basic phase-shift oscillator (A), a chain of RC networks — three or more — provide the feedback and phase shift necessary for oscillation, at the cost of low Q and considerable loop loss. Many commercial transceivers have used a phase-lead oscillator similar to that shown at B as a sidetone generator. Using a single RC circuit with a Schmitt trigger at C produces a simple oscillator with a very wide tuning range and a square wave output.

coefficient. The 8 pF and the 18 pF capacitors should have an N150 temperature coefficient to partially compensate for their drift. After 1 hour, the observed frequency drift for this circuit was less than 10 Hz / hour.

THE K7HFD LOW-NOISE DIFFERENTIAL OSCILLATOR

The other high performance oscillator example, shown in **Fig 9.15**, is designed for low-noise performance by Linley Gumm, K7HFD, and appears on page 126 of the ARRL's *Solid State Design for the Radio Amateur* (out of print, but available used and through libraries). This circuit uses no unusual components and looks simple, yet it is a subtle and sophisticated circuit.

The effects of limiting in reducing AM oscillator noise were covered previously. However, because AM noise sidebands can

The Vackar Oscillator

The original Vackar oscillator is named for Jirí Vackár, who invented the circuit in the late 1940s. The circuit's description — a refinement of the Clapp oscillator — can be found in older editions of the Radio Society of Great Britain's *Radio Communication Handbook*, with some further comments on the oscillator in RSGB's *Amateur Radio Techniques*. The circuit is also described in the Nov 1955 *QST* "Technical Correspondence" column by W9IK. The Vackar circuit optimized the Clapp oscillator for frequency stability: the oscillator transistor is isolated from the resonator, tuning does not affect the feedback coupling, and the transistor's collector output impedance is kept low so that gain is the minimum necessary to sustain oscillation.

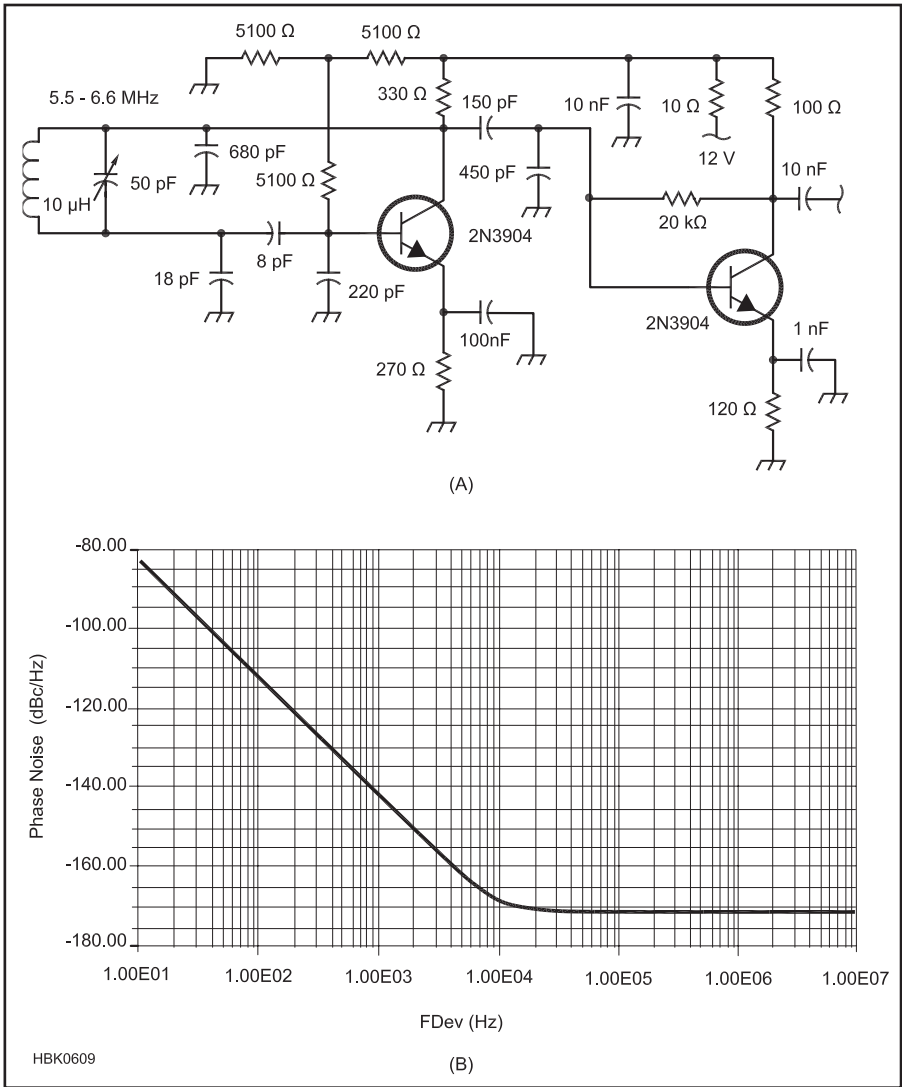

Fig 9.14 — At A, N1UL's Modified Vackar VFO is tuned from 5.5 to 6.6 MHz using the 50 pF capacitor. Tuning may be restricted to narrower ranges by placing a fixed capacitor in parallel with a smaller variable capacitor. The resonant frequency of the oscillator is determined by the 10 µH inductor and 50 pF tuning capacitor. B shows the excellent phase noise performance of the modified Vackar VFO in this *Harmonica* simulation. At 1 kHz from the carrier, noise is -144 dBc.

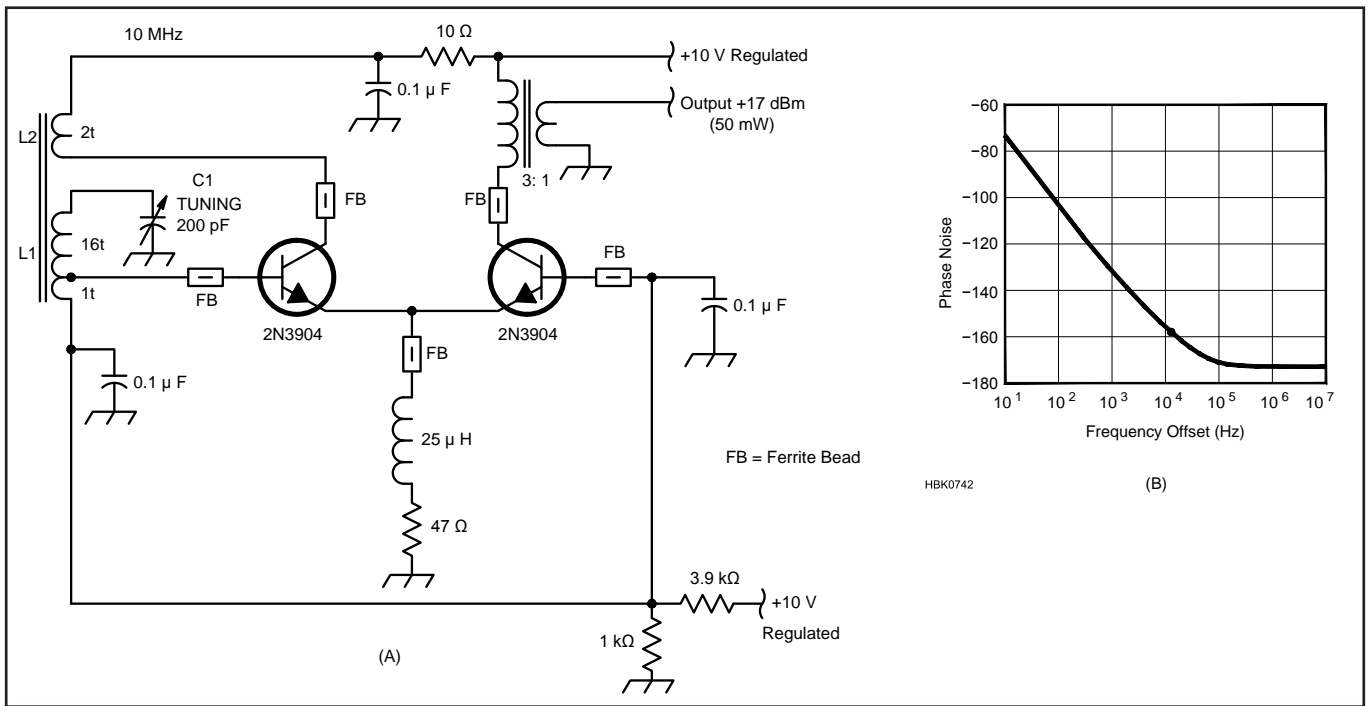

Fig 9.15 — At A, this low-noise oscillator design by K7HFD operates at an unusually high power level to achieve a high C/N (carrier-to-noise) ratio. L1 is 1.2 µH and uses 17 turns of wire on a T-68-6 toroid core. The tap is at 1 turn. Q at 10 MHz is 160. L2 is a 2 turn link over L1. At B, modeling of the differential oscillator by Dr Ulrich Rohde, N1UL, shows its excellent phase-noise performance.

get translated into PM noise sidebands by imperfect limiting, there is an advantage to stripping off the AM as early as possible, in the oscillator itself. An ALC system in the oscillator will counteract and cancel only the AM components within its bandwidth, but an oscillator based on a limiter will do this over a broad bandwidth. K7HFD's oscillator uses a differential pair of bipolar transistors as a limiting amplifier. The dc bias voltage at the bases and the resistor in the common emitter path to ground establishes a controlled dc bias current, here 25 to 27 mA. The ac voltage between the bases switches this current between the two collectors. This applies a rectangular pulse of current into link winding L2, which drives the series-resonant tank L1-C1. The output impedance of the collector is high in both the current-on and current-off states. Along with the small number of turns of the link winding, this presents very high impedance to the tank circuit, which minimizes degradation of the tank Q. The input impedance of this limiter is also quite high and is applied across only a

one-turn tap of L1, which similarly minimizes any impact on the tank Q. The input transistor base is driven into conduction only on one peak of the tank waveform. The output transformer has the inverse of the current pulse applied to it, so the output is not a low distortion sine wave, although the output harmonics will not be as extensive as simple theory would suggest because the circuit's high output impedance allows stray capacitances to attenuate high-frequency components. The low-frequency transistors used here also act to reduce the harmonic power.

With an output of +17 dBm, this is a power oscillator, running with nearly 300 mW of dc input power, so appreciable heating is present that can cause temperature-induced drift. The circuit's high-power operation is a deliberate ploy to create a high signal-to-noise ratio by having as high a signal power as possible. This also reduces the problem of the oscillator's broadband noise output. The limitation on the signal level in the tank is the transistors' base-emitter-junction breakdown

voltage. The circuit runs with a few volts peak-to-peak across the one-turn tap, so the full tank is running at over 50 V_{p-p}.

Excessive voltage levels for the transistors can easily be generated by this circuit. The single easiest way to damage a bipolar transistor is to reverse bias the base-emitter junction until it avalanches. Most devices are rated to withstand only 5 V applied this way, the current needed to do damage is small, and very little power is needed. If the avalanche current is limited to less than that needed to perform immediate destruction of the transistor, it is likely that there will be some degradation of the device, a reduction in its bandwidth and gain along with an increase in its noise. These changes are irreversible and cumulative. Small, fast signal diodes have breakdown voltages of over 30 V and less capacitance than the transistor bases, so one possible experiment would be to try the effect of adding a fast signal diode in series with the base of each transistor and running the circuit at even higher levels.

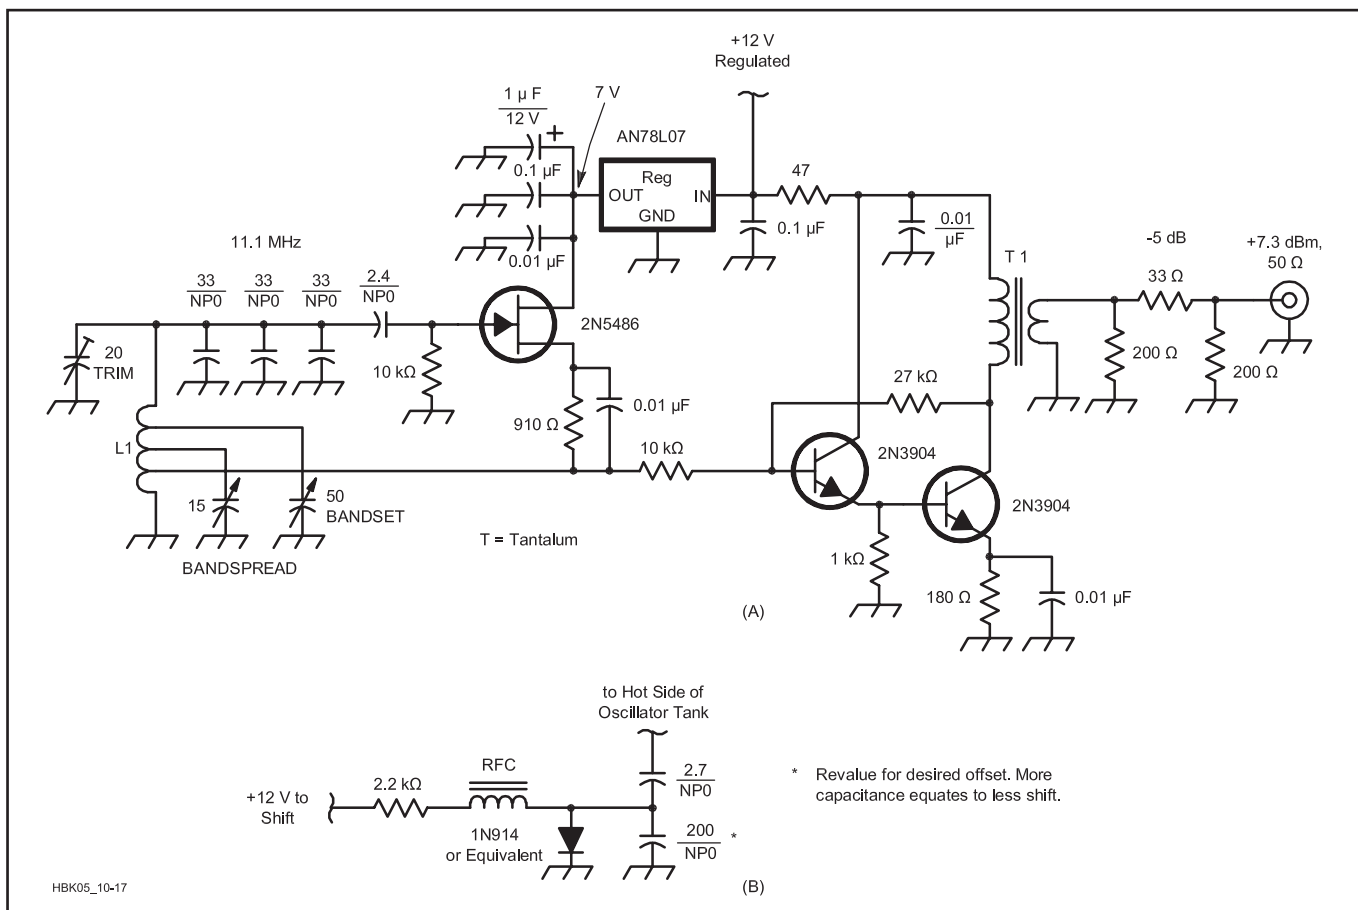

Fig 9.16 — Incorporating ideas from N1UL, KA7EXM, W7ZOI and W7EL, the oscillator at A achieves excellent stability and output at 11.1 MHz without the use of a gate-clamping diode, as well as end-running the shrinking availability of reduction drives through the use of bandset and bandspread capacitors. L1 consists of 10 turns of B & W #3041 Miniductor (#22 tinned wire, 5/8 inch in diameter, 24 turns per inch). The source tap is 2½ turns above ground; the tuning-capacitor taps are positioned as necessary for bandset and bandspread ranges required. T1's primary consists of 15 turns of #28 enameled wire on an FT-37-72 ferrite core; its secondary, 3 turns over the primary. B shows a system for adding fixed TR offset that can be applied to any LC oscillator. The RF choke consists of 20 turns of #26 enameled wire on an FT-37-43 core.

The oscillation amplitude is controlled by the drive current limit. The voltage on L2 must never allow the collector of the transistor driving it to go into saturation, for if this happens the transistor presents very low impedance to L2 and badly loads the tank, wrecking the Q and the noise performance. The circuit can be checked to verify the margin from saturation by probing the hot end of L2 and the emitter with an oscilloscope. Another, less obvious, test is to vary the power-supply voltage and monitor the output power. While the circuit is under current control, there is very little change in output power, but if the supply is low enough to allow saturation, the output power will change significantly with varying supply voltage.

The use of the 2N3904 is interesting, as it is not normally associated with RF oscillators. It is a cheap, plain, general-purpose type more often used at dc or audio frequencies. There is evidence that suggests some transistors that have good noise performance at RF have worse noise performance at low frequencies, and that the low-frequency noise they create can modulate an oscillator, creating noise sidebands. Experiments with low-noise audio transistors may be worthwhile, but many such devices have high junction capacitances.

In the description of this circuit in *Solid State Design for the Radio Amateur*, the results of a phase-noise test made using a spectrum analyzer with a crystal filter as a pre-selector are given. Ten kilohertz out from the carrier, in a 3 kHz measurement bandwidth, the noise was more than 120 dB below the carrier level. This translates into better than $-120 - 10 \log(3000)$, which equals -154.8 dBc/Hz, SSB, consistent with the modeled phase noise performance shown in Fig 9.15B. At this offset, -140 dBc is usually considered

VFO Construction

These suggestions by G3PDM can be applied to any analog VFO circuit. Following these guidelines minimizes the effects of temperature change and mechanical vibration (microphonics) on the VFO.

- Use silvered-mica or other highly-stable capacitors for all fixed-value capacitors in the oscillator circuit. Power-supply decoupling capacitors may be any convenient type, such as ceramic or film.
- Tuning capacitors should be a high-quality component with double ball-bearings and silver-plated surfaces and contacts.
- The resonant circuit inductor should be wound on a ceramic form and solidly mounted.
- All oscillator components should be clean and attached to a solid support to minimize thermal changes and mechanical vibration.
- The enclosure should be solid and isolated from mechanical vibration.
- The power supply should be well-regulated, liberally decoupled and free of noise.
- Keep component leads short and if point-to-point wiring is employed, use heavy wire (#16 to #18 AWG).
- Single-point grounding of the oscillator components is recommended to avoid stray inductance and to minimize noise introduced from other sources. If a PCB is used, include a ground-plane.

to be excellent. This VFO provides state-of-the-art performance by today's standards — in a 1977 publication.

A JFET HARTLEY VFO

Fig 9.16 shows an 11.1 MHz version of a VFO and buffer closely patterned after that used in 7 MHz transceiver designs published by Roger Hayward, KA7EXM, and Wes Hayward, W7ZOI (“The Ugly Weekender”) and Roy Lewallen, W7EL (“The Optimized QRP Transceiver”). In it, a Hartley oscillator using a 2N5486 JFET drives the two-2N3904 buffer attributed to Lewallen. This version diverges from the originals in that its JFET uses source bias (the bypassed 910 Ω resistor) instead of a gate-clamping diode and is powered from a low-current 7 V regulator

IC instead of a Zener diode and dropping resistor. The 5 dB pad sets the buffer's output to a level appropriate for “Level 7” (+7 dBm LO) diode ring mixers.

The circuit shown was originally built with a gate-clamping diode, no source bias and a 3 dB output pad. Adjusting the oscillator bias as shown increased its output by 2 dB without degrading its frequency stability (200 to 300 Hz drift at power up, stability within ± 20 Hz thereafter at a constant room temperature).

In recognition that precision mechanical tuning components are hard to obtain, the resonator uses “Bandset” and “Bandspread” variable capacitors. These terms are from the early days of radio: bandset is for coarse-tuning and bandspread is for fine-tuning.

9.4 Building an Oscillator

We've covered a lot of ground about how oscillators work, their limitations and a number of interesting circuits, so the inevitable question arises of how to design one. Let's make an embarrassing confession right here: Very few oscillators you see in published circuits or commercial equipment were designed by the equipment's designer. Almost all have been adopted from other sources. While recycling in general is important for the environment, it means in this case that very few professional or amateur designers have ever designed an oscillator from scratch. We all have collections of circuits we've “harvested,” and we adjust a few values or change a device type to produce something to suit a new project.

Oscillators aren't designed, they evolve. They seem to have a life of their own. The

Clarke & Hess book listed in the references contains one of the few published classical design processes. The ARRL book *Experimental Methods in RF Design* contains extensive material on oscillator circuits that is well worth reading. A demonstration by David Stockton, GM4ZNX, of oscillator design based on a simulation of how oscillators start up by the free *LTSpice* simulation program is available on the CD-ROM.

9.4.1 VFO Components and Construction

TUNING CAPACITORS AND REDUCTION DRIVES

As most commercially made radios now use frequency synthesizers, it has become

increasingly difficult to find certain key components needed to construct a good VFO. Slow-motion drives and variable capacitors are available from *QST* advertiser National RF (www.nationalrf.com), Dan's Small Parts and Kits (www.danssmallpartsandkits.net), and Antique Electronic Supply (www.tubesandmore.com). An alternate approach is also available: Scavenge suitable parts from old equipment; use tuning diodes instead of variable capacitors — an approach that, if uncorrected through phase locking, generally degrades stability and phase-noise performance; or use two tuning capacitors, one with a capacitance range $\frac{1}{5}$ to $\frac{1}{10}$ that of the other, in a bandset/bandspread approach.

Assembling a variable capacitor to a chassis and its reduction drive to a front panel

can result in *backlash* — an annoying tuning effect in which rotating the capacitor shaft deforms the chassis and/or panel rather than tuning the capacitor. One way of minimizing this is to use the reduction drive to support the capacitor, and use the capacitor to support the oscillator circuit board, which is then attached to the chassis.

FIXED CAPACITORS

Traditionally, silver-mica fixed capacitors have been used extensively in oscillators, but their temperature coefficient is not as low as can be achieved with other types, and some silver micas have been known to behave erratically. Polystyrene film has become a proven alternative. One warning is worth noting: polystyrene capacitors exhibit a permanent change in value should they ever be exposed to temperatures much above 70 °C; they do not return to their old value on cooling. Particularly suitable for oscillator construction are the low-temperature-coefficient ceramic capacitors, often described as NP0 or C0G types. (NP0 and

C0G are equivalent) These names are actually temperature-coefficient codes. **Fig 9.17** contains graphs showing the behavior of three common temperature coefficients. Some ceramic capacitors are available with deliberate, controlled temperature coefficients so that they can be used to compensate for other causes of frequency drift with temperature. For example, the code N750 denotes a part with a temperature coefficient of -750 parts per million per degree Celsius. These parts are now somewhat difficult to obtain, so other methods are needed. (Values for temperature coefficients and other attributes of capacitors are presented in the **Component Data and References** chapter.)

In a Colpitts circuit, the two large-value capacitors that form the voltage divider for the active device still need careful selection. It is tempting to use any available capacitor of the right value, because the effect of these components on the tank frequency is reduced by the proportions of the capacitance values

in the circuit. This reduction is not as great as the difference between the temperature stability of an NP0 ceramic part and some of the low-cost, decoupling-quality X7R-dielectric ceramic capacitors. It's worth using low-temperature coefficient parts even in the seemingly less-critical parts of a VFO circuit — even for the bypass capacitors. Chasing the cause of temperature drift is more challenging than fun. Buy critical components like high-stability capacitors from trustworthy sources.

TUNING CAPACITOR NETWORKS

Often an available variable capacitor has greater capacitance than required for a desired frequency range. While plates can sometimes be removed, a better solution embeds the variable capacitor in a network of fixed capacitors. The evolution of this network is shown in the middle section of **Fig 9.18**. The variable capacitor, C_V and C_2 are paralleled to form the equivalent C_{2V} . This is then placed in series with C_1 for the equivalent C_{12V} . This

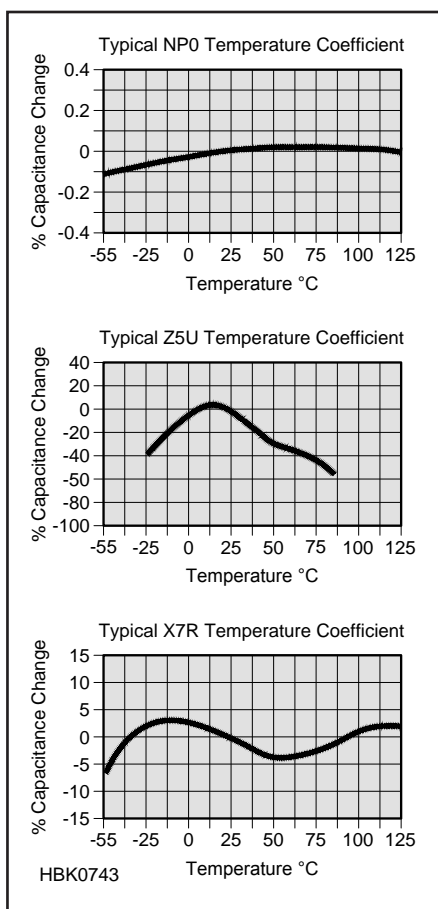

Fig 9.17 — EIA capacitor temperature coefficients specify change in capacitance with temperature. See the Component Data and References chapter for a complete table of temperature coefficient identifiers and characteristics.

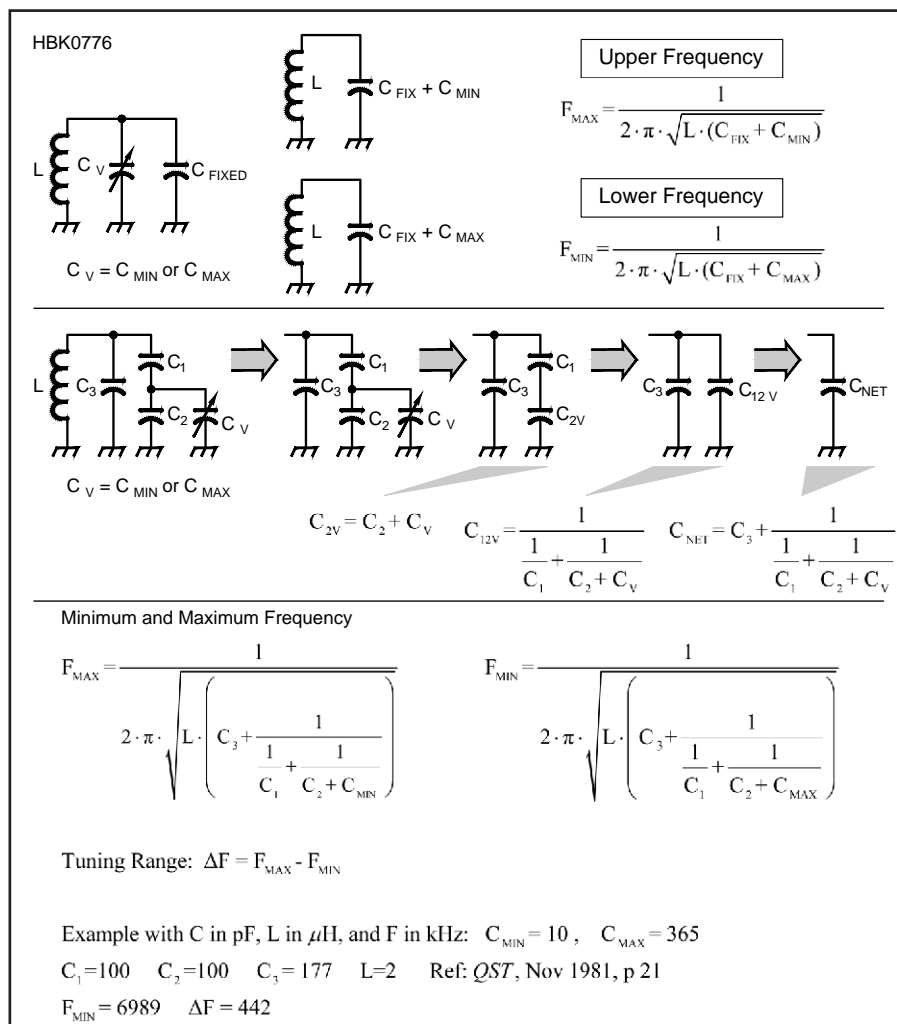

Fig 9.18 — A simple resonant circuit is tuned with parallel capacitors as shown in the top section. The tuning range is controlled by the ratio of the variable capacitance to the fixed capacitance.

is, in turn, paralleled by C_3 to form the total capacitor, C_{NET} . The overall frequency is calculated from the usual resonance relationship. The equations are shown, with capacitance in farads, inductance in henries, and frequency in Hz.

There is considerable flexibility available to the designer, afforded by picking C_1 and C_2 values. Some combinations with C_1 much smaller than the variable capacitor can produce highly nonlinear tuning.

INDUCTORS

Ceramic coil forms can give excellent results, as can self-supporting air-wound coils (Miniductor). If you use a magnetic core, support it securely and use powdered iron. Do not use ferrite because of its temperature instability. Stable VFOs have been made using toroidal cores. Micrometals mix #6 has a low temperature coefficient and works well in conjunction with NP0 ceramic capacitors. Coil forms in other materials have to be assessed on an individual basis.

A material's temperature stability will not be apparent until you try it in an oscillator, but you can apply a quick test to identify those nonmetallic materials that are lossy enough to spoil a coil's Q. Put a sample of the coil-form material into a microwave oven along with a glass of water and cook it about 10 seconds on low power. Do not include any metal fittings or ferromagnetic cores. Good materials will be completely unaffected; poor ones will heat and may even melt, smoke, or burst into flame. (This operation is a fire hazard if you try more than a tiny sample of an unknown material. Observe your experiment continuously and do not leave it unattended!)

W7ZOI suggests annealing toroidal VFO coils after winding. W7EL reports achieving success with this method by boiling his coils in water and letting them cool in air.

VOLTAGE REGULATORS

VFO circuits are often run from locally regulated power supplies, usually from resistor/Zener diode combinations. Zener diodes have some idiosyncrasies that could spoil the oscillator. They are noisy, so decoupling is needed down to audio frequencies to filter this out. Zener diodes are often run at much less than their specified optimum bias current. Although this saves power, it results in a lower output voltage than intended and the diode's impedance is much greater, increasing its sensitivity to variations in input voltage, output current and temperature. Some common Zener types may be designed to run at as much as 20 mA; check the data sheet for your diode family to find the optimum current.

True Zener diodes are low-voltage devices; above a couple of volts, so-called Zener diodes are actually avalanche types. The temperature coefficient of these diodes depends on their breakdown voltage and crosses through zero for diodes rated at about 5 V. If you intend to use nothing fancier than a common-variety Zener, designing the oscillator to run from 5 V and using a 5.1 V Zener will give you a free advantage in voltage-versus-temperature stability.

There are some diodes available with especially low temperature coefficients, usually referred to as reference or temperature-compensated diodes. These usually consist of a series pair of diodes designed to cancel each other's temperature drift. The 1N821A

diode has a temperature coefficient of ± 100 ppm/ $^{\circ}\text{C}$. Running at 7.5 mA, the 1N829A provides $6.2\text{ V} \pm 5\%$ and a temperature coefficient of just ± 5 parts per million (ppm) maximum per degree Celsius. A change in bias current of 10% will shift the voltage less than 7.5 mV, but this increases rapidly for greater current variation. The curves in Fig 9.19 show how the temperature coefficients of these diodes are dependent on bias current.

The LM399 is a complex IC that behaves like a superb Zener at 6.95 V, ± 0.3 ppm/ $^{\circ}\text{C}$. Precision, low-power, three-terminal regulators are also available that are designed to be used as voltage references, some of which can provide enough current to run a VFO. There are comprehensive tables of all these devices between pages 334 and 337 of Horowitz and Hill, *The Art of Electronics, 2nd ed.*

OSCILLATOR DEVICES

The 2N3819 FET, a classic from the 1960s, has proven to work well in VFOs but, like the MPF102 which is also long-popular with ham builders, it is manufactured to wide tolerances. Considering an oscillator's importance in receiver stability, you should not hesitate to spend a bit more on a better device. The 2N5484, 2N5485 and 2N5486 are worth considering; together, their transconductance ranges span that of the MPF102, but each is a better-controlled subset of that range. The 2N5245 is a more recent device with better-than-average noise performance that runs at low currents like the 2N3819. The 2N4416/A, also available as the plastic-cased PN4416, is a low-noise device, designed for VHF/UHF amplifier use, which has been featured in a

Fig 9.19 — The temperature coefficient of temperature-compensated diodes varies with bias current. To obtain the best temperature performance, use the specific bias current for the diode.

number of good oscillators up to the VHF region. Its low internal capacitance contributes to low frequency drift. The J310 (plastic; the metal-cased U310 is similar) is another popular JFET for use in oscillators.

The 2N5179 (plastic, PN5179 or MPS5179) is a bipolar transistor capable of good performance in oscillators up to the top of the VHF region. Care is needed because its absolute-maximum collector-emitter voltage is only 12 V, and its collector current must not exceed 50 mA. Although these characteristics may seem to convey fragility, the 2N5179 is sufficient for circuits powered by stabilized 6 V power supplies.

VHF-UHF capable transistors are not really necessary in LC VFOs because such circuits are rarely used above 10 MHz. (High-bandwidth transistors also increase high-frequency harmonic content in the output signal.) Absolute frequency stability is progressively harder to achieve with increasing frequency, so free-running oscillators are used only rarely to generate VHF-UHF signals for radio communication. Instead, VHF-UHF radios usually use voltage-tuned, phase-locked oscillators in some form of synthesizer. Bipolar devices like the BFR90 and MRF901, with f_T in the 5 GHz region and mounted in stripline packages, are needed for successful oscillator design at UHF.

The popular SA/NE602 mixer IC has a built-in oscillator and can be found in many published circuits. This device has separate input and output pins to the tank and has proved to be quite tame. It may not have been "improved" yet (so far, it has progressed from the SA/NE602 to the SA/NE602A, the A version affording somewhat higher dynamic range than the original SA/NE602). It might be a good idea for anyone laying out a board using one to take a little extra care to keep PCB traces short in the oscillator section to build in some safety margin so that the board can be used reliably in the future. Experienced (read: "bitten") professional designers know that their designs are going to be built for possibly more than 10 years and have learned to make allowances for the progressive improvement of semiconductor manufacture.

9.4.2 Temperature Compensation

The general principle for creating a high-stability VFO is to use components with minimal temperature coefficients in circuits that are as insensitive as possible to changes in components' secondary characteristics. Even after careful minimization of the causes of temperature sensitivity, further improvement can still be desirable. The traditional method was to split one of the capacitors in the tank so that it could be apportioned between low-temperature-coefficient parts

and parts with deliberate temperature dependency. Only a limited number of different, controlled temperature coefficients are available, so the proportioning between low coefficient and controlled coefficient parts was varied to "dilute" the temperature sensitivity of a part more sensitive than desired. This is a tedious process, involving much trial and error, an undertaking made more complicated by the difficulty of arranging means of heating and cooling the unit being compensated. (Hayward described such a means in December 1993 *QST*.) As commercial and military equipment have been based on frequency synthesizers for some time, supplies of capacitors with controlled temperature sensitivity are drying up. An alternative approach is needed.

A temperature-compensated crystal oscillator (TCXO) is an improved-stability version of a crystal oscillator that is used widely in industry. Instead of using controlled-temperature coefficient capacitors, most TCXOs use a network of thermistors and normal resistors to control the bias of a tuning diode. Manufacturers measure the temperature vs. frequency characteristic of sample oscillators, and then use a computer program to calculate the optimum normal resistor values for production. This can reliably achieve at least a tenfold improvement in stability. We here are not interested in mass manufacture, but the idea of a thermistor tuning a varactor is worth adopting. The parts involved are likely to be available for a long time.

Browsing through component suppliers' catalogs shows ready availability of 4.5 to 5 k Ω bead thermistors intended for temperature-compensation purposes, at less than a

dollar each. **Fig 9.20** shows a circuit based on this form of temperature compensation. Commonly available thermistors have negative temperature coefficients, so as temperature rises, the voltage at the counterclockwise (CCW) end of R8 increases, while that at the clockwise (CW) end drops. Somewhere near the center there is no change. Increasing the voltage on the tuning diode decreases its capacitance, so settings toward R8's CCW end simulate a negative-temperature-coefficient capacitor; toward its clockwise end, a positive-temperature-coefficient part. Choose R1 to pass 8.5 mA from whatever supply voltage is available to the 6.2 V reference diode, D1. The 1N821A/1N829A-family diode used has a very low temperature coefficient and needs 7.5 mA bias for best performance; the bridge takes the other 1 mA. R7 and R8 should be good-quality multi-turn trimmers. D2 and C1 need to be chosen to suit the oscillator circuit. Choose the least capacitance that provides enough compensation range. This reduces the noise added to the oscillator. (It is possible, though tedious, to solve for the differential varactor voltage with respect to R2 and R5, via differential calculus and circuit theory. The equations in Hayward's 1993 article can then be modified to accommodate the additional capacitors formed by D2 and C1.) Use a single ground point near D2 to reduce the influence of ground currents from other circuits. Use good-quality metal-film components for the circuit's fixed resistors.

The novelty of this circuit is that it is designed to have an easy and direct adjustment process. The circuit requires two adjustments, one at each of two different temperatures, and achieving them requires a stable frequency

Fig 9.20 — Oscillator temperature compensation is difficult because of the scarcity of negative-temperature-coefficient capacitors. This circuit by GM4ZNX uses a bridge containing two identical thermistors to steer a tuning diode for drift correction. The 6.2 V Zener diode used (a 1N821A or 1N829A) must be a temperature-compensated part; just any 6.2 V Zener will not do.

counter that can be kept far enough from the radio so that the radio, not the counter, is subjected to the temperature extremes. (Using a receiver to listen to the oscillator under test can speed the adjustments.) After connecting the counter to the oscillator to be corrected, run the radio containing the oscillator and compensator in a room-temperature, draft-free environment until the oscillator's frequency reaches its stable operating temperature (rise over the ambient temperature). Lock its tuning, if possible. Adjust R7 to balance the bridge. This causes a drop of 0 V across R8, a condition you can reach by winding R8 back and forth across its range while slowly adjusting R7. When the bridge is balanced and 0 V appears across R8, adjusting R8 causes no frequency shift. When you've found this R7 setting, leave it there, set R8 to the exact center of its range and record the oscillator frequency.

Run the radio in a hot environment and allow its frequency to stabilize. Adjust R8 to restore the frequency to the recorded value. The sensitivity of the oscillator to temperature should now be significantly reduced between the temperatures at which you performed the adjustments. You will also have somewhat improved the oscillator's stability outside this range.

For best results with any temperature-compensation scheme, it's important to group all the oscillator and compensator components in the same enclosure, avoiding differences in airflow over components. A good oscillator should not dissipate much power, so it's feasible, even advisable, to mount all of the oscillator components in an unventilated box. In the real world, temperatures change and if the components being compensated and the components doing the compensating have different thermal time constants, a change in

temperature can cause a temporary change in frequency until the slower components have caught up. One cure for this is to build the oscillator in a thick-walled metal box that's slow to heat or cool, and so dominates and reduces the possible rate of change of temperature of the circuits inside. This is sometimes called a *cold oven*.

9.4.3 Shielding and Isolation

It is important to remember that any inductor acts as half of a transformer. Oscillators contain inductors running at moderate power levels and so can radiate strong enough signals to cause interference with other parts of a radio, or with other radios. This is the tank (or other) inductor behaving as a transformer primary. Oscillators are also sensitive to radiated signals or other nearby varying magnetic fields. This is the tank (or other) inductor also behaving as a transformer secondary. Effective shielding is therefore vital.

Any oscillator is particularly sensitive to interference on the same or very nearby frequency. If this interference is strong enough an effect called *injection locking* will occur. The oscillator effectively stops oscillating and instead directly follows the interfering signal. This situation is very bad. For example, a VFO used to directly drive a power amplifier and antenna (to form a simple CW transmitter) can prove surprisingly difficult to shield well enough because of injection locking from any leakage of the power amplifier's high-level signal back into the oscillator. Even if injection locking does not fully kick in, the wrestling inside the VFO between its own oscillation and the interference can affect its frequency, resulting in a very poor transmitted note. If the radio gear is in the station antenna's near field, there are also

strong fields that are coherent with the VFO oscillation, making sufficient shielding even more difficult.

The following rules of thumb continue to serve ham builders well:

- Use a complete metal box, with as few holes drilled in it as possible, with good contact around surface(s) where its lid(s) fit(s) on.

- Use feedthrough capacitors on power and control lines that pass in and out of the VFO enclosure and on the transmitter or transceiver enclosure as well.

- Use buffer amplifier circuitry that amplifies the signal by the desired amount and provides sufficient attenuation of signal energy flowing in the reverse direction. This is known as *reverse isolation* and is a frequently overlooked loophole in shielding. Figs 9.15 and 9.16 include buffer circuitry of proven performance. Another (and higher-cost) option is to consider using a high-speed buffer-amplifier IC (such as the LM6321N by National Semiconductor, a part that combines the high input impedance of an op amp with the ability to drive 50-Ω loads directly up into the VHF range).

- Use a mixing-based frequency-generation scheme instead of one that operates straight through or by means of multiplication. Such a system's oscillator stages can operate on frequencies with no direct frequency relationship to its output frequency. This essentially eliminates the possibility of injection locking the VFO.

- Use the time-tested technique of running your VFO at a sub-harmonic of the output signal desired — say, 3.5 MHz in a 7 MHz transmitter — and multiply its output frequency in a suitably nonlinear stage for further amplification at the desired frequency. This does reduce the tendency to injection lock.

9.5 Crystal Oscillators

Because crystals afford Q values and frequency stabilities that are orders of magnitude better than those achievable with LC circuits, fixed-frequency oscillators usually use quartz crystal resonators. Master references for frequency counters and synthesizers are always based on crystal oscillators.

So glowing is the executive summary of the crystal's reputation for stability that newcomers to radio experimentation naturally believe that the presence of a crystal in an oscillator will force oscillation at the frequency stamped on the can. This impression is usually revised after the first few experiences to the contrary! There is no sure-fire crystal oscillator circuit (although some are better than others); reading and experience soon provide a learner with plenty of anecdotes

to the effect that:

- Some circuits have a reputation of being temperamental, even to the point of not always starting.

- Crystals sometimes mysteriously oscillate on unexpected frequencies.

Even crystal manufacturers have these problems, so don't be discouraged from building crystal oscillators. The occasional uncooperative oscillator is a nuisance, not a disaster, and it just needs a little individual attention. Knowing how a crystal behaves is the key to a cure.

Dr Ulrich Rohde, NIUL, has generously contributed a pair of detailed papers that discuss the crystal oscillator along with several HF and VHF designs. Both papers, "Quartz Crystal Oscillator Design" and "A Novel

Grounded Base Oscillator Design for VHF/UHF Frequencies" are included on the CD-ROM accompanying this book.

9.5.1 Quartz and the Piezoelectric Effect

Quartz is a crystalline material with a regular atomic structure that can be distorted by the simple application of force. Remove the force, and the distorted structure springs back to its original form with very little energy loss. This property allows *acoustic waves* — sound — to propagate rapidly through quartz with very little attenuation, because the velocity of an acoustic wave depends on the elasticity and density (mass/volume) of the medium through which the wave travels.

If you heat a material, it expands. Heating may cause other characteristics of a material to change — such as elasticity, which affects the speed of sound in the material. In quartz, however, expansion and change in the speed of sound are very small and tend to cancel, which means that the transit time for sound to pass through a piece of quartz is very stable.

The third property of this wonder material is that it is *piezoelectric*. Apply an electric field to a piece of quartz and the crystal lattice distorts just as if a force had been applied. The electric field applies a force to electrical charges locked in the lattice structure. These charges are captive and cannot move around in the lattice as they can in a semiconductor, for quartz is an insulator. A capacitor's dielectric stores energy by creating physical distortion on an atomic or molecular scale. In a piezoelectric crystal's lattice, the distortion affects the entire structure. In some piezoelectric materials, this effect is sufficiently pronounced that special shapes can be made that bend *visibly* when a field is applied.

Consider a rod made of quartz. Any sound wave propagating along it eventually hits an end, where there is a large and abrupt change in acoustic impedance. Just as when an RF wave hits the end of an unterminated transmission line, a strong reflection occurs. The rod's other end similarly reflects the wave. At some frequency, the phase shift of a round trip will be such that waves from successive round trips exactly coincide in phase and reinforce each other, dramatically increasing the wave's amplitude. This is *resonance*.

The passage of waves in opposite directions forms a standing wave with antinodes at the rod ends. Here we encounter a seeming ambiguity: not just one, but a family of different frequencies, causes standing waves — a family fitting the pattern of $\frac{1}{2}$, $\frac{3}{4}$, $\frac{5}{8}$, $\frac{7}{8}$ and so on, wavelengths into the length of the rod. And this is the case: A quartz rod can resonate at any and all of these frequencies.

The lowest of these frequencies, where the crystal is $\frac{1}{2}$ wavelength long, is called the *fundamental mode*. The others are named the third, fifth, seventh and so on, *overtones*. There is a small phase-shift error during reflection at the ends, which causes the frequencies of the overtone modes to differ slightly from odd integer multiples of the fundamental. Thus, a crystal's third overtone is very close to, but not exactly, three times its fundamental frequency. Many people are confused by overtones and harmonics. Harmonics are additional signals at exact integer multiples of the fundamental frequency. Overtone modes are additional resonances that can be exploited if a circuit is configured to excite them.

The crystals we use most often resonate in the 1 to 30 MHz region and are of the *AT-cut*, *thickness shear* type, although these last two characteristics are rarely mentioned.

A 15 MHz fundamental crystal of this type is about 0.15 mm thick. Because of the widespread use of reprocessed war-surplus, pressure-mounted FT-243 crystals, you may think of crystals as small rectangles on the order of a half-inch in size. The crystals we commonly use today are discs, etched and/or doped to their final dimensions, with metal electrodes deposited directly on the quartz. A crystal's diameter does not directly affect its frequency; diameters of 8 to 15 mm are typical. (Quartz crystals are also discussed in the **RF and AF Filters** chapter.)

AT-cut is one of a number of possible standard designations for the orientation at which a crystal disc is sawed from the original quartz crystal. The crystal lattice atomic structure is asymmetric, and the orientation of this with respect to the faces of the disc influences the crystal's performance. *Thickness shear* is one of a number of possible orientations of the crystal's mechanical vibration with respect to the disc. In this case, the crystal vibrates perpendicularly to its thickness. This is not easy to visualize, and diagrams don't help much, but **Fig 9.21** is an attempt at illustrating this. Place a moist bathroom sponge between the palms of your hands, move one hand up and down, and you'll see thickness shear in action.

There is a limit to how thin a disc can be made, given requirements of accuracy and price. Traditionally, fundamental-mode crystals have been made up to 20 MHz, although 30 MHz is now common at a moderately

raised price. Using techniques pioneered in the semiconductor industry, crystals have been made with a central region etched down to a thin membrane, surrounded by a thick ring for robustness. This approach can push fundamental resonances to over 100 MHz, but these are more lab curiosities than parts for everyday use. The easy solution for higher frequencies is to use a nice, manufacturably-thick crystal on an overtone mode. All crystals have multiple modes, so if you order a 28.060 MHz, third-overtone unit for a little QRP transmitter, you'll get a crystal with a fundamental resonance somewhere near 9.353333 MHz, but its manufacturer will have adjusted the thickness to plant the third overtone exactly on the ordered frequency. An accomplished manufacturer can do tricks with the flatness of the disc faces to make the wanted overtone mode a little more active and the other modes a little less active. (As some builders discover, however, this does not *guarantee* that the wanted mode is the most active!)

Quartz's piezoelectric property provides a simple way of driving the crystal electrically. Early crystals were placed between a pair of electrodes in a case. This gave amateurs the opportunity to buy surplus crystals, open them and grind them a little to reduce their thickness, thus moving them to higher frequencies. The frequency could be reduced very slightly by loading the face with extra mass, such as by blackening it with a soft pencil. Modern crystals have metal electrodes deposited directly onto their surfaces (Fig 9.21B), and such tricks no longer work.

The piezoelectric effect works both ways. Deformation of the crystal produces voltage across its electrodes, so the mechanical energy in the resonating crystal can also be extracted electrically by the same electrodes. Seen electrically, at the electrodes, the mechanical resonances look like electrical resonances. Their Q is very high. A Q of 10,000 would characterize a *poor* crystal today; 100,000 is often reached by high-quality parts. For comparison, a Q of over 200 for an LC tank is considered good.

9.5.2 Frequency Accuracy

A crystal's frequency accuracy is as outstanding as its Q. Several factors determine a crystal's frequency accuracy. First, the manufacturer makes parts with certain tolerances: ± 200 ppm for a low-quality crystal for use as in a microprocessor clock oscillator, ± 10 ppm for a good-quality part for professional radio use. Anything much better than this starts to get expensive! A crystal's resonant frequency is influenced by the impedance presented to its terminals, and manufacturers assume that once a crystal is brought within several parts per million of the nominal frequency, its user will perform fine adjustments electrically.

Fig 9.21 — Thickness-shear vibration at a crystal's fundamental and third overtone (A); B shows how the modern crystals commonly used by radio amateurs consist of etched quartz discs with electrodes deposited directly on the crystal surface.

Fig 9.22 — Slight changes in a crystal cut's orientation shift its frequency-versus-temperature curve.

Second, a crystal ages after manufacture. Aging could give increasing or decreasing frequency; whichever, a given crystal usually keeps aging in the same direction. Aging is rapid at first and then slows down. Aging is influenced by the care in polishing the surface of the crystal (time and money) and by its holder style. The cheapest holder is a soldered-together, two-part metal can with glass bead insulation for the connection pins. Soldering debris lands on the crystal and affects its frequency. Alternatively, a two-part metal case can be made with flanges that are pressed together until they fuse, a process called *cold-welding*. This is much cleaner and improves aging rates roughly fivefold compared to soldered cans. An all-glass case can be made in two parts and fused together by heating in a vacuum. The vacuum raises the Q, and the cleanliness results in aging that's roughly 10 times slower than that achievable with a soldered can. The best crystal holders borrow from vacuum-tube assembly processes and have a *getter*, a highly reactive chemical substance that traps remaining gas molecules, but such crystals are used only for special purposes.

Third, temperature influences a crystal. A reasonable, professional quality part might be specified to shift not more than ± 10 ppm over 0 to 70 °C. An AT-cut crystal has an S-shaped frequency-versus-temperature characteristic, which can be varied by slightly changing the crystal cut's orientation. Fig 9.22 shows the general shape and the effect of changing the cut angle by only a few seconds of arc. Notice how all the curves converge at 25 °C. This is because this temperature is normally chosen as the reference for specifying a crystal. The temperature stability specification sets how accurate the manufacturer must make the cut. Better stability may be needed for a crystal used as a receiver frequency standard, frequency counter clock and so on. A crystal's temperature characteristic shows a little hysteresis. In other words, there's a bit of offset to the curve depending on whether temperature is increasing or decreasing. This is usually of no consequence except in the

highest-precision circuits.

It is the temperature of the quartz that is important, and as the usual holders for crystals all give effective thermal insulation, only a couple of milliwatts dissipation by the crystal itself can be tolerated before self-heating becomes troublesome. Because such heating occurs in the quartz itself and does not come from the surrounding environment, it defeats the effects of temperature compensators and ovens.

The techniques shown earlier for VFO temperature compensation can also be applied to crystal oscillators. An after-compensation drift of 1 ppm is routine and 0.5 ppm is good. The result is a *temperature-compensated crystal oscillator (TCXO)*. Recently, oscillators have appeared with built-in digital thermometers, microprocessors and ROM look-up tables customized on a unit-by-unit basis to control a tuning diode via a digital-to-analog converter (DAC) for temperature compensation. These *digitally temperature-compensated oscillators (DTCXOs)* can reach 0.1 ppm over the temperature range. With automated production and adjustment, they promise to become the cheapest way to achieve this level of stability.

Oscillators have long been placed in temperature-controlled *ovens*, which are typically held at 80 °C. Stability of several parts per billion can be achieved over temperature, but this is a limited benefit as aging can easily dominate the accuracy. These are usually called *oven-controlled crystal oscillators (OCXOs)*.

Fourth, the crystal is influenced by the impedance presented to it by the circuit in which it is used. This means that care is needed to make the rest of an oscillator circuit stable, in terms of impedance and phase shift.

Gravity can slightly affect crystal resonance. Turning an oscillator upside down usually produces a small frequency shift, usually much less than 1 ppm; turning the oscillator back over reverses this. This effect is quantified for the highest-quality reference oscillators.

9.5.3 The Equivalent Circuit of a Crystal

Because a crystal is a passive, two-terminal device, its electrical appearance is that of an impedance that varies with frequency. Fig 9.23A shows a very simplified sketch

Fig 9.23 — Exploring a crystal's impedance (A) and equivalent circuit (B) through simplified diagrams. C and D extend the investigation to include overtones; E, to spurious responses not easily predictable by theory or controllable through manufacture. A crystal may oscillate on any of its resonances under the right conditions.

of the magnitude (phase is ignored) of the impedance of a quartz crystal. The general trend of dropping impedance with increasing frequency implies capacitance across the crystal. The sharp fall to a low value resembles a series-tuned tank, and the sharp peak resembles a parallel-tuned tank. These are referred to as series and parallel resonances. Fig 9.23B shows a simple circuit that will produce this impedance characteristic. The impedance looks purely resistive at the exact centers of both resonances, and the region between them has impedance increasing with frequency, which looks inductive.

C_1 (sometimes called *motional capacitance*, C_m , to distinguish it from the lumped capacitance it approximates) and L_1 (*motional inductance*, L_m) create the series resonance, and as C_0 and R_1 are both fairly small, the impedance at the bottom of the dip is very close to R_1 . At parallel resonance, L_1 is resonating with C_1 and C_0 in series, hence the higher frequency. The impedance of the parallel tank is extremely high; the terminals are connected to a capacitive tap, which causes them to see only a small fraction of what is still a very large impedance. The overtones should not be neglected, so Figs 9.23C and 9.23D include them. Each overtone has series and parallel resonances and so appears as a series tank in the equivalent circuit. C_0 again provides the shifted parallel resonance.

This is still simplified, because real-life crystals have a number of spurious, unwanted modes that add yet more resonances, as shown in Fig 9.23E. These are not well controlled and may vary a lot even between crystals made to the same specification. Crystal manufacturers work hard to suppress these spurs and have evolved a number of recipes for shaping crystals to minimize them. Just where they switch from one design to another varies from manufacturer to manufacturer.

Always remember that the equivalent circuit is just a representation of crystal behavior and does not represent circuit components actually present. Its only use is as an aid in designing and analyzing circuits using crystals. **Table 9.1** lists typical equivalent-circuit values for a variety of crystals. It is impossible to build a circuit with 0.026 to 0.0006 pF capacitors; such values would simply be swamped by strays. Similarly, the inductor must have a Q that is orders of magnitude better than is practically achievable,

and impossibly low stray C in its winding.

The values given in Table 9.1 are nothing more than rough guides. A crystal's frequency is tightly specified, but this still allows inductance to be traded for capacitance. A good manufacturer could hold these characteristics within a $\pm 25\%$ band or could vary them over a 5:1 range by special design. Similarly marked parts from different sources vary widely in motional inductance and capacitance.

Quartz is not the only material that behaves in this way, but it is the best. Resonators can be made out of lithium tantalate and a group of similar materials that have lower Q , allowing them to be *pulled* over a larger frequency range in VCXOs. Much more common, however, are ceramic resonators based on the technology of the well-known ceramic IF filters. These have much lower Q than quartz and much poorer frequency precision. They serve mainly as clock resonators for cheap microprocessor systems in which every last cent must be saved. A ceramic resonator could be used as the basis of a wide range, cheap VXO, but its frequency stability would not be as good as a good LC VFO.

9.5.4 Crystal Oscillator Circuits

(See also the papers "Quartz Crystal Oscillator Design" and "A Novel Grounded Base Oscillator Design for VHF/UHF Frequencies" by Dr Ulrich Rohde, NIUL, included on the CD-ROM accompanying this book.)

Crystal oscillator circuits are usually categorized as series- or parallel-mode types, depending on whether the crystal's low- or high-impedance resonance comes into play at the operating frequency. The series mode is now the most common; parallel-mode operation was more often used with vacuum tubes. **Fig 9.24** shows a basic series-mode oscillator. Some people would say that it is an overtone circuit, used to run a crystal on one of its overtones, but this is not necessarily true. The tank (L - C_1 - C_2) tunes the collector of the common-base amplifier. C_1 is larger than C_2 , so the tank is tapped in a way that transforms to lower impedance, decreasing signal voltage, but increasing current. The current is fed back into the emitter via the crystal. The common-base stage provides a current gain

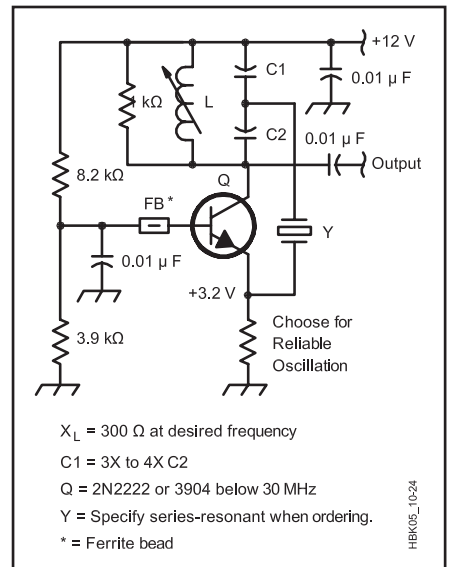

Fig 9.24 — A basic series-mode crystal oscillator. A 2N5179 can be used in this circuit if a lower supply voltage is used; see text.

of less than unity, so the transformer in the form of the tapped tank is essential to give loop gain. There are *two* tuned circuits, the obvious collector tank and the series-mode one "in" the crystal. The tank kills the amplifier's gain away from its tuned frequency, and the crystal will only pass current at the series resonant frequencies of its many modes. The tank resonance is much broader than any of the crystal's modes, so it can be thought of as the crystal setting the frequency, but the tank selecting which of the crystal's modes is active. The tank could be tuned to the crystal's fundamental, or one of its overtones.

Fundamental oscillators can be built without a tank quite successfully, but there is always the occasional one that starts up on an overtone or spurious mode. Some simple oscillators have been known to change modes while running (an effect triggered by changes in temperature or loading) or to not always start in the same mode! A series-mode oscillator should present low impedance to the crystal at the operating frequency. In Fig 9.24, the tapped collector tank presents a transformed fraction of the 1-k Ω collector load resistor to one end of the crystal, and the emitter presents a low impedance to the other. To build a practical oscillator from this circuit, choose an inductor with a reactance of about 300 Ω at the wanted frequency and calculate C_1 in series with C_2 to resonate with it. Choose C_1 to be 3 to 4 times larger than C_2 . The amplifier's quiescent ("idling") current sets the gain and hence the operating level. This is not easily calculable, but can be found by experiment. Too little quiescent current and the oscillator will not start reliably; too much and the transistor can drive

Table 9.1
Typical Equivalent Circuit Values for a Variety of Crystals

Crystal Type	Series L	Series C (pF)	Series R (Ω)	Shunt C (pF)
1 MHz fundamental	3.5 H	0.007	340	3.0
10 MHz fundamental	9.8 mH	0.026	7	6.3
30 MHz third overtone	14.9 mH	0.0018	27	6.2
100 MHz fifth overtone	4.28 mH	0.0006	45	7.0

itself into saturation. If an oscilloscope is available, it can be used to check the collector waveform; otherwise, some form of RF voltmeter can be used to allow the collector voltage to be set to 2 to 3 V RMS. 3.3 kΩ would be a suitable starting point for the emitter bias resistor. The transistor type is not critical; 2N2222A or 2N3904 would be fine up to 30 MHz; a 2N5179 would allow operation as an overtone oscillator to over 100 MHz (because of the low collector voltage rating of the 2N5179, a supply voltage lower than 12 V is required). The ferrite bead on the base gives some protection against parasitic oscillation at UHF.

If the crystal is shorted, this circuit should still oscillate. This gives an easy way of adjusting the tank; it is even better to temporarily replace the crystal with a small-value (tens of ohms) resistor to simulate its *equivalent series resistance* (ESR), and adjust L until the circuit oscillates close to the wanted frequency. Then restore the crystal and set the quiescent current. If a lot of these oscillators were built, it would sometimes be necessary to adjust the current individually due to the different equivalent series resistance of individual crystals. One variant of this circuit has the emitter connected directly to the C1/C2 junction, while the crystal is a decoupler for the transistor base (the existing capacitor and ferrite bead not being used). This works, but with a greater risk of parasitic oscillation.

We commonly want to trim a crystal oscillator's frequency. While off-tuning the tank a little will pull the frequency slightly, too much detuning spoils the mode control and can stop oscillation (or worse, make the circuit unreliable). The answer to this is to add a trimmer capacitor, which will act as part of the equivalent series tuned circuit, in series with the crystal. This will shift the frequency in one way only, so the crystal frequency must be re-specified to allow the frequency to be varying around the required value. It is common to specify a crystal's frequency with a standard load (30 pF is commonly specified), so that the manufacturer grinds the crystal such that the series resonance of the specified mode is accurate when measured with a capacitor of this value in series. A 15 to 50 pF trimmer can be used in series with the crystal to give fine frequency adjustment. Too little capacitance can stop oscillation or prevent reliable starting. The Q of crystals is so high that marginal oscillators can take several seconds to start!

This circuit can be improved by driving the crystal's lower series-resonant impedance with an emitter follower as in **Fig 9.25**. This is the *Butler* oscillator. Again the tank controls the mode to either force the wanted overtone or protect the fundamental mode. The tank need not be tapped because Q2 provides current gain, although the circuit is sometimes seen with C split, driving Q2

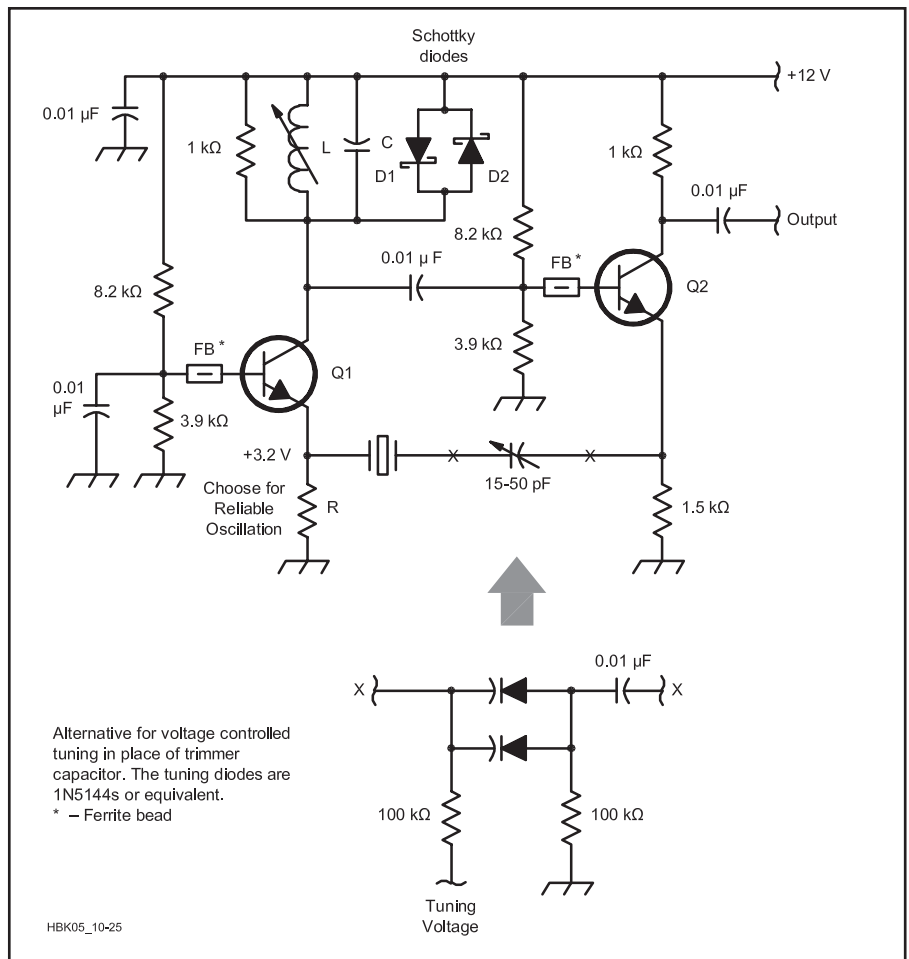

Fig 9.25 — A Butler crystal oscillator with Q2 connected as an emitter follower to drive the crystal's low series-resonant impedance.

from a tap. The position between the emitters offers a good, low-impedance environment to keep the crystal's in-circuit Q high. R, in the emitter of Q1, is again selected to give reliable oscillation. The circuit has been shown with a capacitive load for the crystal, to suit a unit specified for a 30 pF load. An alternative circuit to give electrical fine tuning is also shown. The diodes across the tank act as limiters to stabilize the operating amplitude and limit the power dissipated in the crystal by clipping the drive voltage to Q2. The tank should be adjusted to peak at the operating frequency, not used to trim the frequency. The capacitance in series with the crystal is the proper frequency trimmer.

The Butler circuit works well, and has been used in critical applications to 140 MHz (seventh-overtone crystal, 2N5179 transistor). Although the component count is high, the extra parts are cheap ones. Increasing the capacitance in series with the crystal reduces the oscillation frequency but has a progressively diminishing effect. Decreasing the capacitance pulls the frequency higher, to a point at which oscillation stops; before this

point is reached, start-up will become unreliable. The possible amount of adjustment, called *pulling range*, depends on the crystal; it can range from less than 10 to several hundred parts per million. Overtone crystals have much less pulling range than fundamental crystals on the same frequency; the reduction in pulling is roughly proportional to the square of the overtone number.

LOW-NOISE CRYSTAL OSCILLATORS

Fig 9.26A shows a crystal operating in its series mode in a series-tuned Colpitts circuit. Because it does not include an LC tank to prevent operation on unwanted modes, this circuit is intended for fundamental mode operation only and relies on that mode being the most active. If the crystal is ordered for 30 pF loading, the frequency trimming capacitor can be adjusted to compensate for the loading of the capacitive divider of the Colpitts circuit. An unloaded crystal without a trimmer would operate slightly off the exact series resonant frequency in order to create an inductive impedance to resonate

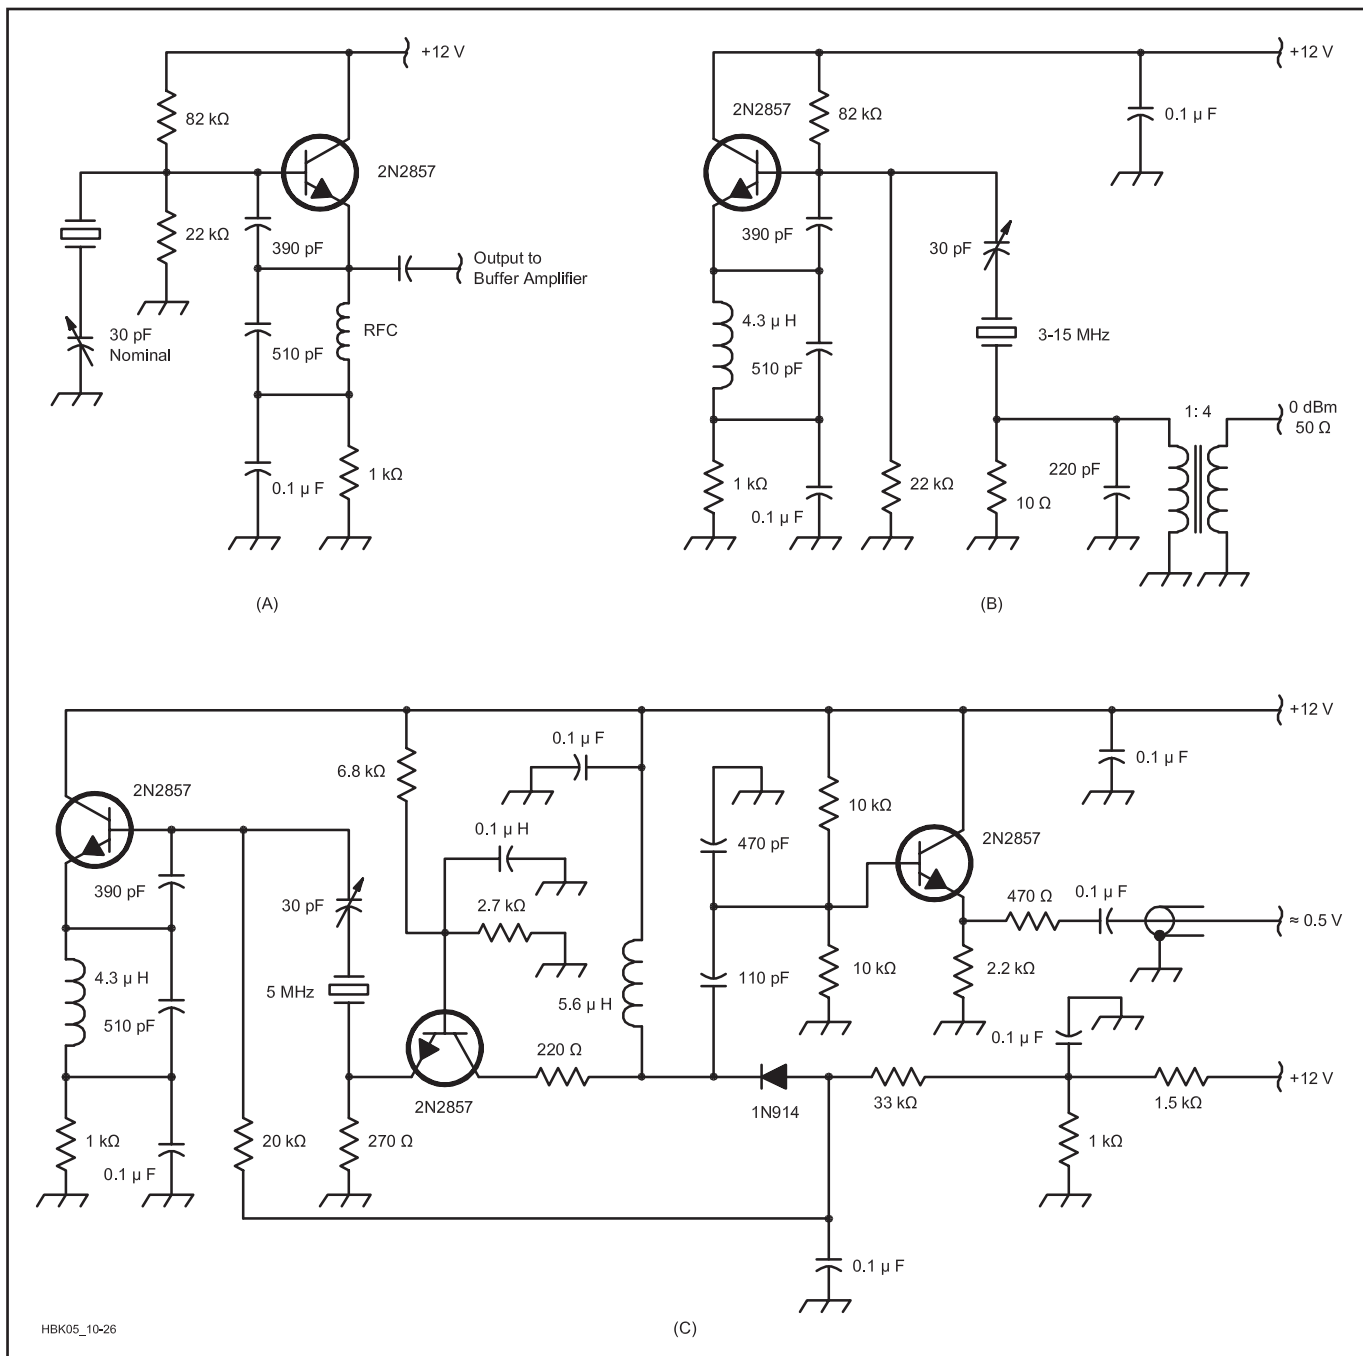

Fig 9.26 — The crystal in the series-tuned Colpitts oscillator at A operates in its series-resonant mode. B shows N1UL's low-noise version, which uses the crystal as a filter and features high harmonic suppression (from Rohde, *Microwave and Wireless Synthesizers Theory and Design*; see references). The circuit at C builds on the B version by adding a common-base output amplifier and ALC loop.

with the divider capacitors. Dr Ulrich Rohde, N1UL, in Figure 4-47 of his book *Digital PLL Frequency Synthesizers — Theory and Design*, published an elegant alternative method of extracting an output signal from this type of circuit, shown in Fig 9.26B. This taps off a signal from the current in the crystal itself. This can be thought of as using the crystal as a band-pass filter for the oscillator output. The RF choke in the emitter keeps the emitter bias resistor from loading the tank

and degrading the Q. In this case (3 MHz operation), it has been chosen to resonate close to 3 MHz with the parallel capacitor (510 pF) as a means of forcing operation on the wanted mode. The 10-Ω resistor and the transformed load impedance will reduce the in-circuit Q of the crystal, so a further development substituted a common base amplifier for the resistor and transformer. This is shown in Fig 9.26C. The common-base amplifier is run at a large quiescent current to give a very

low input impedance. Its collector is tuned to give an output with low harmonic content and an emitter follower is used to buffer this from the load. This oscillator sports a simple ALC system, in which the amplified and rectified signal is used to reduce the bias voltage on the oscillator transistor's base. This circuit is described as achieving a phase noise level of -168 dBc/Hz a few kilohertz out from the carrier. This may seem far beyond what may ever be needed, but frequency multiplication

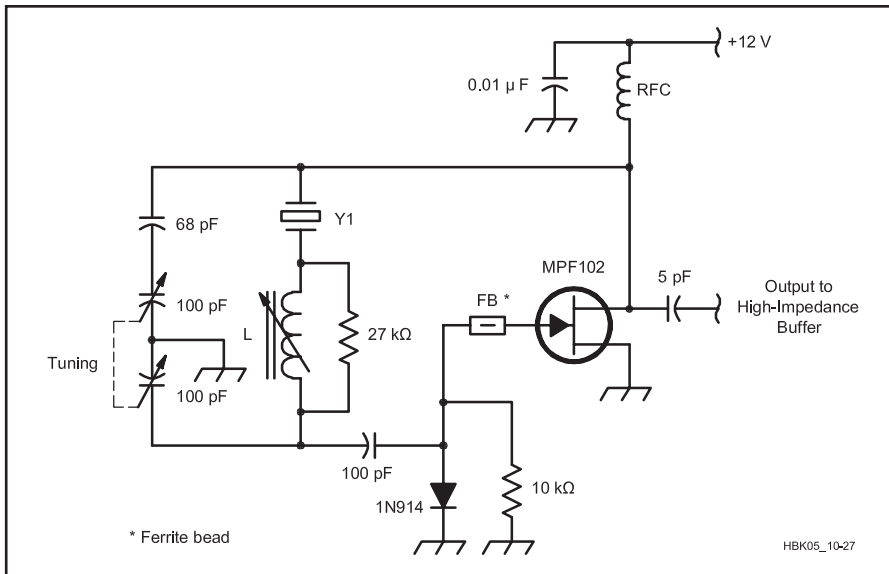

Fig 9.27 — A wide-range variable-crystal oscillator (VXO) by W7ZOI and W1FB. It was originally designed for use in low-power radios without the usual wide-range VFO.

to high frequencies, whether by classic multipliers or by frequency synthesizers, multiplies the deviation of any FM/PM sidebands as well as the carrier frequency. This means that phase noise worsens by 20 dB for each tenfold multiplication of frequency. A clean crystal oscillator and a multiplier chain is still the best way of generating clean microwave signals for use with narrow-band modulation schemes.

It has already been mentioned that overtone crystals are much harder to pull than fundamental ones. This is another way of saying that overtone crystals are less influenced by their surrounding circuit, which is helpful in a frequency-standard oscillator like this one. Even though 5 MHz is in the main range of fundamental-mode crystals and this circuit will work well with them, an overtone crystal has been used. To further help stability, the power dissipated in the crystal is kept to about 50 μW. The common-base stage is effectively driven from a higher impedance than its own input impedance, under which conditions it gives a very low noise figure.

9.5.5 VXOs

Some crystal oscillators have frequency trimmers. If the trimmer is replaced by a variable capacitor as a front-panel control, we have a *variable crystal oscillator (VXO)*: a crystal-based VFO with a narrow tuning range, but good stability and noise performance. VXOs are often used in small, simple QRP transmitters to tune a few kilohertz around common calling frequencies. Artful constructors, using optimized circuits and components, have achieved 1000-ppm tuning ranges. Poor-quality “soft” crystals are more pull-able than high-Q ones. Overtone

crystals are not suited to VXOs. For frequencies beyond the usual limit for fundamental mode crystals, use a fundamental unit and frequency multipliers.

ICOM and Mizuho made some 2 meter SSB transceivers based on multiplied VXO local oscillators. This system is simple and can yield better performance than many expensive synthesized radios. SSB filters are available at 9 or 10.7 MHz, to yield sufficient image rejection with a single conversion. Choice of VXO frequency depends on whether the LO is to be above or below signal frequency and how much multiplication can be tolerated. Below 8 MHz, multiplier filtering is difficult. Above 15 MHz, the tuning range per crystal narrows. A 50-200 kHz range per crystal should work with a modern front-end design feeding a good 9 MHz IF, for a contest quality 2 meter SSB receiver.

The circuit in **Fig 9.27** is a JFET VXO from Wes Hayward, W7ZOI, and Doug DeMaw, W1FB, optimized for wide-range pulling. Published in *Solid State Design for the Radio Amateur*, many have been built and its ability to pull crystals as far as possible has been proven. Dr Ulrich Rohde, N1UL, has shown that the diode arrangement as used here to make signal-dependent negative bias for the gate confers a phase-noise disadvantage, but oscillators like this that pull crystals as far as possible need any available means to stabilize their amplitude and aid start-up. In this case, the noise penalty is worth paying. This circuit can achieve a 2000-ppm tuning range with amenable crystals. If you have some overtone crystals in your junk box whose fundamental frequency is close to the wanted value, they are worth trying.

This sort of circuit doesn’t necessarily stop pulling at the extremes of the possible tuning

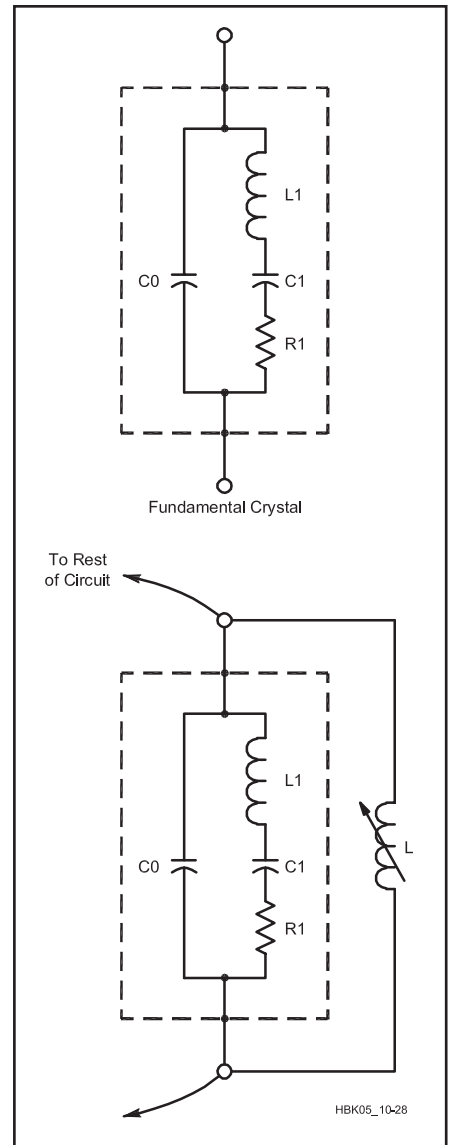

Fig 9.28 — Using an inductor to “tune out” C0 can increase a crystal oscillator’s pulling range.

range; sometimes the range is set by the onset of undesirable behavior such as jumping mode or simply stopping oscillating. L was a 16 μH slug-tuned inductor for 10 MHz operation. It is important to minimize the stray and interwinding capacitance of L since this dilutes the range of impedance presented to the crystal.

One trick that can be used to aid the pulling range of oscillators is to tune out the C0 of the equivalent circuit with an added inductor. **Fig 9.28** shows how. L is chosen to resonate with C0 for the individual crystal, turning it into a high-impedance parallel-tuned circuit. The Q of this circuit is orders of magnitude less than the Q of the true series resonance of the crystal, so its tuning is much broader. The value of C0 is usually just a few picofarads, so L has to be a fairly large value considering the frequency at which it is resonated. This means

that L has to have low stray capacitance or else it will self-resonate at a lower frequency. The tolerance on C0 and the variations of the stray C of the inductor means that individual adjustment is needed. This technique can also work wonders in crystal ladder filters.

9.5.6 Logic-Gate Crystal Oscillators

The frequency-determining network of an RC oscillator has a Q of less than one, which means that phase shift changes very slowly with different frequencies (see section 9.3.2 on RC Oscillators above). The Pierce crystal oscillator discussed previously is a converted phase-shift oscillator, with the crystal taking the place of one series resistor. The crystal provides a much faster phase shift than an RC stage, so the crystal “controls” the frequency of oscillation.

The actual frequency of oscillation is the frequency at which the Barkhausen criteria are met. The crystal must operate near its series resonance in order for the loop gain to be unity. Oscillation then settles at the frequency where the crystal phase shift, added to the RC phase shifts, equals 180 degrees. The crystal usually provides between 45 and 60 degrees of phase shift, so the oscillation frequency is above the series resonance and below the parallel resonance of the crystal where the crystal behaves as a large inductor. (See the figure showing crystal response in the section Quartz Crystal Filters in the **RF and AF Filters** chapter.)

The Pierce circuit is rarely seen in this full form. Instead, a cut-down version is the

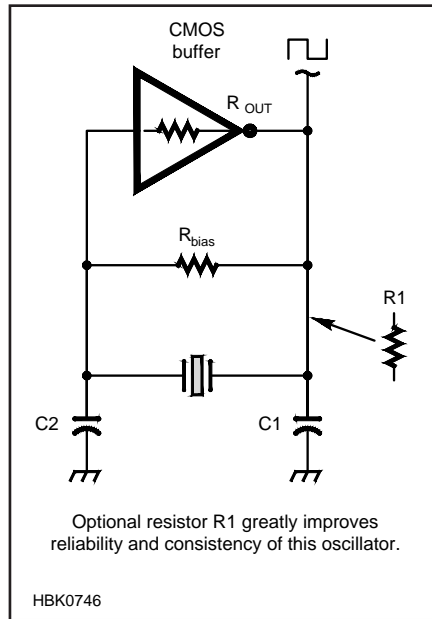

Fig 9.29 — The simplified Pierce oscillator using a logic-gate for the inverting amplifier. Adding R1 improves oscillator design and reliability.

most common circuit in many microprocessors and other digital ICs that need a crystal-controlled clock. Fig 9.29 shows this minimalist Pierce, using a CMOS logic inverter as the amplifier. R_{bias} provides dc negative feedback to bias the gate into its linear region. This value is not critical, anything between 100 k Ω and 10 M Ω works fine. The RC phase shifts needed to make this

work come from R_{out} -C1 and $R_{crystal}$ -C2. This circuit has a reputation of being temperamental, mainly because neither R_{out} nor $R_{crystal}$ are well documented or controlled in manufacturing. There is also a general belief that this circuit requires $C1 = C2$, which is not true.

A great improvement in performance is achieved by adding one resistor, R1, as shown in Fig 9.29. R_{bias} remains connected directly across the CMOS inverter. R1 is inserted in series from the gate output to the feedback network. The benefits are multiple:

- The edge speed of modern CMOS gates is extremely fast, so R1C1 eliminates the possibility of this fast edge exciting overtone operation.
- Phase shift into the crystal can be intentionally designed by R1 and C1 value selection.
- Drive from the inverter output is reduced into the crystal, possibly saving it from being damaged.
- Loop gain can now be controlled for best waveform and startup characteristics.

Design values are strongly dependent on the actual crystal frequency needed. C2 is selected first, to provide around 60 degrees of phase shift working against the crystal equivalent series resistance (usually a few tens of ohms, but the value needs to be verified!). The time constant R1 C1 is usefully chosen to be the reciprocal of the crystal radian frequency ($1/2\pi f_{XTAL}$). Higher values of R1 reduce the loop gain and provide better protection for the crystal, until the loop gain gets too small and oscillation stops.

9.6 Oscillators at UHF and Above

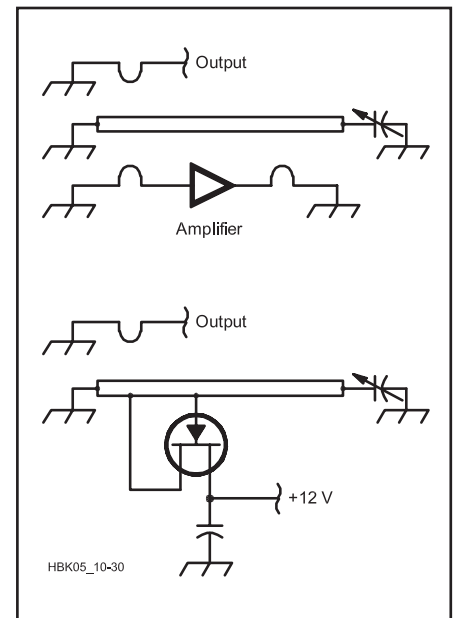

The traditional way to make signals at higher frequencies is to make a signal at a lower frequency (where oscillators are easier) and multiply it up to the wanted range. Frequency multiplication is still one of the easiest and best ways of making a clean UHF/microwave signal. The design of a multiplier depends on whether the multiplication factor is an odd or even number. For odd multiplication, a Class-C biased amplifier can be used to create a series of harmonics; a filter selects the one wanted. For even multiplication factors, a full-wave-rectifier arrangement of distorting devices can be used to create a series of harmonics with strong even-order components, with a filter selecting the wanted component. At higher frequencies, diode-based passive circuits are commonly used. Oscillators using some of the LC circuits already described can, with care in construction, be used in the VHF range. At UHF, different approaches become necessary.

9.6.1 UHF Oscillators: Intentional and Accidental

The biggest change when working at UHF and microwave frequencies is that lumped circuit elements effectively disappear. Stray reactances and resistance dominates everything. Success at these high frequencies requires making peace with the situation and developing a very good sense of where “stray” circuit elements reside in your layout and their approximate magnitude.

Fig 9.30 shows a pair of oscillators based on a resonant length of line, which is a distributed circuit element. The first one is a return to basics: a resonator, an amplifier and

Fig 9.30 — Oscillators that use transmission-line segments as resonators. Such oscillators are more common than many of us may think, as Fig 9.31 reveals.

a pair of coupling loops. The amplifier can be a single bipolar or FET device or one of the monolithic microwave integrated circuit (MMIC) amplifiers. The second circuit is really a Hartley oscillator, and one is made as a test oscillator for the 70 cm band from a 10 cm length of wire suspended 10 mm over an unetched PC board as a ground plane, bent down and soldered at one end, with a trimmer at the other end. The FET is a BF981 dual-gate device used as a source follower.

No free-running oscillator is really stable enough on these bands. Oscillators in this range are almost invariably tuned with tuning diodes controlled by phase-locked-loop synthesizers, which are themselves controlled by a crystal oscillator. This transfers the same stability of the crystal oscillator to the UHF oscillator.

There is one extremely common UHF oscillator that is almost always an undesired accident, being a very common form of spurious VHF/UHF oscillation in circuitry intended to process lower-frequency signals. **Fig 9.31A** shows the circuit in its simplest

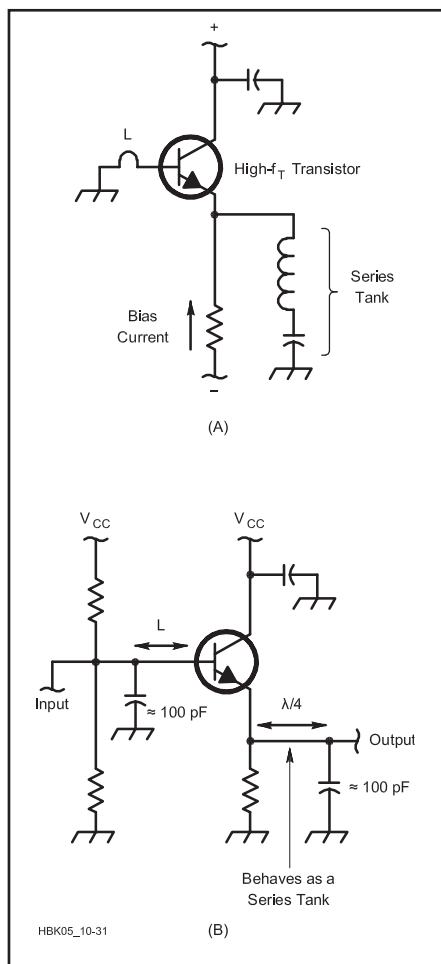

Fig 9.31 — High device gain at UHF and resonances in circuit board traces can result in spurious oscillations even in non-RF equipment.

form. Analyzing this circuit using a comprehensive model of the UHF transistor reveals that the emitter presents an impedance that is small, resistive, and negative to the outside world. If this negative resistance is large enough to more than cancel the effective series resistance of a tank placed on the emitter, oscillation will occur.

At UHF your schematic diagram probably will not show a tank circuit is present. But the high frequency transistor will know it is there, since it “sees” all of the stray reactances present in the layout. Fig 9.31B shows a very basic emitter-follower circuit with some capacitance to ground on both the input and output. If the capacitor shunting the input is a distance away from the transistor, the trace to the transistor’s base looks like an inductor. The trace at the emitter of the transistor also looks like an inductor, and any nearby conductor will look like a capacitor to that trace (two conductors separated by a dielectric, which here is air and the PC board material). Any intentional capacitors add to this. If the transistor has gain at any frequency where the phasing from all of these stray reactances is right for oscillation (see Barkhausen criteria in previous sections) then oscillation will happen. This circuit is effectively the same as that in Fig 9.31A. This is a good reason to use the lowest-frequency transistor that you can for any application.

Stray reactances do not always have to cause headaches. Indeed you can use them, knowing that they are there. The circuit of Fig 9.31A can be deliberately built as a useful wide-tuning oscillator covering say, 500 MHz to 1 GHz! This circuit is well-suited to construction with printed-circuit inductors. Common FR4 glass-epoxy board is lossy at these frequencies; better performance is achieved by using (the much more expensive) glass-Teflon board. If you can get surplus pieces of this type of material, it has many uses at UHF and microwave, but it is difficult to use as the adhesion between the copper and the substrate can be weak. A high-UHF transistor with a 5 GHz f_T such as the BFR90 is suitable; the base inductor can be 30 mm of 1 mm trace folded into a hairpin shape (inductance, less than 10 nH).

The upshot of this is that there is no longer any branch of electronics where RF design and layout techniques can be ignored safely. A circuit must not just be designed to do what it should do; it must also be designed so that it cannot do what it should not do.

If you have an accidental oscillator, there are three ways of taming such a circuit: adding a small resistor of perhaps 50 to 100 Ω in the collector lead close to the transistor, or adding a similar resistor in the base lead under the transistor. Extra resistors can disturb dc conditions, depending on the circuit and its operating currents. Ferrite beads have

the advantage that they can be easily added to existing equipment and have no effect at dc and low frequencies. Beware of some electrically conductive ferrite materials that can short transistor leads! If an HF oscillator uses beads to prevent any risk of spurs (such as shown in Fig 9.15), the beads should be anchored with a spot of adhesive to prevent movement which can cause small frequency shifts. Ferrite beads of Fair-Rite #43 material are especially suitable for this purpose; they are specified in terms of impedance, not inductance. Ferrites at frequencies above their normal usable range become very lossy and can make a lead look not inductive, but like a few tens of ohms, resistive.

9.6.2 Microwave Oscillators

Using conventional PC-board techniques with surface-mount components and extraordinarily careful layout allows the construction of circuits up to 4 GHz or so. Above this, commercial techniques and fancier materials become necessary unless we take the step to the ultimate distributed circuit — the cavity resonator.

Older than stripline techniques and far more amenable to home construction, cavity-based oscillators can give the highest possible performance at microwave frequencies. Air is a very low-loss dielectric with a dielectric constant of 1, so it gives high Q and does not force excessive miniaturization. **Fig 9.32** shows a series of structures used by G. R. Jessop, G6JP, to illustrate the evolution of a cavity from a tank made of lumped components. All cavities have a number of different modes of resonance, the orientation of the

Fig 9.32 — Evolution of the cavity resonator.

currents and fields are shown in **Fig 9.33**. The cavity can take different shapes, but the one shown here has proven to suppress unwanted modes well. The gap need not be central and is often right at the top. A screw can be fitted through the top, protruding into the gap, to adjust the frequency.

Fig 9.33 — Currents and fields in a cavity.

Fig 9.34 — A Gunn diode oscillator uses negative resistance and a cavity resonator to produce radio energy.

SEMICONDUCTOR CAVITY OSCILLATORS

To make an oscillator using a cavity, an amplifier is needed. Gunn and tunnel diodes have regions in their characteristics where their current falls with increasing bias voltage. This is negative resistance. If such a device is mounted in a loop in a cavity and bias is applied, the negative resistance can more than cancel the effective loss resistance of the cavity, causing oscillation. These diodes are capable of operating at extremely high frequencies and were discovered long before transistors were developed that had any gain at microwave frequencies.

A Gunn-diode cavity oscillator is the basis of many of the Doppler radar modules used to detect traffic or intruders and of the Gunnplexer 10 GHz transceiver modules used by amateurs. **Fig 9.34** shows a common configuration. The coupling loop and coax output connector could be replaced with a simple aperture to couple into waveguide or a mixer cavity. **Fig 9.35** shows a transistor cavity oscillator version using a modern microwave transistor, which can be either a FET or bipolar device. The two coupling loops are electrically completed by the capacitance of the feedthrough capacitors.

DIELECTRIC-RESONATOR OSCILLATORS (DRO)

The dielectric-resonator oscillator (DRO) is a very common microwave oscillator, as it is used in the downconverter of satellite TV receivers. The dielectric resonator itself is a ceramic cylinder, like a miniature hockey puck, several millimeters in diameter. The ceramic has a very high dielectric constant, so the surface (where ceramic meets air in an abrupt dielectric mismatch) reflects electromagnetic waves and makes the ceramic body act as a resonant cavity. It is mounted on a substrate and coupled to the active device of the oscillator by a stripline that runs past it. At 10 GHz, a FET made of gallium arsenide (GaAsFET), rather than silicon, is normally used. The dielectric resonator elements are made at frequencies appropriate to mass ap-

Fig 9.35 — A transistor can also directly excite a cavity resonator.

plications like satellite TV. The setup charge to manufacture small quantities at special frequencies is likely to be prohibitive for the foreseeable future.

The challenge with these devices is to devise new ways of using oscillators on industry standard frequencies. Their chief attraction is their low cost in large quantities and compatibility with microwave stripline (microstrip) techniques. Frequency stability and Q are competitive with good cavities, but are inferior to that achievable with a crystal oscillator and chain of frequency multipliers.

YIG TUNED OSCILLATORS (YTO)

The yttrium-iron garnet (YIG) oscillator is a fundamental microwave source with a very wide tuning range and a linear tuning characteristic. Many YIG oscillators can be tuned over more than an octave and some tune more than 5 octaves! They are complete units that appear as heavy blocks of metal with low-frequency connections for power supplies and tuning, and an SMA connector for the RF output. The manufacturer's label usually states the tuning range and often the power supply voltages. This is very helpful because, with new units being very expensive, it is important to be able to identify the characteristics of surplus units. The majority of YTOs operate within the 2 to 18 GHz region, although units down to 500 MHz and up to 40 GHz are occasionally found. At microwave frequencies there is no octave-tunable device that can equal their signal cleanliness and stability. A typical stability for a 3 GHz YTO is less than 1 kHz per second drift. This may seem poor — until we realize that this is 0.33 ppm per second. Still, any YIG application involving narrow-band modulation will require some form of frequency stabilizer.

Nearly all surplus RF spectrum analyzers use YTOs as their first LO. For example, a 0 to 1500 MHz analyzer usually uses a 2 to 3.5 GHz YTO with a 2.0 GHz first IF. To understand the YTO tuning circuits, should there be need for troubleshooting and repair, a basic understanding of YIG oscillators definitely helps.

Fig 9.36 shows the construction of a YIG oscillator. A YTO is based on a YIG sphere that is carefully oriented within a coupling loop. This resonator is connected to a negative-resistance device and the whole assembly is placed between the poles of an electromagnet. Negative-resistance (Gunn) diodes were originally used in these oscillators, but transistor circuits are now essentially universal and use much less power. The support for the YIG sphere often contains a controlled heater to reduce temperature variation. YIG spheres are resonant at a frequency controlled not only by their physical dimensions, but also by any magnetic field around them. Hence the electromagnet: by varying

Fig 9.36 — A yttrium-iron-garnet (YIG) sphere serves as the resonator in the sweep oscillators used in many spectrum analyzers.

the current through the electromagnet's windings, a controlled variable magnetic field is applied across the YIG sphere. This tunes the oscillator across a very wide range. The frequency/current relationship can have excellent linearity, typically around 20 MHz/mA.

Magnetically tuned oscillators bring some unique problems with them. The first problem is that magnetic fields, especially at low frequencies, are extremely difficult to shield. Therefore YTO tuning is influenced by any local magnetic fields, causing frequency modulation. The YTO's magnetic core must be carefully designed to be all-enclosing in an attempt at self-shielding, and then one or more nested mu-metal cans are fitted around everything. It is still important to place the YTO away from obvious sources of magnetic fields, like power transformers. Cooling fans are also sources of fluctuating magnetic fields, with some fans generating fields 20 dB than from a well-designed 200 W 50/60-Hz transformer.

The second new problem is that the YTO's internal tuning coil needs significant current

from the power supply to create the strong tuning field. This can be eased by adding a permanent magnet as a fixed "bias" field, but the bias shifts as the magnet ages. The main tuning coil still has many turns, and therefore high inductance (often more than 0.1 henrys). Large inductances require a high supply voltage for rapid tuning, with correspondingly high power consumption. The usual compromise is to have dual coils: One with many turns for slow tuning over a wide range, and a second coil with far fewer turns for fast tuning or FM over a limited range. This "FM coil" has a sensitivity around 1% to 2% of the main coil, perhaps 500 kHz/mA.

9.6.3 Klystrons, Magnetrons, and Traveling Wave Tubes

There are a number of thermionic (vacuum-tube) devices that are widely used as amplifiers or fundamental oscillators at microwave frequencies. Standard vacuum tubes (see the **RF Amplifiers** chapter for an introduction to vacuum tubes) work well for frequencies

up to hundreds of megahertz. At frequencies higher than this, the amount of time that the electrons take to move between the cathode and the plate becomes a limiting factor. There are several special tubes designed to work at microwave frequencies, usually providing more power than can be obtained from solid-state devices.

Two of the following tubes (klystrons and traveling wave tubes) use the principle of *velocity-modulation* to extract RF energy from an electron beam. The general principles of velocity modulation and basic properties of devices using it are presented in the online tutorial www.radartutorial.eu/druk/Book5.pdf. Additional resources are described below.

THE KLYSTRON

The klystron tube uses the principle of velocity modulation of the electrons to avoid transit time limitations. The beam of electrons travels down a metal drift tube that has interaction gaps along its sides. RF voltages are applied to the gaps and the electric fields that they generate accelerate or decelerate the passing electrons. The relative positions of the electrons shift due to their changing velocities, causing the electron density of the beam to vary. This variation of electron beam density is used to perform amplification or oscillation.

Klystron tubes can be relatively large, and they can easily provide hundreds of watts to hundreds of kilowatts of microwave power. These power levels are useful for UHF broadcasting and particle accelerators, for example. Unfortunately klystrons have relatively narrow bandwidths, and may not be re-tunable for operation on amateur frequencies. A video titled "How a Klystron Tube Works" can be found at the YouTube online video service and a detailed history and tutorial is available at www.slac.stanford.edu/cgi-wrap/getdoc/slac-pub-7731.pdf.

THE MAGNETRON

The magnetron tube is an efficient oscillator for microwave frequencies. Magnetrons are most commonly found in microwave ovens and high-powered radar equipment. The anode of a magnetron is made up of a number of coupled resonant cavities that surround the cathode. The applied magnetic field causes the electrons to rotate around the cathode and the energy that they give off as they approach the anode adds to the RF electric field. The RF power is obtained from the anode through a vacuum window.

Magnetrons are self-oscillating with the frequency determined by the construction of their anodes; however, they can be tuned by coupling either inductance or capacitance to the resonant anode. The range of frequencies depends on how fast the tuning must be ac-

complished. The tube may be tuned slowly over a range of approximately 10% of the center frequency. If faster tuning is necessary, such as is required for frequency modulation, the range decreases to about 5%.

Excellent drawings showing how magnets work are available at hyperphysics.phy-astr.gsu.edu/hbase/waves/magnetron.html and a thorough introduction for the interested reader is can be downloaded from www.cpii.com/docs/related/2/Mag%20tech%20art.pdf.

THE TRAVELING WAVE TUBE

A third type of tube operating in the microwave range is the traveling wave tube (TWT). For wide-band amplifiers in the microwave range this is the tube of choice. Either permanent magnets or electromagnets are used to focus the beam of electrons that travels through the TWT. This electron beam passes through a helical slow-wave structure, in which electrons are accelerated or decelerated, providing density modulation due to the

applied RF signal, similar to that in the klystron. The modulated electron beam induces voltages in the helix that provides an amplified output signal whose gain is proportional to the length of the slow-wave structure. After the RF energy is extracted from the electron beam by the helix, the electrons are collected and recycled to the cathode. Traveling wave tubes can often be operated outside their designed frequencies by carefully optimizing the beam voltage.

9.7 Frequency Synthesizers

Like many of our modern technologies, the origins of frequency synthesis can be traced back to WW II. The driving force was the desire for stable, rapidly switchable and accurate frequency control technology to meet the demands of narrow-band, frequency-agile HF communications systems without resorting to large banks of switched crystals. Early synthesizers were cumbersome and expensive, and therefore their use was limited to only the most sophisticated communications systems. With the help of the same technologies that have taken computers from room-sized to now fitting into the palms of our hands, frequency synthesis techniques have become one of the most enabling technologies in modern communications equipment.

Every communications device manufactured today, be it a handheld transceiver, cell phone, pager, AM/FM entertainment radio, scanner, television, HF communications equipment, or test equipment, contains a frequency synthesizer. Synthesis is the technology that allows an easy interface with both computers and microprocessor controllers. It provides amateurs with many desirable features, such as the feel of an analog knob with precision 10-Hz frequency increments, wide-band accuracy and stability determined by a single precision crystal oscillator, frequency memories, and continuously variable precision frequency splits. Now reduced in size to small integrated circuits, frequency synthesizers have long replaced the cumbersome chains of frequency multipliers and filters in VHF, UHF and microwave equipment, giving rise to the highly portable communications devices we use today. Frequency synthesis has also had a major impact in lowering the cost of modern equipment, particularly by reducing manufacturing complexity.

Frequency synthesizers are categorized in two general types: *direct synthesizers*, where the output signal is the result of operations directly performed on the input signal; and *indirect synthesizers*, where selected characteristics of the input signal are transferred onto a separately generated output signal.

One defining feature of any direct synthesizer is that no feedback is used, so there is never any dynamic stability problem. Indirect synthesizers always include feedback control loops, so dynamic stability is a major design concern.

Direct synthesizers include the major techniques of *direct analog synthesis* (DAS) and *direct digital synthesis* (DDS). Direct analog synthesizers consist primarily of frequency multipliers, frequency dividers, mixers, and filters. DAS is very useful for generating small numbers of signals, with widely spaced frequencies, from a reference oscillator. DAS is particularly useful when more than one output signal is required at the same time. Direct digital synthesizers are essentially dedicated microprocessors that have one program, to create an output signal waveform given a desired frequency (in digital form) using the applied reference signal. Unlike DAS, the output frequencies from a DDS can easily be separated by millihertz (0.001 Hz) while keeping all of the stability of the reference oscillator. Both being direct techniques, neither DAS nor DDS use feedback control loops, so switching from one frequency to another happens in nanoseconds.

Indirect synthesizers include the major techniques of frequency-locked loops (FLL) and phase-locked loops (PLL). The whole idea behind any indirect synthesizer is to transfer characteristics of one signal onto another separate signal. An FLL transfers only frequency characteristics of the input signal onto the output signal. Major FLL applications used by radio amateurs include *automatic frequency control* (AFC) loops and tone decoders. PLLs are more precise because not only frequency characteristics of the reference oscillator, but also its phase characteristics, are transferred to the oscillator generating the output signal. There are two main application classes in which PLLs find wide use. The first is as a *frequency generator*, where we call it a *frequency synthesizer*. In transmitters this synthesizer may also include modulation, particularly for FM and FSK

signals. The second PLL application class is as an angle (frequency or phase) demodulator, where we call it a *tracking demodulator* or *synchronizer*. Tracking demodulators used in deep space communication and clock recovery used in digital communication are major applications today.

It is curious to note that using modern digital circuitry, it actually is easier to make a PLL than an FLL. This turns out to be fortuitous! This section will focus on the PLL used as a frequency synthesizer. For readers interested in PLL use as a demodulator or as a synchronizer, there are many textbooks available that discuss these applications in great detail.

9.7.1 Phase-Locked Loops

As mentioned above, the PLL is a key component of any indirect synthesizer. The sidebar “An Introduction to Phase-Locked Loops” provides an overview of this technology. This section presents a detailed discussion of design and performance topics of PLL synthesizers and the circuits used to construct them. The digital logic circuits and terms included in this discussion are covered in the **Digital Basics** chapter.

ARCHITECTURE

The principle of the PLL synthesizer is straightforward. A tunable oscillator is first built to cover the required output frequency range; then the PLL system is constructed around this oscillator to keep it tuned to the desired frequency. This is done by continuously comparing the phase of the oscillator to a stable reference, such as a crystal oscillator, and using the result to steer tuning of the oscillator. If the oscillator frequency is too high, the phase of its output will start to lead that of the reference by an increasing amount. This is detected and is used to decrease the frequency of the oscillator. Too low a frequency causes an increasing phase lag, which is detected and used to increase the frequency of the oscillator. In this way,

An Introduction to Phase-Locked Loops

By Jerry DeHaven, WA0ACF

Phase locked loops (PLLs) are used in many applications from tone decoders, to stabilizing the pictures in your television set, to demodulating your local FM station or 2 meter repeater. They are used for recovering weak signals from deep space satellites and digging out noisy instrumentation signals. Perhaps the most common usage for PLLs in Amateur Radio is to combine the variability of an LC oscillator with the long term stability and accuracy of a crystal oscillator in PLL frequency synthesizers. Strictly speaking a PLL is not necessarily a frequency synthesizer and a frequency synthesizer is not necessarily a PLL, although the terms are used interchangeably.

PLL Block Diagram

The block diagram in Fig 9.A3 shows a basic *control loop*. An example of a control loop is the furnace or air conditioning system in your house or the cruise control in your car. You input a desired output and the control loop causes the system output to change to and remain at that desired output (called a *setpoint*) until you change the setpoint. Control loops are characterized by an input, an output and a feedback mechanism as shown in the simple control loop diagram in Fig 9.A3. The setpoint in this general feedback loop is called the *reference*.

In the case of a heating system in your house, the reference would be the temperature that you set at the thermostat. The feedback element would be the temperature sensor inside the thermostat. The thermostat performs the comparison function as well. The generator would be the furnace which is turned on or off depending on the output of the comparison stage. In general terms, you can see that the reference input is controlling the output of the generator.

Like other control loops, the design of a PLL is based on feedback, comparison and correction as shown in Fig 9.A3. In this section we will focus on the concepts of using a phase locked loop to generate (synthesize) one or more frequencies based on a single reference frequency.

In a typical PLL frequency synthesizer there are six basic functional blocks as shown in Fig 9.A4. The PLL frequency synthesizer block diagram is only slightly more complicated than the simple control loop diagram, so the similarity should be evident. After a brief description of the function of each block we will describe the operational behavior of a PLL frequency synthesizer.

In Fig 9.A4, the general control loop is implemented with a bit more detail.

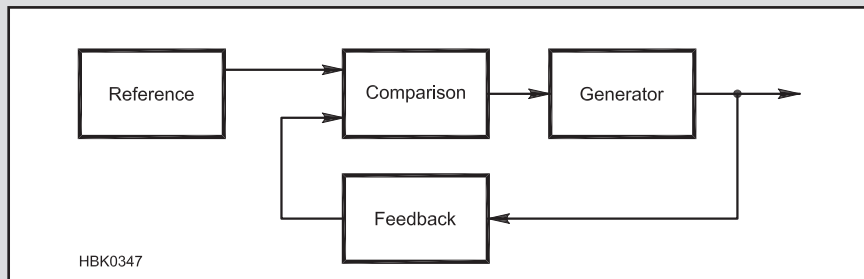

Fig 9.A3 — Simple control loop. The Comparison block creates a control signal for the Generator by comparing the output of the Reference and Feedback blocks.

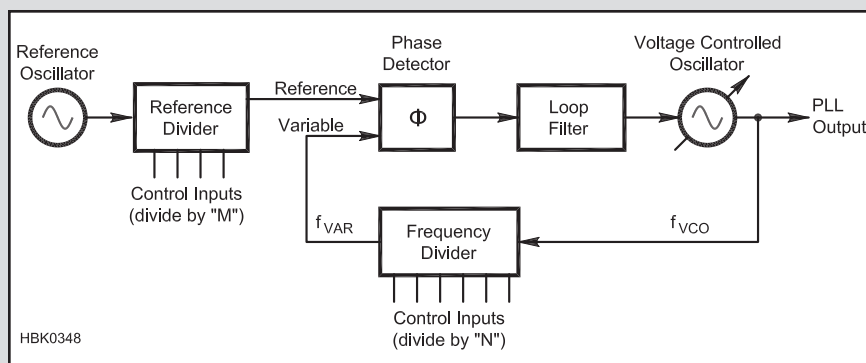

Fig 9.A4 — PLL frequency synthesizer block diagram. The PLL is locked when the frequency PLL Output / N is the same as that of the Reference Oscillator / M.

The Reference block is composed of the Reference Oscillator and the Reference Divider. The Comparison block consists of the Phase Detector and Loop Filter. The Generator is replaced by the Voltage-Controlled Oscillator (or VCO) and the Feedback block is replaced by the Frequency Divider. The two signals being compared are both frequencies; the reference frequency and variable frequency signals. The output of the Loop Filter is made up of dc and low frequency ac components that act to change the VCO frequency. The output of the PLL is an integer multiple of the reference frequency (the output of the Reference Divider). It is probably not obvious why, but read on to find out!

The Reference Oscillator — The reference oscillator is usually a crystal oscillator with special attention paid to thermal stability and low mechanical and electronic noise. The main function of the reference oscillator is to generate a stable frequency for the PLL. Let us make a distinction between the reference oscillator frequency and the reference frequency. The output of the reference oscillator is at the crystal frequency, say 5.000 MHz. The choice of the actual crystal frequency depends on the PLL design, the availability of another oscillator in the radio, the

avoidance of spurious responses in the receiver, and so on.

The *reference frequency* is the output of the reference (crystal) oscillator divided by the integer M to a relatively low frequency, say 10 kHz. In this case, 10 kHz is the reference frequency. The reference frequency equals the step size between the PLL output frequencies. In this simple example the crystal frequency can be any frequency that is an integer multiple of 10 kHz and within the operating range of the Reference Divider.

The Phase Detector — There are many types of phase detectors, but for now let us consider just a basic mixer, or a multiplier. The phase detector has two inputs and one output. In its simplest form, the output of the phase detector is a dc voltage proportional to the phase difference between the two inputs. In practice, a phase detector can be built using a diode double-balanced mixer or an active multiplier.

The output of the mixer consists of products at many frequencies both from multiplication and from nonlinearities. In this application, the desired output is the low frequency and dc terms so all of the RF products are

[continued on next 2 pages]

terminated in a load and the low frequency and dc output is passed to the PLL loop filter.

When the PLL is locked — meaning that the output frequency is the desired multiple of the reference frequency — the phase detector output is a steady dc voltage somewhere between ground and the PLL power supply voltage. When the PLL is commanded to change to another frequency, the phase detector output will be a complex, time-varying signal that gradually settles in on its final value.

The Loop Filter — The loop filter is a low-pass filter that filters the output of the phase detector. The loop filter can be a simple resistor-capacitor (RC) low-pass filter or an active circuit built with bipolar transistors or operational amplifiers. The cutoff frequency of the low pass filter is on the order of 100 Hz to 10 kHz. Although the frequencies involved are dc and low audio frequencies the design of the loop filter is critical for good reference suppression and low noise performance of the PLL frequency synthesizer.

The output of the loop filter is a dc voltage that “steers” the following stage, the Voltage Controlled Oscillator. The dc value can vary over a substantial portion of the PLL power supply. For example, if the loop filter runs off a 9 V power supply you may expect to see the output voltage range from about 2 V to 7 V depending on the VCO frequency range.

The Voltage Controlled Oscillator (VCO) — The VCO is probably the most critical stage in the PLL frequency synthesizer. This stage is the subject of many conflicting design goals. The VCO must be electrically tunable over the desired frequency range with low noise and very good mechanical stability. Ideally, the output frequency of the VCO will be directly proportional to the input control voltage. A key characteristic is the *VCO constant* or *tuning gain*, usually expressed in MHz per volt (MHz/V). The VCO has one input, the dc voltage from the loop filter, and usually two outputs; one for the PLL output, the other driving the feedback stage — the frequency divider.

The Frequency Divider — The VCO frequency divider that acts as the feedback block is a programmable frequency divider or counter. The division ratio N is set either by thumbwheel switches, diode arrays or a microprocessor. The input to the divider is the VCO output frequency. The output of the divider is the VCO output frequency divided by N .

When the PLL is unlocked, such as when the PLL is first turned on, or commanded to change to another frequency, the frequency divider's output frequency will vary in a non-linear manner until the PLL locks. Under locked conditions, the divider's

output frequency (VCO Output / N) is the same as the reference frequency (Reference Oscillator / M).

The function of the frequency divider as the feedback element is easier to understand with an example. Let's assume that the desired PLL output frequency is 14.000 MHz to 14.300 MHz and it should change in steps of 10 kHz (0.010 MHz). A step size of 10 kHz means that the reference frequency must be 10 kHz. There are 31 output frequencies available — one at a time, not simultaneously. (Don't forget to count 14.000 MHz.) Let us arbitrarily choose the reference oscillator as a 5.000 MHz crystal oscillator. To generate the 10 kHz reference frequency, the reference divider must divide by $M = 500 = 5.000 \text{ MHz} / 0.010 \text{ MHz}$. (Use the same units, don't divide MHz by kHz.)

To generate a matching 10 kHz signal from the VCO output frequency, the Frequency Divider (the feedback stage) must be programmable to divide by $N = 1400$ to $1430 = 14.000$ to $14.300 \text{ MHz} / 0.010 \text{ MHz}$. The reference divisor ($M = 500$) is fixed, but the Frequency Divider stage needs to be programmable to divide by $N = 1400$ to 1430 in steps of 1. In this way, the output frequency of the PLL is compared and locked to the stable, crystal-generated value of the reference frequency.

PLL Start-up Operation

Let's visualize the PLL start-up from power on to steady state, visualizing in sequence what each part of the PLL is doing. Some portions of the loop will act quickly, in microseconds; other parts will react more slowly, in tens or hundreds of milliseconds.

The reference oscillator and its dividers will probably start oscillating and stabilize within tens of microseconds. The reference oscillator divider provides the reference frequency to one input of the phase detector.

The VCO will take a bit longer to come up to operation because of extensive power supply filtering with high-value capacitors. The VCO and the programmable dividers will probably reach full output within a few hundred microseconds, although the VCO will not yet be oscillating at the correct frequency.

At this point the phase detector has two inputs but they are at different frequencies. The mixer action of the phase detector produces a beat note at its output. The beat note, which could be tens or hundreds of kHz, is low-pass filtered by the PLL loop filter. That low-pass filter action averages the beat note and applies a complicated time-varying ac/dc voltage to the VCO input.

Now the VCO can begin responding to the control voltage applied to its input. An important design consideration is that the filtered VCO control signal must steer the VCO in the

correct direction. If the polarity of the control signal is incorrect, it will steer the VCO away from the right frequency and the loop will never lock. Assuming correct design, the control voltage will begin steering the VCO in such a direction that the VCO divider frequency will now get closer to the reference frequency.

With the phase detector inputs a little bit closer in frequency, the beat note will be lower in frequency and the low pass filtered average of the phase detector output will change to a new level. That new control voltage will continue to steer the VCO in the right direction even closer to the “right” frequency. With each successive imaginary trip around the loop you can visualize that eventually a certain value of VCO control voltage will be reached at which the VCO output frequency, when divided by the frequency divider, will produce zero frequency difference at the inputs to the phase detector. In this state, the loop is *locked*. Once running, the range over which a PLL can detect and lock on to a signal is its *capture range*.

PLL Steady-state Operation

When the divided-down VCO frequency matches the reference frequency, the PLL will be in its steady-state condition. Since the comparison stage is a phase detector, not just a frequency mixer, the control signal from the loop filter to the VCO will act in such a way that maintains a constant relationship between the *phase* of the reference frequency and the frequency divider output. For example, the loop might stabilize with a 90° difference between the inputs to the phase detector. As long as the phase difference is constant, the reference frequency and the output of the frequency divider (and by extension, the VCO output) must also be the same.

As the divisor of the frequency divider is changed, the loop's control action will keep the divided-down VCO output phase locked to the reference frequency, but with a phase difference that gets closer to 0 or 180° , depending on which direction the input frequency changes. The range over which the phase difference at the phase detector's input varies between 0° and 180° is the widest range over which the PLL can keep the input and VCO signals locked together. This is called the loop's *lock range*.

If the divisor of the frequency divider is changed even further, the output of the loop filter will actually start to move in the opposite direction and the loop will no longer be able to keep the VCO output locked to the reference frequency and the loop is said to be *out of lock* or *lost lock*.

Loop Bandwidth

Whether you picture a control loop

such as the thermostat in your house, the speed control in your car or a PLL frequency synthesizer, they all have "bandwidth," that is, they can only respond at a certain speed. Your house will take several minutes to heat up or cool down, your car will need a few seconds to respond to a hill if you are using the speed control. Likewise, the PLL will need a finite time to stabilize, several milliseconds or more depending on the design.

This brings up the concept of *loop bandwidth*. The basic idea is that disturbances outside the loop have a low-pass characteristic up to the loop bandwidth, and that disturbances inside the loop have a high-pass characteristic up to the loop bandwidth. The loop bandwidth is determined by the phase detector gain, the loop filter gain and cutoff frequency, the VCO gain and the divider ratio. Loop bandwidth and the phase response of the PLL determine the stability and transient response of the PLL.

PLLs and Noise

Whether the PLL frequency synthesizer output is being used to control a receiver or a transmitter frequency, the spectral cleanliness of the output is important. Since the loop filter output voltage goes directly to the VCO, any noise or spurious frequencies on the loop filter output will modulate the VCO causing FM sidebands. On your transmitted signal, the sidebands are heard as noise by adjacent stations. On receive, they can mix with other signals, resulting in a higher noise floor in the receiver.

A common path for noise to contaminate the loop filter output is via the power supply. This type of noise tends to be audible in your receiver or transmitter audio. Use a well-regulated supply to minimize 120-Hz power supply ripple. Use a dedicated low-power regulator separate from the receiver audio stages so you do not couple audio variations from the speaker amplifier into the loop filter output. If you have a computer / sound card interface, be careful not to share power supplies or route digital signals near the loop filter or VCO.

A more complicated spectral concern is the amount of reference frequency feed-through to the VCO. This type of spurious output is above the audio range (typically a few kHz) so it may not be heard but it will be noticed, for example, in degraded receiver adjacent channel rejection. In the example above, Fig 9.A4, the reference frequency is 10 kHz. High amounts of reference feed-through on the VCO control input will result in FM sidebands on the VCO output.

Loop filter design and optimization is a complicated subject with many trade-offs. This subject is covered in detail in

the PLL references, but the basic trade-off is between loop bandwidth (which affects the speed at which a PLL can change frequency and lock) and reference rejection. Improved phase detectors can be used which will minimize the amount of reference feed-through for the loop filter to deal with. Another cause of high reference sidebands is inadequate buffering between the VCO output and the frequency divider stage.

One indication of PLL design difficulty is the spread of the VCO range expressed either in percent or in octaves. It is fairly difficult to make a VCO that can tune over one octave, a two-to-one frequency spread. Typically, the greater the spread of the VCO tuning range, the worse the noise performance gets. The conflicting design requirements can sometimes be conquered by trading off complexity, cost, size, and power consumption.

A common source of noise in the VCO is microphonics. Very small variations in capacitance can frequency modulate the VCO and impose audible modulation on the VCO output. Those microphonic products will be heard on your transmit audio or they will be superimposed on your receiver audio output. Under vibration, an air-wound inductor used in a VCO can move slightly relative to a metal shield for example. A common technique to minimize microphonics is to cover the sensitive parts with wax, Q-Dope, epoxy or a silicone sealer. As with the loop filter use a well-filtered, dedicated regulator for the VCO to minimize modulation by conducted electrical noise.

Types of PLLs

One of the disadvantages of a single loop PLL frequency synthesizer is that the reference frequency determines the step size of the output frequency. For two-way radio and other systems with fixed channel spacing that is generally not a problem. For applications like amateur radio CW and SSB operation, tuning steps smaller than 10 Hz is almost a necessity. Like so many design requirements, there are trade-offs with making the reference frequency smaller and smaller. Most evident is that the loop filter bandwidth would have to keep getting lower and lower to preserve spectral cleanliness and loop stability. Because low frequency filters take longer to settle, a single-loop PLL with a 10 Hz loop bandwidth would take an unacceptably long time to settle to the next frequency.

Creative circuit architectures involving two or more PLLs operating together achieve finer tuning increments with only moderate complexity. Once you understand the basics of a single loop PLL you will be able to learn and understand the operation of a multi-loop PLL.

the oscillator is locked into a fixed-phase relationship with the reference, which means that their frequencies are held exactly equal.

A representative block diagram of a PLL is shown in **Fig 9.37**. Measurement of any error in the output signal phase is made by the *phase detector* (PD). The measured error is supplied to the *loop filter* and *loop amplifier* which work together to tune the *voltage controlled oscillator* (VCO) just enough to make the error go to zero. The phase detector determines the actual frequency and phase of the VCO through the *feedback divider* (N). The phase detector operates at a lower frequency which is a sub-multiple of both the crystal oscillator frequency reference (f_{XO}) and the output frequency (f_{OUT}). This lower frequency is correctly called the *PLL reference frequency* (f_{REF}) because it sets the operating conditions of the PLL.

There is unfortunate history about the term reference frequency. It is often used to refer to both the operating frequency of the phase detector and to the frequency reference applied to the PLL. If the *reference divider* (R) is not present then of course these two frequencies are the same. But in general, the reference divider is present and these frequencies are different. Ambiguity here is widespread and a big problem, even today many decades into the widespread use of PLLs. We must be very careful in the words we choose to use!

FREQUENCY RESOLUTION (STEP SIZE)

Frequency of the output signal can be easily changed by changing the divide ratio of the feedback divider. For example if the reference frequency (at the phase detector!) is 100 kHz and the output frequency is 147.5 MHz, the feedback divider number must be $N = 1475$. If we changed the value of N to 1474, the frequency at the output of the feedback divider becomes 100.068 kHz. The phase detector notices that the frequency of the VCO is too high, and "tells" the loop filter to reduce the frequency of the VCO until the frequency out of the feedback divider becomes exactly 100.000 kHz. This will happen when the VCO is retuned to a frequency of 147.4 MHz.

By changing the value of N by 1, we have just tuned the frequency synthesizer by its smallest available step. This is called the *frequency resolution* of the synthesizer, or equivalently the synthesizer *step size*. Here we note that this step size is $(147.5 - 147.4) = 0.1$ MHz. It is no accident that this frequency is exactly equal to the PLL reference frequency f_{REF} . This result is an important reason to avoid all ambiguity in the term "reference frequency." f_{REF} is equal to the synthesizer output frequency step size.

There certainly are applications where we want the step size to be a small number, say 10 Hz. You might guess — correctly — that there are problems in building a PLL synthe-

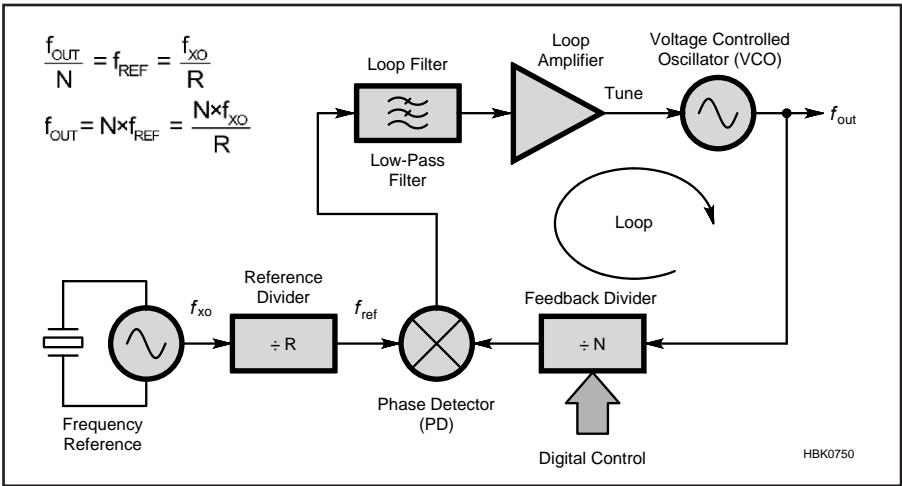

Fig 9.37 — A basic phase-locked-loop (PLL) synthesizer acts to keep the divided-down signal from its voltage-controlled oscillator (VCO) phase-locked to the divided-down signal from its reference oscillator. Fine tuning steps are therefore possible without the complication of direct synthesis.

sizer for a very low f_{REF} . The usual solution is to combine multiple PLLs with some DAS techniques to get around these problems.

DYNAMIC STABILITY AND LOOP BANDWIDTH

Because feedback control is required to transfer the frequency and phase characteristics from the crystal oscillator onto the VCO, all of the stability problems inherent in feedback control apply to PLL design. If the gain and phase responses are not well designed the PLL can oscillate. In this case instead of getting the stability transfer we want, the output is essentially a frequency modulated signal spread across the entire tuning bandwidth of the synthesizer — clearly a very bad thing. How to perform this design is discussed in section 9.7.2.

For the moment let us assume that our PLL dynamics are properly designed. One other characteristic of feedback control is now important: how fast can the output frequency be changed from one value to another? This is controlled by the *loop bandwidth* of the PLL. For practical reasons the loop bandwidth should be less than 5% of f_{REF} . Using the example above in which $f_{REF} = 100$ kHz, the loop bandwidth we design for cannot exceed 5 kHz. To answer our question, we can use the rule of thumb that in a well-designed loop, the settling time should be between 1 and 2 times the reciprocal of the loop bandwidth. For a 5 kHz loop bandwidth the settling time should not exceed $2/5000 = 400 \mu s$. We can begin to see one problem with PLL design if f_{REF} is very small: To get a 1 kHz step size from a PLL synthesizer the maximum loop bandwidth available is 50 Hz. This is impractically small.

This loop bandwidth also influences how we can modulate our PLL synthesizer in an FM transmitter. Imagine now that we apply a very small amount of FM to the reference oscillator f_{XO} . The amount of deviation will be amplified by N/R — but this is true only for low modulating frequencies. If the modulating frequency is increased, the VCO has to change frequency at a higher rate. As the modulating frequency continues to increase, eventually the VCO has to move faster than

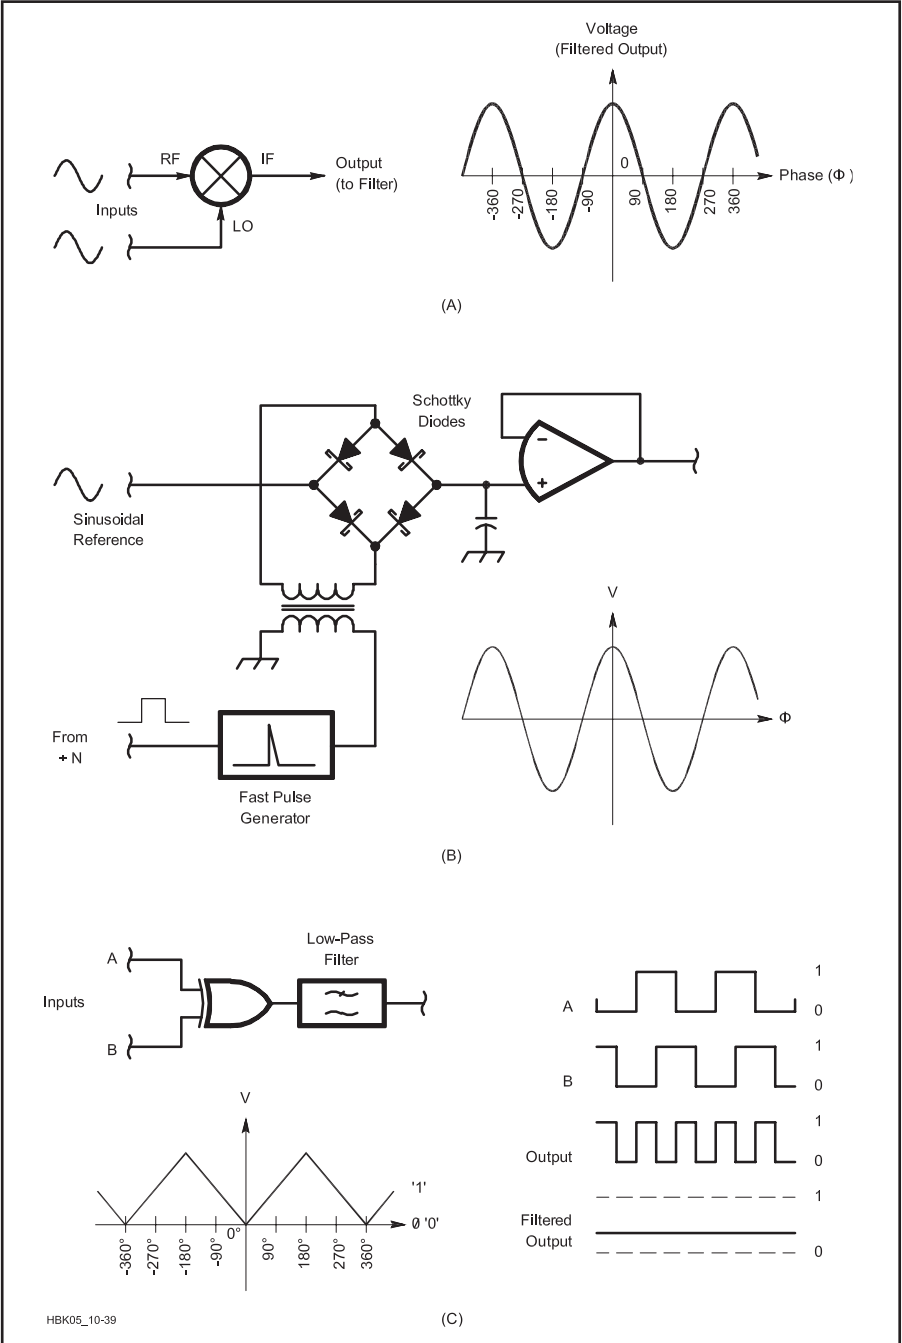

Fig 9.38 — Simple phase detectors: a mixer (A), a sampler (B) and an exclusive-OR gate (C).

the available *settling time*. The PLL now acts as a low-pass filter, reducing the available deviation from higher modulating frequencies. The cut-off frequency of this PLL low-pass action is equal to this same loop bandwidth.

PLL COMPONENTS

Let us continue our discussion of phase-locked loop synthesizers by examining the role of each of the component pieces of the system. They are the phase detector, the VCO, the dividers (with possible prescalers), the loop filter, and of course the reference oscillator.

Phase Detectors

Phase detection is the key operation in any PLL. Remembering that we are making a phase locked loop, what we really need is not *absolute* phase measurement but a *relative* phase measurement. We need to know only how the phase of the VCO output signal f_{OUT} is changing with respect to the phase of the crystal reference f_{XO} .

As usual, there are both analog and digital circuit techniques available to perform

phase detection. For frequency synthesizer design the analog techniques are seldom used. Analog phase detectors are used only in receiver and demodulator applications. There are two that sometimes still appear in ham equipment, the multiplier/mixer of Fig 9.38A and the sampling phase detector shown in Fig 9.38B.

The mixer is a very low noise device when used as a phase detector, which explains why it is not yet completely gone from synthesizer design. It remains only in PLL designs where f_{REF} is very high, greater than 10-100 MHz. The main reason for this is that a PLL using a mixer for the PD is subject to a phenomenon called *false lock*, where the PLL may act like it is locked even though it really isn't. Detecting and eliminating a false lock condition is much easier to do at higher frequencies. The sampling phase detector is now used only in synthesizers with output frequencies in the high microwave region, typically well above 10 GHz. The gain of this sampling circuit is very low, so it is used only if there is no viable alternative.

The most widely used digital phase detec-

tor is the exclusive-OR (XOR) gate shown in Fig 9.38C. (See the **Digital Basics** chapter for XOR gate operation.) If inputs A and B in Fig 9.38C are almost in phase, the output will be low most of the time, and its average filtered value will be close to the logic 0 level. If inputs A and B are almost in phase opposition, the output will be high most of the time, and its average voltage will be close to logic 1. The average voltage is near its mid-value when the inputs are shifted in phase by 90 degrees. In this respect the XOR gate is much like the analog mixer. To achieve this circuit's full output-voltage range, it's important that the reference and VCO signals at its input have a 50% duty cycle.

Phase-Frequency Detector

One problem common to *all* phase detectors is the possibility of false lock. This happens because the output of any phase detector can have an average value of zero even when the frequencies at its inputs are not equal. This is a very serious problem that requires any PLL using them to have additional circuitry to serve as an acquisition aid. If the PLL

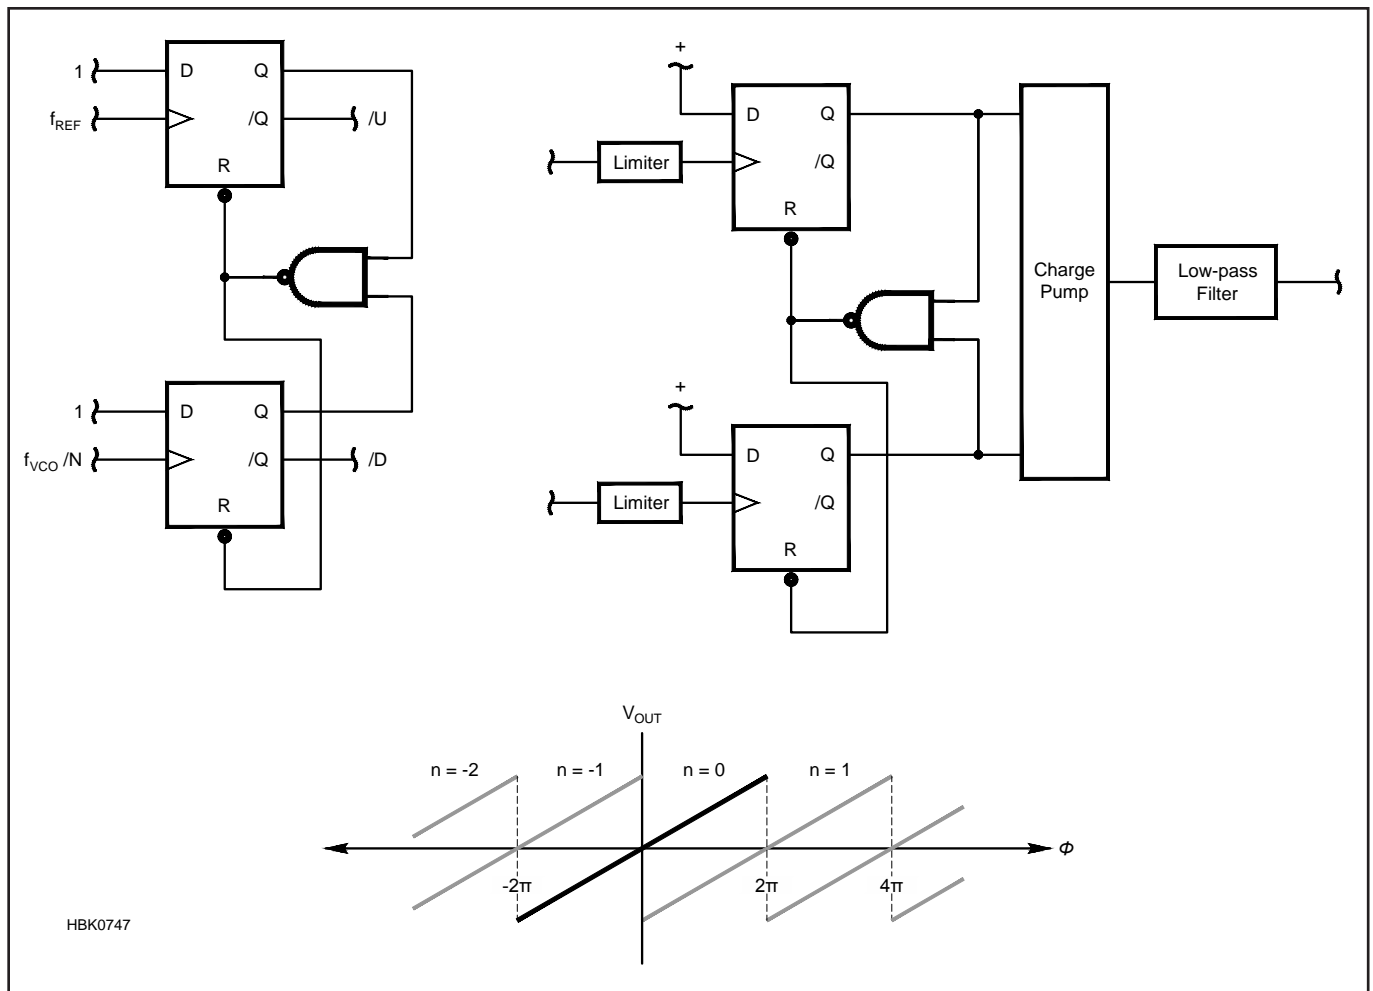

Fig 9.39 — The phase frequency detector (PFD) makes a measurement of the time difference between two rising edges of the input signals.

tries to settle when the PD inputs are not at the same frequency, this acquisition aid must prod the PLL to keep moving toward the true lock frequency. Such acquisition aids are not needed when a *phase-frequency detector* (PFD) is used.

The benefit of the PFD is that if the input signals are at different frequencies, even if they are at very different frequencies, the output is never zero. The PFD output always produces a dc shift in the direction the PLL needs to move until the lock condition is achieved. No acquisition aids are ever needed. This alone is enough to explain its nearly universal adoption today.

As seen in Fig 9.39A, the PFD is a simple digital circuit. This also helps make it attractive to use in this era of CMOS integrated circuits. Other designs for the PFD exist, but they all follow the logic shown in Fig 9.39A. Of particular importance is that the PFD has two outputs.

The PFD operates by measuring the time difference between the rising edges of the reference signal and the divided VCO. The first signal to arrive sets its flip-flop. The second edge to arrive also sets its flip-flop, which immediately causes both flip-flops to be reset, ready for the next set of signal edges. By operating at high speed, the PFD is very sensitive to phase differences between the input signals. The PFD does require an equal number of edges for each signal, so it is not useful when the signals have varying numbers of edges, such in a receiver's demodulator or a synchronizer.

If the VCO frequency is too low only the /U output is active, causing the loop filter to raise the VCO frequency. On the other hand, when the VCO frequency is high only the /D output is active, causing the loop filter to lower the VCO frequency. It is interesting to note that unlike the mixer and XOR phase detectors, which require the inputs to be in phase quadrature, the PFD locks when the input signals are in exact phase alignment.

Being an edge triggered circuit, PFD operation is essentially independent of input signal duty cycle. This eliminates the need for input waveform processing. If the input frequencies are different, the time differences measured by the PFD will be either constantly increasing or decreasing. As a result only one of the PFD output signals will be active, informing the PLL unambiguously which way to correct the controlled source to achieve phase lock.

Charge Pumps

Because the PFD has two outputs and most loop filters have only one input, something is needed to bridge the PFD and the loop filter. The usual technique is the *charge pump*, shown in Fig 9.39B. The charge pump gets its name by allowing current to flow only for the brief interval, here when the /D or

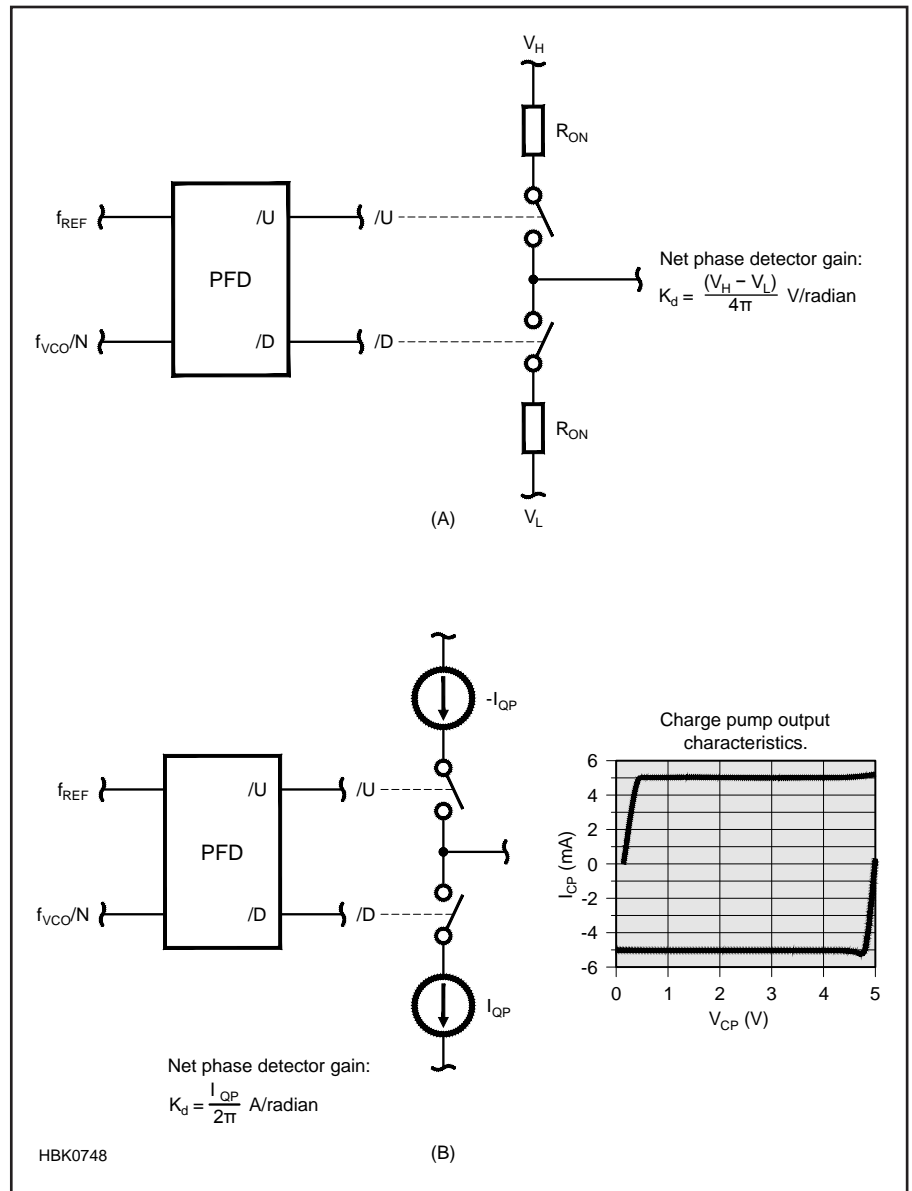

Fig 9.40 — The charge pump delivers short bursts of current to the loop filter under the control of the phase frequency detector (PFD) outputs. A voltage mode charge pump is shown at A and a current mode charge pump at B.

/U outputs are active. Current flow in short bursts is equivalent to a finite charge transfer.

Charge pumps come in two configurations, voltage mode and current mode, as shown in Fig 9.40. Voltage mode (Fig 9.40A) was the original version, though now current mode (Fig 9.40B) is most widely used with integrated circuit PLLs.

The voltage mode charge pump directly connects voltage sources to the loop filter when the PFD output signals are active. When the PFD output signals are at rest (both high) both voltage sources are disconnected from the loop filter. These voltage spikes transfer charge to the integrator in accordance with the PLL loop filter time constant. One voltage source inputs current to the loop filter and the other removes it.

The current mode charge pump is architecturally similar to the voltage mode charge pump, with voltage sources replaced by current sources. Like the voltage mode charge pump, this circuit disconnects both sources when the PFD output signals are at rest. In this case, current spikes transfer charge to and from the loop filter integrator. This transfer is independent of the loop filter series resistances.

The current mode charge pump has some advantages to the frequency synthesizer designer. Three are particularly significant:

- Pump current flows at a constant value independent of the loop filter voltage. Unless V_H and V_L are both very large compared with any possible loop filter voltage, the amount of charge transfer will vary with different loop

filter voltage values.

- During the PFD reset time, both output sources are active. The voltage mode charge pump will attempt to connect both voltage sources to the loop filter during this brief period, which can generate some undesirably large power supply current spikes. During PFD reset, the current mode charge pump loads the power supply with a single current value of I_{QP} . If both current sources are well matched, their currents completely cancel at the loop filter input, effectively disconnecting them that much earlier.

- At low offset frequencies, the loop gain flattens out with a voltage mode charge pump. Loop gain continues to increase with a current mode charge pump, effectively matching active filter performance.

VCO

The design and characteristics of oscillators, including tunable oscillators, is the major topic of this chapter so it will not be repeated here. Of particular importance to PLL design are the tuning characteristic of the VCO and the VCO tuning bandwidth.

The tuning characteristic of an oscillator shows the output frequency versus the tuning voltage, such as the example of Fig 9.41A. The slope of this curve is called the VCO's *modulation gain* (K_0) and it is this modulation gain that is most important to PLL design. For wideband VCOs the variation of K_0 can exceed 5:1 from minimum to maximum frequency. In section 9.7.2 the design method shows how a wide gain variation such as this is handled with a single loop filter design.

It is important to realize that the VCO has no idea that it is controlled by a PLL. While it is oscillating it continues to drift and jitter with time and temperature like any other oscillator. You must characterize these variations to be assured that the tuning capability has sufficient range for the PLL to "find" a tuning voltage value that will retune the VCO to the required frequency, under all circumstances.

The primary VCO characteristic of interest to the synthesizer designer is the tuning gain "constant," K_0 . Almost never a constant, K_0 is a local measure of how much the VCO output frequency changes with a change in tuning voltage.

VCO designers go to great lengths to make K_0 an actual constant. This additional effort often increases the VCO design complexity and usually results in a more expensive design. If no linearization effort is undertaken, K_0 can easily vary from 3:1 to 10:1 over the tuning band. This also complicates the frequency synthesizer design. Specific applications will dictate where effort needs to be expended: in the VCO design or the PLL design.

All PLL design algorithms assume that there is no delay between when the loop filter

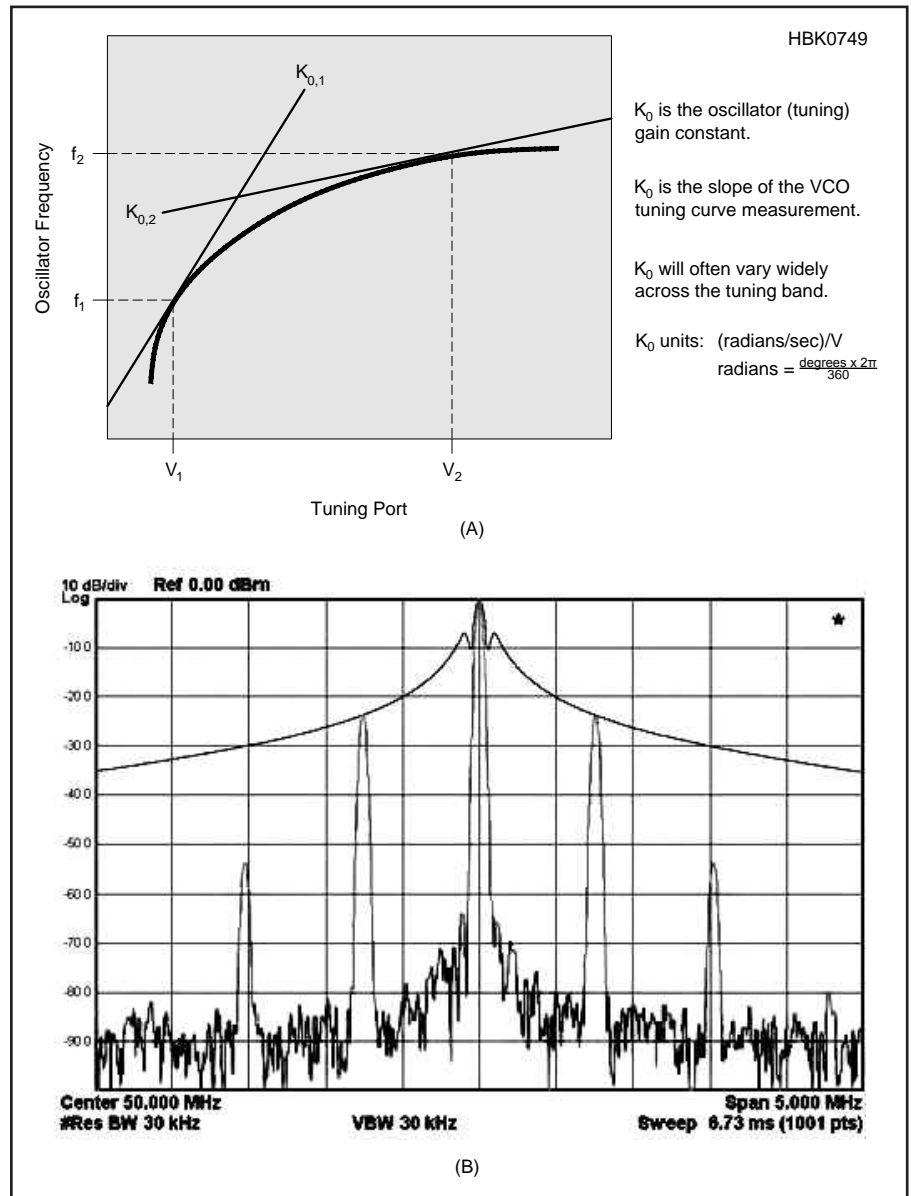

Fig 9.41 — (A) Measurement of the VCO tuning characteristic provides a curve describing frequency versus tuning voltage. The VCO tuning gain at a particular frequency (or tuning voltage) is the slope of this curve at that point. (B) A spectrum analyzer is used to measure frequency deviation of the VCO and the modulating frequency varies. FM sideband peak amplitudes follow the top profile when deviation is constant. VCO tuning bandwidth is determined by increasing the modulating frequency until the first sidebands are no longer 10 dB greater than all other sidebands.

presents a tuning change command to the VCO and when the VCO frequency actually changes. This situation is true when the VCO tuning bandwidth is much greater than the PLL loop bandwidth. If the VCO tuning bandwidth is not much greater than the PLL loop bandwidth, there are additional phase shifts that will cause problems with PLL stability. It is usually much easier to narrow the loop bandwidth than to redesign the VCO. If redesigning the VCO is a possibility, reduce the capacitance seen at the tuning input to increase the tuning bandwidth.

The VCO tuning bandwidth is important

mainly for PLL designs that have wide loop bandwidths. Measuring the frequency deviation as the modulating frequency varies is best done by looking at the FM sidebands on a spectrum analyzer, as shown in Fig 9.41B. For constant deviation, FM sidebands follow the top profile. When the modulating frequency doubles, the sidebands drop below the profile by 6 dB, and if it triples, by 10 dB. The first FM sideband must exceed all other sidebands by 10 dB for proper VCO *characterization* — the process of determining the VCO's characteristic parameters such as the tuning sensitivity, noise spectrum, dynamic

Fig 9.42 — A typical implementation of a dual-modulus prescaler.

response to changes in the tuning input signal, and so on. (See the Agilent application note “Boosting PLL Design Efficiency” in the References section.) VCO tuning bandwidth is determined by the point at which increasing the modulating frequency deviates from (drops below) the profile shown in Fig 9.41B.

Reference Divider

The reference divider is one of the easiest parts of a PLL to design, though technically it is outside the PLL. The input frequency is well known — it is the crystal reference. The output frequency is also well known, being the phase detector frequency f_{REF} . The ratio of these two frequencies is the required counter divide-by ratio or *modulus*.

When designing PLL synthesizers, f_{REF} is usually specified but f_{XO} is not. This provides some flexibility in design to use easy counter implementations if the resulting f_{XO} is also easy to get. The easiest digital counters to use for any divider are those operating with binary numbers (divide by 2, 4, 8, 16, ..., 128, ...). For example, if $f_{REF} = 20$ kHz and you choose $R = 512$ then $f_{XO} = 10.24$ MHz, which is a readily available crystal frequency.

Feedback Divider and Prescalers

The feedback divider is more of a challenge. First and foremost, this divider must work properly with whatever possible frequency it may ever see at its input. Whatever the highest and lowest frequencies the VCO may be, the divider must handle them all.

The feedback divider is almost always programmable so that the output frequency can be changed. Programmable counters

are always slower than non-programmable designs, so some speed limitation occurs. Fortunately in this era of tiny CMOS integrated circuits the problems of past years in getting programmable counters to operate at hundreds of MHz are nearly over. Older equipment still has feedback divider designs that are carefully crafted to handle the frequencies at which they must operate.

Fixed Prescaler

When the programmable counter does not have sufficient speed to handle the frequencies required, then the VCO frequency must be divided down ahead of the programmable counter to assure that everything works reliably. This additional divider usually has a fixed binary value so it will go fast enough without using too much power. Called a *prescaler*, as long as the output frequency from the prescaler is always within the operating range of the programmable divider the PLL will be reliable.

Of course, there are consequences: when a prescaler is used, the PLL step size is multiplied by the prescaler divider value. For our $f_{REF} = 100$ kHz, if we adopt a divide-by-16 prescaler then the step size increases by a factor of 16 to 1.6 MHz. The direct way to correct for this is to reduce f_{REF} by the same factor of 16, which unfortunately means that the PLL loop bandwidth is also reduced by a factor of 16. Is there a solution with fewer compromises?

Dual-Modulus Prescaling

Yes, there is such a solution. If the prescaler is designed to divide by two values separated

by 1, say 16 and 17, or 8 and 9, then we call this a *dual-modulus P/P+1 prescaler*. Using dual-modulus prescaling we can leave f_{REF} unchanged, keeping our step size and loop bandwidth while gaining much higher operating frequency for the feedback divider.

Dual modulus prescaling is a cooperative effort between a high speed prescaler and a much lower speed programmable counter. The result of this cooperation is a programmable counter that operates at a very high input frequency while maintaining unit division resolution. Dual-modulus prescaling works by allocating quotient and remainder values from the division N/P as shown in Fig 9.42A.

The improvement comes from viewing the operation of division in a slightly different way. The division ratio (N) of any two integers will always provide a quotient (Q) and a remainder (R). If Q counts of prescaled f_{in}/P are followed by R counts of f_{in} directly, then $N = QP + R$. One way to build this counter would be to first count a quotient's worth of prescaled input, and then count a remainder's amount of the input frequency directly. This last step is hard because of the high frequency.

A second approach is to add the remainder counts to the prescaled output as follows: If $Q - R$ counts of prescaled f_{in}/P are followed by R counts of prescaled $f_{in}/(P + 1)$, then $N = (Q - R)P + R(P + 1)$. This is the same as $N = QP - RP + RP + R = QP + R$.

If the remainder counts are distributed among the quotient counts by increasing the prescaler modulus by one from P to $P + 1$ for the remainder's amount of cycles, then returning the prescaler to its nominal division ratio while the rest of the quotient counts are made, the same result is achieved. This design always operates the programmable counter at a much lower frequency than the input frequency, which is a much more robust design.

The catch, however, is that there have to be enough quotient counts over which to distribute any amount of remainder counts. If you run out of quotient counts before remainder counts the technique falls apart and that particular loop divisor will not be *realizable*. For real dividers, all of the terms — Q , P , and R — must be positive integers, so $Q - R$ must be greater than zero for $N = QP + R$ to be realizable.

The maximum remainder, $R_{max} = P - 1$. The minimum quotient is equal to R_{max} . So the minimum remainder, $R_{min} = 0$. That means:

$$N_{min} = Q_{min} P + R_{min} = (P - 1) P + 0 = P^2 - P$$

If the PLL design always requires N to be greater than $P^2 - P$ then there are no problems. If N does need to go below $P^2 - P$, then the only solution is to choose a dual modulus

prescaler with a smaller value of P. Various values of P and N_{min} are:

P	N_{min}
8	56
16	240
64	4032
128	16256

Dual-modulus prescaling therefore implies a minimum divisor value before continuous divider value coverage is realized. The value of this minimum divisor depends on the base modulus of the prescaler, P, and increases quadratically. Proper choice of prescaler modulus is one of the important decisions the frequency synthesizer designer has to make.

Fig 9.42B shows how a typical dual-modulus prescaler is implemented. Each cycle of the system begins with the last output pulse having loaded the frequency control word, shown as “Division Control Data,” into both the main divider and the prescaler controller. If the division control data’s least significant bits (which make up R) loaded into the prescaler controller are not zero, the prescaler is set to divide by $P + 1$, 1 greater than its normal ratio, P. The main divider counts Q pulses from the prescaler.

Each cycle out of the prescaler then clocks the down counter. Eventually, the down counter reaches zero, and two things happen: The counter is designed to hold (stop counting) at zero (and it will remain held until it is next reloaded) and the prescaler is switched back to its normal ratio, P, until the next reload.

Because the technique is widely used, dual-modulus prescaler ICs are widely used and widely available. Devices for use to a few hundred megahertz are cheap, and devices in the 2.5 GHz region are commonly available. Common prescaler IC division ratio pairs are: 8-9, 10-11, 16-17, 32-33, 64-65 and so on. Many ICs containing programmable dividers are available in versions with and without built-in prescaler controllers.

Loop Filter

When designing PLL synthesizers we usually just have to measure and accept the VCO characteristics of K_0 and the PFD output characteristics. Output frequency range and step size are also not flexible. We pull all of these together into a working and stable synthesizer by proper design of the loop filter.

Loop filter design is usually shrouded in mystery, which has given PLL synthesizer design an aura of a “black art.” This is not at all warranted because very reliable design algorithms have been around for decades. Unfortunately these have usually been published in obscure places so they are not well known. The best algorithms known to this author are presented in section 9.7.2. These methods have served extremely well for over 30 years and should provide you with fast

design times and very stable PLL synthesizers. No iteration should be needed.

Loop filters come in active and passive structures. In general the easiest designs use passive (RC) loop filters if the output voltage range from the phase detector (including the PD or PFD and its charge pump) is sufficient to tune the VCO over its required frequency range. If the VCO needs a larger tuning voltage range then an active loop filter structure is necessary.

Passive loop filter circuits for current mode charge pump outputs are shown in Fig 9.43. The loop filter time constant is set by the charge pump current and C1, independent of R and of the loop filter output voltage. R provides a phase leading zero for PLL stability. The first-order filter in Fig 9.43A has a minimum parts count and results in loop dynamics that are consistent with the output frequency.

A second-order filter has the undesirable characteristic of allowing step and impulse changes in the input to appear at the output. This results in significant reference sidebands — a bad thing. Fig 9.43B shows a third-order filter in which C2 changes step changes at the input to slower ramps by rolling off the high frequency response of the loop filter. This results in a significant reduction in reference sidebands.

Active loop filters offer more structures that work well and are easier to design, though more complicated to build. When a voltage mode charge pump is being used, an active loop filter is strongly desired since it removes the PLL response variations with different loop filter voltage values.

In Fig 9.44, the gain of the op-amp isolates the actual loop filter output voltage from the charge pump output voltage, controlling the loop so that the charge pump output voltage is V_{REF} . Each passive component has the same basic function here as in the passive filter.

The third-order active filter in Fig 9.44 adds an additional pole within the feedback loop and reference frequency sidebands are significantly reduced. Charge pump current impulses now cause ramps instead of steps in the output voltage, but they still cause problems at the amplifier inputs. Good design algorithms include this extra pole as part of the fundamental dynamics — not as a disturbance of conventional second-order designs.

Though the design in Fig 9.45 adds another capacitor by splitting the input resistor, the added complexity is usually well worth it. Charge pumps put out very narrow, spiky signals that are usually of sufficient amplitude and duration to temporarily drive the op-amp input into saturation. If this happens the PLL response becomes non-linear and problems often arise.

The improvement of this design is to low-pass filter the charge pump pulses be-

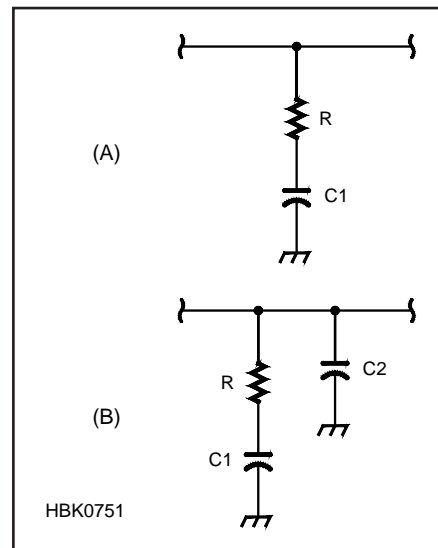

Fig 9.43 — Passive loop filters for current mode charge pump PFD outputs.

Fig 9.44 — Third-order active loop filter isolates the loop filter output voltage from the charge pump outputs.

fore being applied to the op-amp input. The op-amp far prefers the resulting ramps, remaining linear and therefore predictable in behavior. This results in further reduction in reference frequency sidebands and is easily adapted to difference-output digital PDs, including the PFD.

Design equations for these loop filters will be presented after the remaining PLL component blocks are discussed.

Reference Oscillator

Any PLL is simply a stability transfer mechanism, so the behavior of the reference oscillator will not be improved on. The fractional frequency error of the overall frequency synthesizer will match that of the reference oscillator. For example if the output of the PLL synthesizer changes 1 kHz at an output frequency of 1 GHz [$1000/1,000,000,000 = 1:1$ million, or 1 part per million (ppm)] then the reference has changed that same fractional amount. If the crystal reference

Fig 9.45 — Adding additional low-pass filtering by splitting the input resistor and adding C_A improves loop stability and reduces reference frequency sidebands. This design is well-suited for differential-output PFDs.

is 10 MHz (a very common frequency for crystal references) its frequency drift was $(1 \text{ ppm}) \times (10 \text{ MHz}) = 10 \text{ Hz}$. This is not much frequency drift, but it is significant to the ultimate output frequency.

9.7.2 PLL Loop Filter Design

When it is time to design a PLL synthesizer, it is best to do it in steps. Begin with knowing how the hardware you are using behaves:

- VCO tuning characteristics, K_0
 - PFD characteristic (with charge pump), K_d
 - Crystal reference frequency, f_{XO}
- Next, list the requirements of your application
- Output frequency range, f_{OUT}
 - Output frequency step size, f_{STEP}

Now you are ready to choose the two main design parameters:

- Loop bandwidth — this should not exceed 5% of $f_{REF} = f_{STEP}$.
- Phase Margin — this sets the overall stability of the PLL and can be any value between 50 and 60 degrees. A good value is 54 degrees.

With all of this information in place it is time to calculate the values for the two frequency dividers and the loop filter components. Begin with the divider values:

$$R = f_{XO}/f_{REF}$$

$$N = f_{OUT}/f_{REF}$$

$$N_{MIN} = f_{OUT,MIN}/f_{REF}$$

$$N_{MAX} = f_{OUT,MAX}/f_{REF}$$

The best design algorithm for stable PLL design calls for using the geometric mean of the feedback divider value range in the loop

filter design. This same idea is used to manage the range of VCO gain values for K_0 .

$$N_{DESIGN} = \sqrt{N_{MAX} \times N_{MIN}}$$

K_0 design target value =

$$\sqrt{K_{0,MAX} \times K_{0,MIN}}$$

PFD gain depends on whether the charge pump is voltage mode or current mode:

$$\text{(voltage mode) } K_d = (V_H - V_L)/4\pi$$

$$\text{(current mode) } K_d = I_{QP}/2\pi$$

For all of the active loop filter structures

use the voltage mode value.

Everything is now ready. Place these design values into the appropriate design equations for the selected loop filter structure. For a passive loop filter use Fig 9.46. If you are using an active loop filter the appropriate equations are in Fig 9.47 or Fig 9.48. The resistor and capacitor values from these calculations are not critical. Choose values within 30% of what you calculate and the design will be fine. Truly!

Following any loop filter design, it is always a good idea to check the results by directly calculating the filter time constants from the components chosen. Compare these time constants with those derived theoretically. If they match within 10-20%, there should be no problem with loop stability.

The passive third order loop filter design equations of Fig 9.46 look very similar to those of its active filter counterpart. The major difference is that this procedure yields two time constants instead of three, and a term equaling the sum of both filter capacitances.

Unlike the active filter form, there are no arbitrary component choices with the passive filter. From the time constants and the total capacitance, all three loop filter components are uniquely determined.

Since the concepts of natural frequency and damping no longer apply (by definition) in a third-order filter, the more general stability concepts of gain crossover and phase margin are used. A value of 50-60 degrees is usually used for the design phase margin.

The equations for Fig 9.47 and Fig 9.48 include the rolloff pole within the loop dynamics, rather than treating it as a loop perturbation. This allows a greater amount of high frequency rolloff to be achieved as it “kicks in” at a much lower frequency than perturbation techniques would allow.

A usual design strategy is to choose the

$$\tau_2 = \frac{\sec\phi_0 - \tan\phi_0}{\omega_0} = \frac{1 - \sin\phi_0}{\omega_0 \cdot \cos\phi_0}$$

$$\tau_1 = \frac{1}{\omega_0^2 \cdot \tau_2}$$

$$C_T = \frac{K_0 \cdot K_d}{N \cdot \omega_0^2} \cdot \frac{\sqrt{1 + (\omega_0 \cdot \tau_1)^2}}{\sqrt{1 + (\omega_0 \cdot \tau_2)^2}} = \frac{K_0 \cdot K_d}{N} \cdot \frac{\tau_1}{\omega_0}$$

$$\tau_1 = RC_1 \qquad C_2 = \frac{\tau_2}{\tau_1} \times C_T$$

$$\tau_2 = R \left(\frac{C_1 \times C_2}{C_1 + C_2} \right) \qquad C_1 = C_T - C_2$$

$$C_T = C_1 + C_2 \qquad R = \frac{\tau_1}{C_1}$$

$\phi_0 =$ phase margin ($^\circ$)
 $\omega_0 =$ open loop gain crossover frequency (radians/sec)

Fig 9.46 — Design equations for passive loop filters.

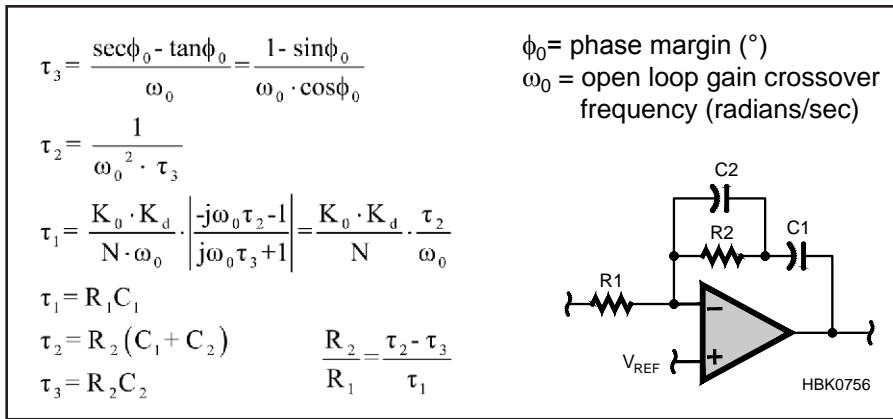

Fig 9.47 — Design equations for third-order active loop filters

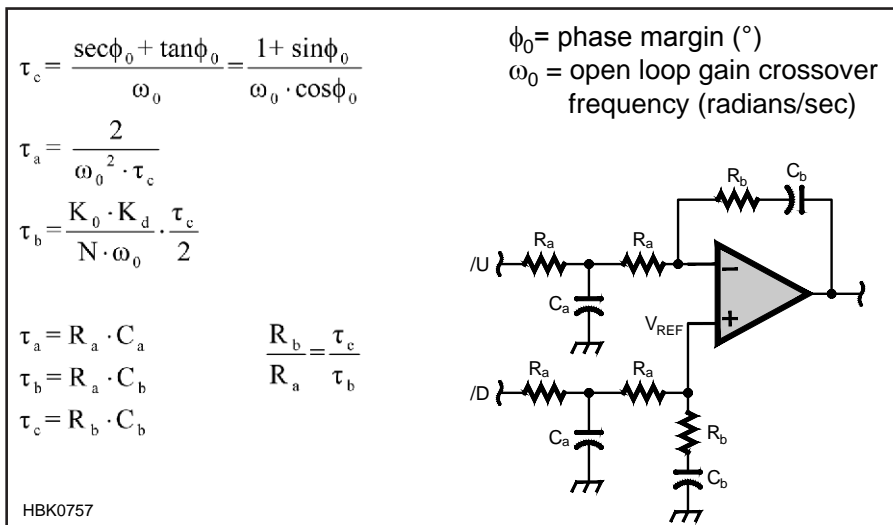

Fig 9.48 — Design equations for differential-input active loop filters

resistors first to achieve the design ratio. This may provide several possible resistor pairs. Calculate the resulting capacitor values for each resistor pair possibility, and choose the set that provides the closest realizable values.

9.7.3 Fractional-N Synthesis

There is one technique that allows the relationship $f_{REF} = \text{step size}$ to be broken. Until now the PLL synthesizer designs have all considered the feedback divider to always operate at a single programmed value. This is called an *integer-N PLL*. In a more complicated system we can change the value programmed into the feedback divider according to some pattern. For example we can use the 2 meter synthesizer from the section on Phase-Locked Loops and divide by 1474 eight times and then divide by 1475 twice. Repeating this pattern gives an average effective divider value, averaged over the pattern, of $(8 \times 1474 + 2 \times 1475) / 10 = 1474.2$.

A PLL that operates with this kind of varied programming value for the feedback divider is called a *fractional-N PLL*.

By using fractional-N techniques the step size gets smaller while f_{REF} does not change. The price for this is increased spurious sidebands and a higher noise level at the PLL output. This technique is very complicated to implement well. Fortunately several suppliers of PLL integrated circuits have done all the homework for us. It is far easier to use any of these PLL parts than to do a fractional-N design from scratch.

9.7.4 PLL Synthesizer Phase Noise

Differences in resonator Q usually make the phase-noise sidebands of a loop's reference oscillator much smaller than those of the VCO. Within its loop bandwidth, a PLL acts toward matching the phase-noise components of its VCO to those of the reference. There are several processes which get in the

way of this actually happening, which are outlined here.

Dividing the reference oscillator signal f_{XO} to produce the signal f_{REF} which is applied to the phase detector also divides the deviation of the reference oscillator's phase-noise sidebands, translating to a 20 dB reduction in phase noise per decade of division. This models as a factor of $-20 \log(R)$ dB, where R is the reference divisor value, since f_{REF} is less than f_{XO} . We also know that within its loop bandwidth the PLL acts as a frequency multiplier and this multiplies the deviation of the phase noise sidebands present at the PFD, again by 20 dB per decade or equivalently by a factor of $20 \log(N)$ dB, where N is the loop divider's value. Between the reference oscillator and the PLL output, the sidebands on the reference signal are increased by $20 \log(N/R)$ dB.

COUNTER AND PFD NOISE

Logic circuits have a noise characteristic that is extremely important to PLL design. Any circuit, when you really get down to it, is always an analog circuit. In this case the switching threshold of the logic circuits has a tiny amount of noise on it. This small amount of noise manifests itself in a very slight variation in when the logic circuit actually switches, even if the input clock is perfectly clean. We can think of this small timing jitter as a small shift in the output signal "zero crossing," which is directly equivalent to a phase modulation.

The amount of this timing jitter is constant, no matter the operating frequency. Thus, the amount of phase shift this represents depends on the operating frequency: 1 nanosecond of jitter at 1 kHz is very small, but represents 36 degrees at 100 MHz. As a result we get different measures of the noise floor from digital circuits that depend on the frequency at which they are operating. This digital noise floor interferes with the PLL action to match the VCO noise to the divided reference oscillator noise as measured at the PFD inputs.

VCO NOISE

The PLL can track only slowly moving noise, well within its bandwidth. Therefore VCO noise components that change slowly enough for the PLL to measure and track will be increasingly canceled successfully. Any VCO noise component that changes at a rate faster than the PLL bandwidth will not be changed at all. At offset frequencies beyond the PLL bandwidth the VCO noise is still present as if the PLL were not even there.

Does this imply that to get a low-noise synthesizer we are encouraged to make the PLL bandwidth very wide? Well, yes, to a certain degree. When we build PLL synthesizers we soon find that the logic noise from the prior section begins to get in the way if the loop bandwidth gets too wide. When this happens

the total PLL output noise actually begins to increase as the bandwidth gets wider. There is a range of loop bandwidth values where the total PLL output noise has a minimum. This range is centered at the offset frequency where the logic noise floor, multiplied by $20 \log(f_{OUT}/f_{REF})$, has the same value as the VCO intrinsic phase noise.

Clearly, having a VCO design with minimum phase noise is very important to a good, low-noise PLL synthesizer. Much effort is spent on this area in industry. A summary of important results from these noise reduction efforts is presented in the section Improving VCO Noise Performance below.

FRACTIONAL DIVISION NOISE

From the brief discussion on fractional-N principles, we note that this whole idea is based on changing the feedback divider value in a semi-randomized way. This inherently jitters the output from the feedback divider, which is a source of phase noise into the PFD. This noise source is algorithmic instead of physical, but the noise is a big problem nonetheless.

OTHER NOISE SOURCES

Phase noise can be introduced into a PLL by other means. Any amplifier stages between the VCO and the circuits that follow it (such as the loop divider) will contribute some noise, as will microphonic effects in loop- and reference-filter components (such as those due to the piezoelectric properties of ceramic capacitors and the crystal filters sometimes used for reference-oscillator filtering). Noise on the power supply to the system's active components can modulate the loop. The fundamental and harmonics of the system's ac line supply can be coupled into the VCO directly or by means of ground loops.

9.7.5 Improving VCO Noise Performance

It is tempting to regard VCO design as a matter of coming up with a suitable oscillator topology with a variable capacitor, simply replacing the variable capacitor with a suitable varactor diode and applying a tuning voltage to the diode. Unfortunately, things are not this simple (as if even this is simple!). There is the matter of applying the tuning voltage to the diode without significantly disturbing the oscillator performance. There is also an issue of not introducing parasitic oscillation with the varactor circuit.

Next, as mentioned earlier, one would not like the tuning voltage to drop below the voltage swing in the oscillator tank. If this is allowed to occur, the tuning diodes go into conduction and the oscillator noise gets worse. A good first approach is to use varactor diodes back to back as shown in **Fig 9.49**. This allows the tank voltage swing

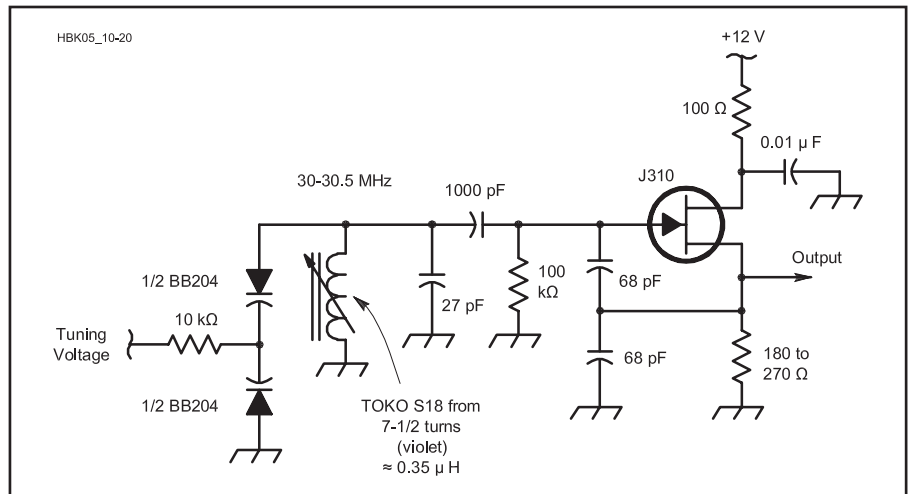

Fig 9.49 — A practical VCO. The tuning diodes are halves of a BB204 dual, common-cathode tuning diode (capacitance per section at 3 V, 39 pF) or equivalent. The ECG617, NTE617 and MV104 are suitable dual-diode substitutes, or use pairs of 1N5451s (39 pF at 4 V) or MV2109s (33 pF at 4 V).

to be developed across two diodes instead of one, as well as allow for a more balanced loading of the oscillator's tank. The semiconductor industry has realized this and there are a number of varactors available prepackaged in this configuration today.

IMPROVING VCO OPERATING Q

Often the Q of passive capacitors available for use in an oscillator tank exceeds the Q of available varactors. One way of reducing the influence of the varactor is to use only the amount of varactor capacitance required to tune the oscillator over its desired range. The balance of the capacitance is supplied to the tank in the form of a higher-Q fixed capacitor. This has the advantage of not requiring the varactor to supply all the capacitance needed to make the circuit function, and often allows for the use of a lower capacitance varactor.

Lower capacitance varactors typically exhibit higher Q values than their larger capacitance counterparts. This concept can be extended by splitting the oscillator tuning range, say 70 MHz to 98 MHz (for a typical lower-side up-converter receiver design popular for the last few decades), into multiple bands. For this example let us consider four oscillators, each with 7 MHz of tuning range. We desire the varactor Q effects to be swamped by high-Q fixed capacitors. This can be further improved through the use of a "segment-tuned VCO" discussed below. A secondary but important benefit of this is to reduce the effective tuning gain (MHz/volt, K_0) of the oscillators, making them less susceptible to other noise voltage sources in the synthesizer loop. These noise sources can come from a variety of places including, but not limited to, varactor leakage current, varactor tuning drive impedance and output noise of the driving operational amplifier or charge pump.

Segment-tuned VCOs provide the designer with additional benefits, but also with additional challenges. By segmented we mean that circuit elements, which could be both inductance and capacitance, are selected for each range that the VCO is expected to tune. **Fig 9.50** shows the frequency range-switching section of a typical VCO in which several diode switches are used to alter the total tank circuit inductance in small steps. These segments create a type of "coarse tuning" for the VCO, and the output of the PLL loop filter performs "fine tuning" with the varactor diode. Usually the component values are arranged in some sort of binary tree. In some integrated designs, 64 or even 128 sub-bands are available from the VCO.

Many times the segmented-VCO concept is applied to an oscillator design that is required to cover several octaves in frequency. For example, this would be the case with a single-IF radio with the IF at about 8 MHz. The VCO would be required to cover 8 MHz to 48 MHz for 100 kHz to 50 MHz coverage of a typical transceiver.

While segmentation allows one to build a multi-octave tunable oscillator, segmentation also imposes some additional constraints. Recalling the earlier section in this chapter on oscillators, the condition for oscillation is an oscillator loop gain of 1 at a phase angle of 0 degrees. Over several octaves, the gain of the oscillating device (typically a transistor) varies, decreasing as operating frequency increases. While conventional limiting in the oscillator circuit will deal with some of this, it is not good practice to let the normal limiting process handle the entire gain variation. This becomes the role of automatic gain control (AGC) in multi-octave oscillator designs. Application of AGC allows for the maintenance of the oscillation criteria, a uniform

Fig 9.50 — The resonator portion of an inductor-switched segment-tuned VCO. A varactor diode provides tuning over a small range. Diode switches will alter the total inductance, changing the frequency in larger steps. Inductor-switched, capacitor-switched, and combinations are all used in VCO designs. (From Hayward, *Introduction to Radio Frequency Design*, Chapter 7. See references.)

output and good starting characteristics, and lower noise across the operating bandwidth.

Finally, a properly designed segmented VCO can improve synthesizer switching speed. The segmentation allows the designer to “pre-steer” the PLL system and reduce the time required for the loop filter to slew the VCO to the desired frequency for lock. Frequency-locked loops (FLL) are often employed for this steering operation to be sure that it happens properly.

9.7.6 A PLL Design Example

As our design example, let us consider a synthesized local oscillator chain for a 10 GHz transverter. **Fig 9.51** is a simplified block diagram of this 10 GHz converter. This example is chosen because it is a departure from the traditional multi-stage multiply-and-filter approach. It permits realization of the oscillator system with two simple loops and minimal RF hardware. It is also representative of what is achievable with current hardware, and can fit in a space of 2 to 3 square inches. This example is intended to be a vehicle to explore the loop design aspects and is not offered as a “construction project.” The multiple design details required are beyond the scope of this chapter.

Two synthesized frequencies, 10 GHz and 340 MHz, are required. Since 10.368 GHz is one of the popular X-band traffic frequencies, we initially mix this with the 10 GHz LO to produce an IF of 368 MHz. The 368 MHz IF signal is subsequently mixed with the 340 MHz LO to produce a 28 MHz final IF, which can be fed into the 10 meter input of any amateur transceiver. We focus our attention on the design of the 10 GHz synthesizer only. Once this is done, the same principles are applied to the 340 MHz section. Our goal is to design a low-noise LO system (by adopt-

ing minimum division ratios) with a loop reference oscillator that is an integer multiple of 10 MHz. Using this technique allows the entire system to be locked at a later time to a 10 MHz standard for precise frequency control.

For the microwave synthesizer we consider using a line of microwave integrated circuits made by Hittite Microwave in gallium-arsenide (GaAs) material. These devices include a selection of prescalers operating to 12 GHz, a 5-bit counter that operates to 2.2 GHz and a phase/frequency detector that operates up to 1.3 GHz. If we use a crystal reference frequency f_{XO} of 100 MHz, and also apply
